21.1 OVERVIEW

Adverse drug reactions (ADRs) are a source of tremendous economic burden to the healthcare community and are common causes of patient morbidity and mortality, estimated to be the fourth to sixth most common causes of death in some series [1–4]. In addition, ADRs are responsible for approximately 3–6% of inpatient admissions and comprise 5–10% of inpatient costs, with expenses approximating $4 billion per year in the United States alone. Although fatal ADRs occur in less than 1% of hospitalized patients, it is estimated that at least 50% of these are preventable [5–8].

ADRs are classified into two categories. Type A ADRs comprise 80% of reported drug reactions and are relatively predictable based on the pharmacologic activity of the drug. Type B ADRs account for <20% of reported drug reactions and are less dependent on dose and not readily anticipated based on pharmacologic principles. It is now appreciated that most Type B reactions are primarily immunologically mediated and that many seemingly idiosyncratic drug reactions may be predicted based on patient immunogenetics [9,10]. This chapter explores our current understanding of the drug reactions that are secondary to T-cell immune responses and the association with particular human leukocyte antigen (HLA) alleles.

21.2 INTRODUCTION

Recent work has established that the HLA family of proteins, encoded within the major histocompatibility complex (MHC), is central to the immunopathogenesis of many

	MHC class I	MHC class II
Structure	Alpha chain and β2-microglobulin heterodimer	Alpha and beta chain heterodimer
Expression	All nucleated cells	Antigen-presenting cells
Source peptide	Cytosolic (intracellular)	Endosomal (extracellular)
Size-bound peptide	9–11 aa	12–25 aa
Loci	A, B, and C	DR, DQ, and DP
Function	Presentation of antigenic peptides to CD8$^+$ T cell/cells and natural killer cell receptor	Presentation of antigenic peptides to CD4$^+$ T cell/cells

FIGURE 21.1 **HLA structure and peptide binding pockets.** (a) Schematic of the MHC class I and II molecules and their respective binding pockets. The MHC class I molecule is a heterodimer containing the transmembrane α domains and β_2-microglobulin. The α1 and α2 domains form the peptide binding pocket that can accommodate peptides 9–11 amino acids in length. The MHC class II is a heterodimer composed of two polypeptide chains, α and β. The peptide binding pocket is formed by α1 and β1. The open-ended pocket can accommodate peptides of 12–25 amino acids in length. (b) Differences between MHC class I and class I molecules. *Source: Adapted from: www.uptomed.ir/Digimed.ir/cecil/Cecil/HTML/188.htm and http://nfs.unipv.it/nfs/minf/dispense/immunology/lectures/files/structure_mhc.html.*

Type B ADRs. Broadly grouped into two structurally and functionally distinct classes, HLA class I and HLA class II (also known as MHC class I and MHC class II), these proteins bind and present peptide antigens to T cells and thus are central to immune surveillance (Figure 21.1). MHC class I molecules are expressed by most nucleated cells and generally serve to display peptides that are derived from intracellular proteins (e.g., misfolded self-proteins and viral proteins) to cytotoxic CD8+ T cells. The expression of MHC class II proteins is restricted to specialized antigen-presenting cells (APCs) (e.g., dendritic cells and monocytes) that interact with CD4+ helper or regulatory T cells [9,11]. All genes encoding the classical MHC proteins are located on chromosome 6—*HLA-A*, *HLA-B*, and *HLA-C* for class I MHC and *HLA-DR*, *HLA-DQ*, and *HLA-DP* for class II MHC proteins. The HLA genes are the most polymorphic genetic elements in the human genome and as a result there exists an extraordinary amount of diversity among MHC proteins [12,13].

21.2.1 MHC Class I

The MHC class I molecule (MHCI) is a heterodimeric protein composed of a transmembrane α heavy chain and a smaller, extracellular β_2-microglobulin polypeptide (Figure 21.1). The α-chain is folded into three distinct domains, α1, α2 and α3. The conserved, membrane-proximal α3 and β_2-microglobulin domains each assume an immunoglobulin-like conformation with the α3 domain serving an anchor to the cell surface. The N-terminal α1α2 domains possess a high degree of polymorphism, and each contributes four antiparallel β strands and an α-helical motif to form the floor and walls of the MHCI peptide binding groove [14]. Within the MHCI binding cleft, chemically distinct binding pockets (denoted pockets A–F) interact with the amino acid side chains of bound peptide thereby conferring specificity to the selection of peptide antigen. Peptide amino acid side chains that are not anchored to the MHCI binding cleft remain exposed and accessible to interaction with the T-cell receptor (TCR) [15]. Importantly, the fidelity of the MHCI interaction with CD8+ T cells (and not APCs displaying CD4) is maintained by CD8 binding to invariant regions of the MHCI molecule [11].

Association of peptide antigen with MHCI occurs in the endoplasmic reticulum (ER) following proteasome-mediated degradation of cellular (either defective self- or pathogen-associated) proteins into short peptide fragments. Resultant peptides are generally 9–11 amino acids in length and are shuttled into the ER via the integral membrane protein TAP (transporter associated with antigen processing). TAP and the nascent MHCI protein then associate with specific chaperone proteins (e.g., ERp57 and tapasin) as well as peptide fragments to form the peptide-loading complex (PLC). The peptide-loaded MHCI complex then traffics to and is expressed on the surface of the cell membrane, primed for contact with T cells. MHCI-peptide binding occurs at nanomolar affinities, thus ensuring that a long-lived complex is available at the cell surface for T-cell surveillance [16–18].

The process of T-cell selection in the thymus generates a pool of CD8+ T cells that interact weakly with self antigens presented on MHCI, thereby failing to elicit a fulminant immune response to self-proteins. If, however, a foreign peptide such as that derived from a viral protein is presented in the context of MHCI, the TCR will bind with high affinity and, with appropriate concomitant costimulatory signals, will elicit a robust cytotoxic response that results in cell-mediated killing of the target cell. In this way, the MHCI protein serves to continuously sample and present intracellular antigens, allowing the CD8+ T-cell repertoire to survey the intracellular peptide pool and destroy cells that are producing “foreign” proteins [9,19].

21.2.2 MHC Class II

The MHC class II molecule (MHCII) is composed of two polypeptide chains, α and β, each of which traverses the cell membrane and associates to form a heterodimer containing two conserved immunoglobulin-like domains proximal to the cell membrane (α2β2) and two polymorphic domains that associate to form the peptide binding site (α1β1) (Figure 21.1). In contrast to MHCI, the peptide binding cleft of the MHCII protein is open-ended and can therefore accommodate larger peptide fragments, generally 12–25 amino acids in length. This feature results in the selection of a broader range of peptides bound and presented in the context MHCII and makes it difficult to predict which peptides will bind to an MHCII molecule based on sequence alone. Structural analysis of the HLA-DR1 protein demonstrates that the peptide binding groove contains a hydrophobic pocket that creates a binding site for the side chain of the “anchoring” peptide residue, with additional hydrogen bonds occurring between the extended peptide main chain and conserved residues of the MHCII binding groove α-helices [20]. These conserved residues in the peptide binding groove are interspersed with variable amino acids that interact with peptide side-chain moieties and thus provide specificity to the peptide pool presented [20–22].

Antigens presented in the context of MHCII are derived from the extracellular environment and are processed into peptide fragments by endosomal machinery following endocytosis. As mentioned previously, the expression of MHCII is restricted to APCs (dendritic cells, macrophages, and B lymphocytes), and peptide displayed in the context of MHCII is restricted to CD4+ T-cell surveillance via CD4–MHCII binding. The immune response elicited following stimulation of the CD4+ T cell by the MHCII/peptide complex is variable and distinct from that elicited by the MHCI/CD8+ T-cell interaction.

21.2.3 HLA Diversity, Linkage Disequilibrium, and Specificity of Peptide Binding

The HLA genes are extraordinarily diverse, with greater than 1000 allelic variants described for the Class I HLA-A, HLA-B, and HLA-C and Class II HLA-DRB1 loci [13] (Figure 21.2). The majority of HLA polymorphism occurs among the peptide binding residues such that each HLA allotype presents a unique repertoire of peptide ligands for T-cell surveillance. Presumably, this high degree of polymorphism is the result of natural selection for protective immunity against infectious pathogens [23,24]. Heterozygosity at the HLA loci theoretically results in a broader repertoire of presented peptides, thereby increasing the probability that a pathogen will be recognized and that an immune response will be elicited [12,13,25–27]. However, the potential overall diversity across the different HLA loci that could be present within a population is reduced by the linkage disequilibrium (LD) observed within and between the HLA class I and HLA class II loci [28]. This results in the formation of MHC haplotypes (also referred to as ancestral haplotypes) that can span megabases of sequence. The LD is greatest between more closely linked HLA molecules (e.g., HLA-B and HLA-C or HLA-DRB1 and HLA-DQB1) but can also include combinations of HLA class I and II genes. The selective advantages conferred by the maintenance of these MHC haplotypes through human history remain unclear. In the context of disease association studies, attempting to disentangle associations with closely linked HLA genes can be difficult and often requires recombinant mapping and genome-wide association studies (GWAS) using single-nucleotide polymorphisms (SNPs) to tag regions of high LD that include one or more HLA loci.

Clinical and laboratory studies have demonstrated that even minor changes in the amino acid sequence of the MHC-peptide binding groove can significantly impact the presentation of antigen and the resultant immune response. For example, Epstein-Barr viral peptides displayed in the context of the HLA-B44 allotypes HLA-B*44:02, HLA-B*44:03, and HLA-B*44:05, which differ from each other at only two amino acids in the peptide binding groove, assume subtle conformational changes that result in marked differences in the affinity of the TCR-MHCI/peptide interaction [29]. Further, the differential peptide selection between the HLA-B*44:02 and HLA-B*44:03 allotypes has been shown to pose a significant barrier to hematopoietic stem cell transplantation with a high rate of acute allograft rejection identified in B*44:02/B*44:03 mismatched donor-recipient pairs [15]. It has also been shown that a single amino acid difference in the peptide binding groove between individuals expressing the HLA-B*35:01 and HLA-B*35:08 alleles results in the selection of distinct sets of immunodominant viral peptides during natural infection with human cytomegalovirus [30]. Similarly, in HIV-infected patients, single amino acid differences in the HLA-B*35:01 allele can influence the rate of progression to AIDS [31]. Such heterologous immune responses also play a significant role in solid-organ transplant rejection and likely in other inflammatory diseases, including drug hypersensitivity [32,33].

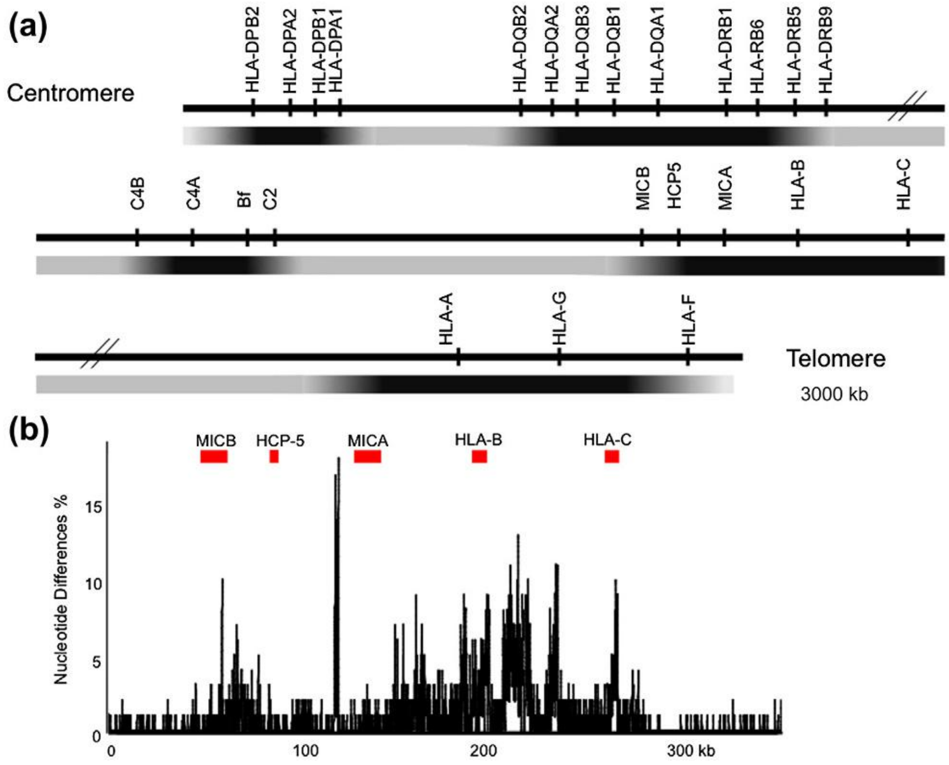

FIGURE 21.2 **Structure of the Major Histocompatibility Complex (MHC).** (a) Map of the MHC including classical class I and II loci and central MHC genes (e.g., MICA, MICB) complement and HCP5. The intensity of the box underneath the different regions reflects the LD observed between different loci (the darker the intensity, the greater the LD). Note the LD from the centromeric to the telomeric end of the MHC covering approximately 3000 kilobases (kb) of sequence [28]. (b) Nucleotide diversity plot between two MHC haplotypes in a 350 kb region containing MICB, MICA, HCP5, HLA-B, and HLA-C [35]. High levels of diversity are associated with low levels of recombination. Accordingly, the region between HLA-C and MICB exhibits high LD (the level of diversity observed here is more than 10-fold elsewhere in the genome [35]). However, note that between HCP5 and HLA-B are areas of diminished diversity that may correspond to the potential recombination spots. The amount of recombination in an area is inversely proportional to the ability of a marker to tag a nearby gene. In this region, recombination is not common and SNPs can act as haplotypic or haplospecific markers for a nearby gene. For example, variations in HCP5 and HLA-B*57:01 are in high LD, but there are individuals in which this is not the case [36], likely representing historical recombination events.

These examples demonstrate that minor differences in the amino acid composition of the peptide binding groove—termed micropolymorphisms—have the capacity to dramatically alter peptide selection and the immune response to viral or foreign-tissue antigens. These concepts translate into the variable susceptibility seen in individuals of differing HLA allotypes to ADRs as described next.

21.3 CLASSIFICATION OF DRUG HYPERSENSITIVITY SYNDROMES

The drug hypersensitivity syndromes (DHS) encompass phenotypically distinct clinical diagnoses. Traditionally, those that are T-cell mediated have been classified as Gell-Coombs type IV reactions, and this classification scheme has recently been modified to include four subtypes to represent the effector cell involved (subtypes a–d; Table 21.1) [34]. The syndromes include drug-induced hypersensitivity syndrome (DIHS)/drug reaction with eosinophilia (DRESS)/hypersensitivity syndrome (HSS), Stevens-Johnson syndrome/toxic epidermal necrolysis (SJS/TEN), acute generalized exanthematous pustulosis (AGEP), drug-induced lupus, fixed drug eruption, and single-organ involvement pathologies such as drug-induced liver disease (DILI). With the exception of DILI, where toxic mechanisms may be important, all of these syndromes are thought to be primarily immunologically mediated. Since many of these DHS are associated with significant cutaneous disease, the term *severe cutaneous adverse reaction* (SCAR) has also been used to collectively refer to DIHS/DRESS, SJS/TEN, and AGEP.

21.3.1 DIHS/DRESS/HSS

DIHS presents as a widespread rash of varying severity, but without skin separation or blistering, accompanied by a minimum criteria of fever, internal organ involvement (usually hepatitis), and hematologic abnormalities (often atypical lymphocytes

TABLE 21.1 Revised Gell and Coombs Classification of Hypersensitivity Reactions

Type of Reaction	Antigen	Immune Reactant	Effector	Clinical Symptoms
Type I (immediate)	Soluble antigen	IgE	Mast cell, basophil	Pruritus, angioedema, urticaria, bronchospasm
Type II (cytotoxic)	Cell- or matrix-associated antigen	IgG	FcR positive cells (phagocytes, NK cells)	Thrombocytopenia, hemolytic anemia
Type III (immune complex)	Soluble antigen	IgG	FcR positive cells, complement	Serum sickness
Type IV (delayed)	Antigen presented by HLA proteins or direct T-cell stimulation	T-cell–mediated		
		IVa	Macrophage	Contact dermatitis
		IVb	Eosinophils	DRESS/DIHS/HSS
		IVc	T cells	SJS/TEN, DILI
		IVd	Neutrophils	AGEP

Source: Adapted from Rive et al. [34].

Ig—immunoglobulin; FcR—Fc receptor; NK cells—natural killer cells; DRESS—drug reaction with eosinophilia and systemic symptoms; DIHS—drug-induced hypersensitivity syndrome; HSS—hypersensitivity syndrome; SJS—Stevens-Johnson syndrome; TEN—toxic epidermal necrolysis; DILI—drug-induced liver injury; AGEP—acute generalized exanthematous pustulosis.

and/or eosinophilia). Diffuse lymphadenopathy, pneumonitis, encephalitis, cardiac failure (myocarditis), and nephritis are variable features of this syndrome, which may mimic a viral illness. Onset of symptoms typically occurs 2–8 weeks following initiation of the inciting drug and can persist for weeks [37]. Prolonged or recurrent symptoms, sometimes weeks following cessation of the offending drug, have been linked to reactivation of the human herpes viruses (HHV-6, CMV) [38,39]. Numerous drugs have been shown to be associated with the development of DIHS, including the antiretrovirals (abacavir, nevirapine, fosamprenavir), allopurinol, antiepileptic medications (carbamazepine, phenytoin, phenobarbital, lamotrigine), beta-lactam antibiotics, NSAIDs, and sulfa antimicrobials. Abacavir does not cause typical DIHS/DRESS/HSS in that it is not characteristically associated with hematological abnormalities or internal organ involvement; rash, which is usually mild to moderate, is a late and inconsistent feature.

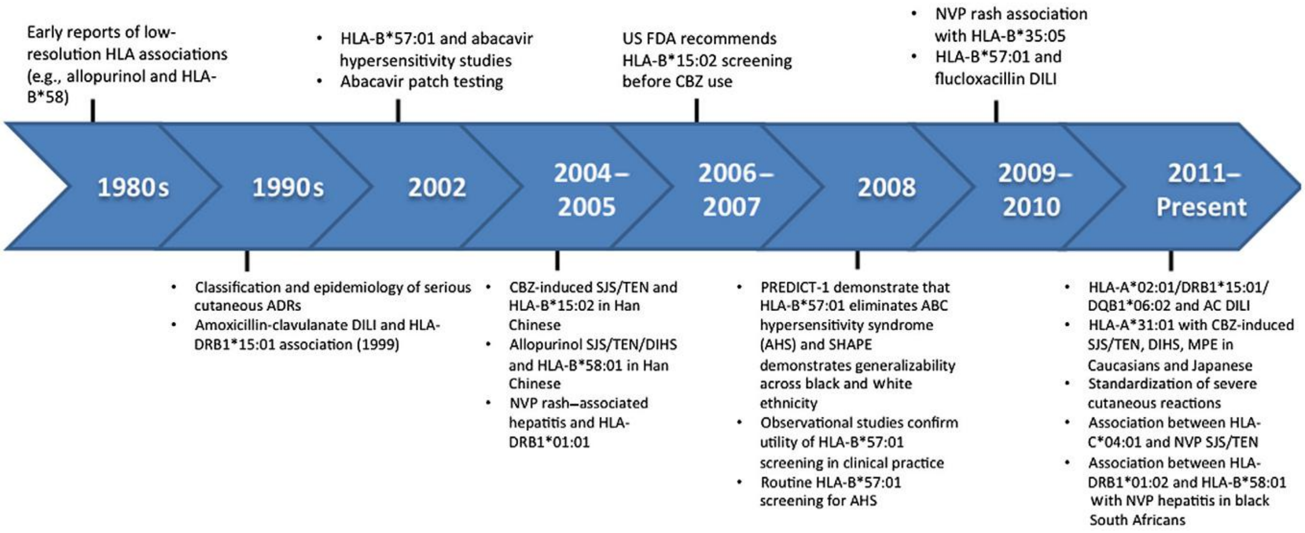
21.3.2 SJS/TEN

SJS and TEN are the most severe cutaneous hypersensitivity syndromes and are thought to be a spectrum of disease defined by the percentage of total body surface area (TBSA) involvement. They are characterized by a painful blistering skin rash that can result in significant epidermal necrosis and detachment, sepsis, and death. These syndromes are often associated with multi-organ involvement (anemia, lymphopenia, complications from epidermal fluid losses, and superimposed bacterial infection/sepsis). Fever is common, and patients may complain of sore throat and/or visual impairment as a result of oropharyngeal mucous membrane and conjunctival erosions. Generally, SJS is used to define cases where blistering and epidermal detachment occur on <10% of TBSA; TEN is diagnosed in instances where >30% of TBSA is affected. SJS/TEN describes the overlap in this spectrum in which 10–30% of TBSA is affected. However, patients with severe epidermal detachment and skin necrosis are classified as TEN regardless of the percentage of TBSA involved.

TEN and SJS are often associated with significant mortality as well as short- and long-term morbidity, including respiratory, gastrointestinal, and genitourinary complications as well as permanent corneal scarring and vision loss [1,40]. The mortality associated with TEN may reach 30–50% [40]. Drugs implicated in the pathogenesis of SJS/TEN include the sulfa antimicrobials (antimicrobial sulfonamides), the antiretroviral drug nevirapine, allopurinol, lamotrigine, the aromatic anticonvulsants, and NSAIDs [10]. The mainstay of treatment is the prompt discontinuation of the inciting medication and supportive therapies, often in a specialized burn or intensive care unit. Rechallenge with an offending drug induces rapid recurrence of symptoms and, given the morbidity and mortality associated with SJS/TEN, permanent avoidance of all suspected offending drugs and structurally related drugs is recommended.

21.3.3 Single-Organ Drug Hypersensitivity Syndromes

Isolated hepatic dysfunction has been associated with the antimicrobial drugs flucloxacillin, amoxicillin-clavulanate



Early reports of low-resolution HLA associations (e.g., allopurinol and HLA-B*58)
• HLA-B*57:01 and abacavir hypersensitivity studies
• Abacavir patch testing
US FDA recommends HLA-B*15:02 screening before CBZ use
• NVP rash association with HLA-B*35:05
• HLA-B*57:01 and flucloxacillin DILI
1980s
1990s
2002
2004–2005
2006–2007
2008
2009–2010
2011–Present
• Classification and epidemiology of serious cutaneous ADRs
• Amoxicillin-clavulanate DILI and HLA-DRB1*15:01 association (1999)
• CBZ-induced SJS/TEN and HLA-B*15:02 in Han Chinese
• Allopurinol SJS/TEN/DIHS and HLA-B*58:01 in Han Chinese
• NVP rash–associated hepatitis and HLA-DRB1*01:01
• PREDICT-1 demonstrate that HLA-B*57:01 eliminates ABC hypersensitivity syndrome (AHS) and SHAPE demonstrates generalizability across black and white ethnicity
• Observational studies confirm utility of HLA-B*57:01 screening in clinical practice
• Routine HLA-B*57:01 screening for AHS
• HLA-A*02:01/DRB1*15:01/DQB1*06:02 and AC DILI
• HLA-A*31:01 with CBZ-induced SJS/TEN, DIHS, MPE in Caucasians and Japanese
• Standardization of severe cutaneous reactions
• Association between HLA-C*04:01 and NVP SJS/TEN
• Association between HLA-DRB1*01:02 and HLA-B*58:01 with NVP hepatitis in black South Africans

FIGURE 21.3 **Timeline of HLA associations with DHSs.** Shown are the key discoveries of HLA-associated DHRs, and their translation.

(AC), and antituberculous drugs such as isoniazid and pyrazinamide, among others [41,42]. This syndrome, termed *drug-induced liver injury* (DILI) may manifest as hepatocellular injury or cholestasis (obstruction of normal bile flow) and has been shown to progress to fulminant hepatic failure in rare instances [43]. The mechanisms underlying these pathologies may include both a toxic and an immunological basis [42,43]. Isolated pancreatitis or tubulointerstitial nephritis are additional examples of drug hypersensitivity reactions with single-organ involvement.

21.4 IMMUNOPATHOGENESIS OF DRUG HYPERSENSITIVITY SYNDROMES

The immune mechanisms underlying DHS just described have been the subject of intense research, and a multitude of data now suggests that T-cell immune responses are central to pathogenesis (Figure 21.3). The initial observations that many delayed drug-induced hypersensitivity reactions occur 2–6 weeks following first drug exposure, resolve with drug discontinuation, and recur rapidly with reexposure, support this hypothesis. This pattern of rapid symptom onset at drug rechallenge suggests that naïve T cells are primed on initial drug exposure and generate a memory pool of T cells that are restimulated on reexposure to the drug, mirroring the natural immune response to infectious pathogens.

Laboratory studies have demonstrated that circulating T cells isolated from individuals with DHS proliferate in response to specific drugs or their metabolites and that these reactions are restricted to peptide presentation in the context of MHC [44–47]. Additionally, the direct observation of cytotoxic T lymphocytes in biopsy specimens of the rash or in positive patch test from patients with cutaneous drug eruptions suggests that these cells play a role in DHS [48–51]. Preexisting cross-reactive memory T-cell responses may also play a role. For instance, in the case of abacavir, some patients who were later found to have patch test–confirmed abacavir hypersensitivity syndrome demonstrated onset of clinical symptoms within 1.5 days of first drug exposure, and 25% of patients in the PREDICT-1 study developed symptoms of hypersensitivity within 5 days of starting abacavir.

These findings raise interesting questions regarding how small-molecule pharmaceutical compounds might stimulate such immune activation. Multiple models may explain these phenomena and have been described—namely, the hapten/prohapten model, the pharmacological interaction (p-i) model, and the altered peptide repertoire model (Figure 21.4).

21.4.1 The Hapten/Prohapten Model

A hapten is a small molecule (e.g., drug or drug metabolite) that covalently binds to a larger protein, thereby altering its structure or chemical composition. The haptenated protein is then hypothesized to undergo intracellular processing to generate chemically modified peptides that are incorporated onto MHC proteins for presentation to T cells. These modified peptides are antigenically distinct from the pool of "self"-antigens and therefore elicit a T-cell response. The hapten/prohapten model also postulates that some chemically inert drugs (prohaptens) may be metabolized to reactive molecules that later serve as haptens [48,52].

Examples of hypersensitivity associated with hapten modification of endogenous proteins include the binding

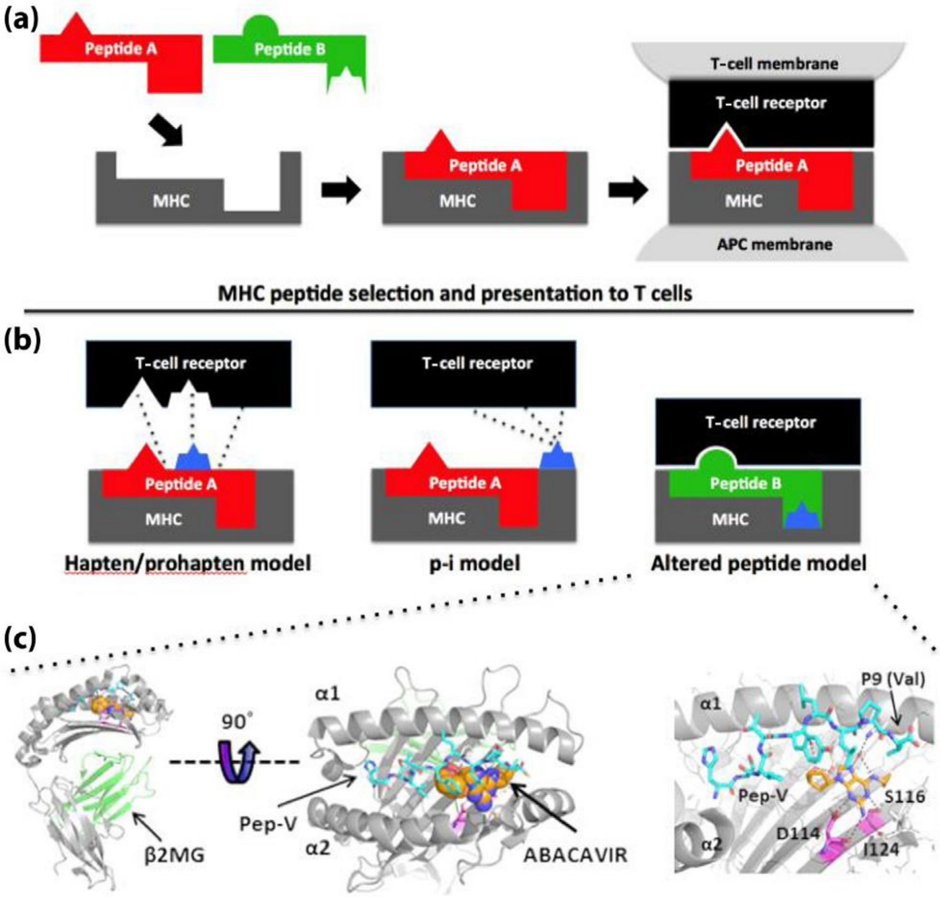


FIGURE 21.4 **Models of T cell activation by small-molecule antigens.** (a) Peptide selection and presentation by MHC. Peptide antigens are bound to the MHC protein in the intracellular environment and expressed on the surface of the antigen-presenting cell. The specificity of the MHC-peptide interaction is determined by the amino acid sequence of the MHC binding cleft and results in the selection of a distinct repertoire of bound peptides. In the example shown, peptide A is able to bind MHC but peptide B is not; thus, B is excluded from the repertoire of ligands presented in the context of this HLA allotype. The interaction of the MHC-bound peptide and the T-cell receptor, along with costimulatory signals, elicits an immune response. (b) Mechanisms of T-cell activation by small molecules. Three models have been proposed to explain T-cell stimulation by small-molecule pharmaceuticals. The hapten/prohapten model postulates that the drug binds to an intracellular protein that then undergoes antigen processing to generate haptenated peptides. These haptenated peptides are incorporated onto and presented by MHC. The haptenated-peptide is recognized as a neo-antigen to stimulate a T-cell response. The p-i model proposes that a small molecule can directly stimulate T cells in a peptide-independent fashion. The altered peptide model postulates that a small molecule can bind noncovalently to the MHC binding cleft to alter the specificity of peptide binding. This results in the presentation of novel peptide ligands to elicit an immune response. (c) The abacavir-HLA-B*57:01 interaction abides by the altered peptide repertoire model. Shown is the crystal structure of the HLA-B*57:01 (gray) oriented with the peptide binding groove facing up in panel C1 and as viewed from above in C2. Abacavir is represented as colored spheres: orange for carbon, blue for nitrogen, and red for oxygen. The peptide HSITYLLPV is shown in cyan. Hydrogen bond interactions between abacavir and HLA-B*57:01 and peptide are shown as black dashes. The amino acids that differ between HLA-B*57:01 and HLA-B*57:03, which does not participate in abacavir-associated hypersensitivity, are highlighted in magenta [55].

of penicillin derivatives to serum albumin [53] and the modification of endogenous proteins by the nitroso-sulfamethoxazole metabolite of sulfamethoxazole [54]. A time-delayed immune response is inherent to this concept, as presentation of haptenated peptides requires that the modified protein move through all steps of antigen processing, MHC loading, and traffic to the cell surface prior to T-cell interaction. It is noteworthy that examples of specific antibody responses (IgE and/or IgG) to the drug or reactive metabolite have been observed.

21.4.2 The p-i Model

The p-i model postulates that some chemically inert drugs may bind noncovalently to the TCR or MHC protein in the absence of a specific peptide ligand to directly activate T cells. This theory is supported by evidence that certain drugs are able to elicit T-cell responses following glutaraldehyde fixation of APCs, which eliminates intracellular antigen processing. It is also supported by evidence that, in some instances, T-cell responses are elicited within seconds of drug exposure, much more rapidly than would be expected if antigen processing were required [44,56,57]. The finding that inhibition of the metabolism of a drug to a chemically active molecule promotes the T-cell response in some cases suggests that inert drug compounds participate in these reactions [38]. Additionally, cell culture data showing that some drug-induced T-cell responses are abrogated when cells are washed to remove the drug implies that the chemical interactions involved are noncovalent [44,56]. The p-i model might explain DHSs that are observed at first encounter with a drug without the sensitization phase required for reactions adhering to the hapten/prohapten concept [52,59]. Examples of DHSs thought to occur via the p-i model include those for lidocaine, lamotrigine, and sulfamethoxazole.

21.4.3 The Altered Peptide Repertoire Model

The altered peptide repertoire concept postulates that small molecules may occupy sites within the peptide binding groove of MHC proteins and thereby change the chemistry and topography of the binding cleft. This, in turn, alters the specificities of MHC-peptide binding and results in selection of self-peptide antigens that are distinct from those normally bound by the unaltered MHC protein [9,10,60]. The specificity of the MHC-drug interaction is integral to this model, and this concept likely explains the numerous reports of strong associations between certain MHC alleles—often only separated from closely related alleles by micropolymorphisms in the binding cleft—with drug-specific DHS [45,47]. Further, recent work has demonstrated that this mechanism is central to the pathogenesis of abacavir hypersensitivity and carbamazepine-induced SJS/TEN in the context of HLA-B*57:01 and HLA-B*15:02, respectively [55,60,61]. These specific examples are discussed at length in the subsequent sections of this chapter.

21.5 HLA AND HYPERSENSITIVITY REACTIONS

Numerous reports in the past decade have described associations between HLA allele carriage and DHS (Table 21.2). They suggest that there exists an opportunity to predict which patients will suffer a DHS in response to drug exposure and to implement screening tests in the clinic to prevent these reactions. Of the reported associations, those involving abacavir, carbamazepine, allopurinol, nevirapine, and AC have been best characterized.

21.5.1 Abacavir

Abacavir is a nucleoside reverse-transcriptase inhibitor that is used in combination with other antiretroviral agents for the treatment of HIV-1 infection. In initial studies it was described that 5–8% of patients developed an AHR within a day and out to 6 weeks following abacavir initiation. AHR was characterized by fever, malaise, gastrointestinal and/or respiratory symptoms [62]. Rash, which is a common and early manifestation of many DHS, is absent in up to 30% of patients with abacavir hypersensitivity and often occurs later in the course of disease [63]. This nonspecific constellation of symptoms mimics the features of many common infections, reactions to other drugs, or a general inflammatory state, as seen with immune restoration following initiation of HIV-1 treatment. It therefore may pose a diagnostic challenge to the clinician. Immediate discontinuation of abacavir is mandatory, and reexposure elicits rapid return of symptoms, which are often more severe than the initial episode and potentially life threatening.

In 2001, it was observed that abacavir hypersensitivity reactions (AHRs) occur more frequently in persons of Caucasian ancestry as opposed to black or Asian individuals [64]. Subsequent studies demonstrated an association between AHR and the MHC class I allele, HLA-B*57:01 [65,66]. The original study involved a recombinant mapping strategy to refine the association to HLA-B*57:01, given the strong LD with HLA-C*06:02 and HLA-DRB1*07:01 observed in Caucasian populations.

HLA-B*57:01 is most prevalent in persons of European descent (5–8% carriage rate) and less frequently found in persons of African American descent (2.4% carriage rate) or other ethnic groups [67] (Figure 21.5). This is consistent with the hypothesis that HLA-B*57:01 expression is linked to AHR. The immunologic basis of AHR was proven through the use of epicutaneous patch-testing studies that demonstrated a marked response to abacavir when applied to the skin of hypersensitive individuals [51,68,69]. Additionally, *ex vivo* studies demonstrated that CD8+ T cells derived from abacavir-hypersensitive patients proliferate and secrete proinflammatory cytokines in response to abacavir stimulation of HLA-B*57:01 expressing APCs, which further supports the concept that MHC-T cell interactions are mechanistic for AHR [70,71]. Seminal studies include the PREDICT-1 trial, which randomized nearly 2000 HIV-positive patients, most of whom were Caucasian, to undergo either prospective HLA-B*57:01 screening with subsequent exclusion of abacavir therapy for HLA-B*57:01 positive patients or abacavir initiation with close clinical monitoring and retrospective HLA-B*57:01 genotyping for patch test–confirmed AHR cases. Pretreatment HLA-B*57:01 screening eliminated patch test–confirmed AHR (0% AHR incidence in prospective screening group vs. 2.7% AHR incidence in controls) with a 100% negative predictive value [68]. The SHAPE trial followed soon thereafter and showed that HLA-B*57:01 screening was 100% sensitive as a marker for immunologically confirmed AHR in black patients [69]. In both studies, the positive predictive value of HLA-B*57:01 carriage for the development of AHR was ~50%, suggesting that

FIGURE 21.5 **Frequency of HLA alleles across diverse populations.** HLA carriage frequency for key HLA-B alleles associated with drug hypersensitivity show marked variation across different ethnic populations. HLA carriage frequencies for HLA-B*57:01 were obtained from Nolan et al. [145]. Carriage frequencies for HLA-B*58:01 and HLA-B*15:02 were calculated from allele frequency data obtained from www.allelefrequencies.net. Note that within-country or within-region data are not shown and the final range indicated is inclusive of most studies or is taken from datasets containing >1000 subjects. *Source: adapted from Phillips et al. [201].*

the HLA-B*57:01 allotype is necessary but not sufficient for AHR [68,69]. It is not clear at present why some HLA-B*57:01 carriers are abacavir-tolerant, and this question is currently under investigation. Through these later studies that utilized patch testing to identify true immunologically-mediated AHR it was also determined that the window for presentation of true-immunologically mediated AHR was within 1.5 days to 3 weeks following abacavir initiation.

The mechanisms underlying AHR have recently been illuminated and are consistent with an altered peptide repertoire model in which abacavir undergoes metabolism-independent, direct and noncovalent interaction with the HLA-B*57:01 binding cleft to allow presentation of novel endogenous peptides (Figure 21.4(c)). The best evidence to support this hypothesis comes from two structural analyses of the abacavir-peptide-HLA-B*57:01 trimolecular complex. In each analysis, unmodified abacavir was shown to adopt an extended conformation within the HLA-B*57:01 peptide binding groove and extensive, noncovalent contacts with the HLA molecule; these contacts include residues within multiple binding pockets (C, D, E, and F pockets). This effectively abrogates peptide binding at these sites, although peptides were shown to maintain contact at the preferential anchor site in the B pocket of the binding cleft. These structures also reveal that bound peptides make very few contacts with the abacavir molecule itself [55,61]. In essence, abacavir association with the HLA-B*57:01 molecule changes the chemistry and topography of the peptide binding groove and results in presentation of an altered repertoire of T-cell epitopes to which the individual has not been tolerized. The "altered self" repertoire of peptides elicits a polyclonal T-cell response that clinically manifests as AHR [55].

The model just described explains many previous findings associated with AHR. First, the abacavir-HLA-B*57:01 molecular contacts identified in the crystal structures are consistent with mutagenesis data demonstrating that certain residues in the peptide binding cleft—namely Asp114 and Ser116—are required to elicit T-cell responses to the abacavir-peptide-HLA-B*57:01 trimolecular complex [45]. Second, elucidation of these contact sites provides an explanation for the absence of AHR seen in individuals with the closely related allotypes HLA-B*58:01, HLA-B*57:02, and B*57:03. In each of these cases, polymorphisms at key residues in the binding cleft prevent abacavir association, and thus peptide selection remains unchanged in the presence of the drug. Third, it has been shown that the peptides eluted from abacavir-treated APCs expressing HLA-B*57:01 in cell culture models display broad sequence diversity and include many neo-epitopes when compared to peptides eluted from abacavir-naïve cells [55,60,61]. Illing et al. demonstrated that 20–25% of peptides recovered from abacavir-treated HLA-B*57:01 APCs were distinct from those isolated from untreated cells, illustrating the dramatic shift in the repertoire of HLA-B*57:01-bound peptides in the presence of abacavir [61]. Further, analysis of the specificities of the T-cell responses elicited by abacavir-treated APCs expressing HLA-B*57:01 demonstrates polyclonal TCR usage consistent with broad diversity in the pool of peptides presented in this context [9,45,61,71]. The simultaneous requirement that the involved peptides be of high sequence diversity and be HLA-B*57:01-restricted is not reconcilable by the hapten/prohapten concept. HLA-B*57:01, B*58:01, B*57:02, and B*57:03 have extensive overlap in their binding specificities; thus, if hapten modification of peptide were central to AHR pathogenesis, we would expect to isolate one or only a few unique HLA-B*57:01-restricted peptides in elution experiments and observe a narrow range of TCR usage in response to stimulation by the abacavir-peptide-HLA-B*57:01 trimolecular complex. Additionally, no abacavir-haptenated peptides were identified in any study, as would be expected if AHR adhered to the hapten/prohapten concept. Finally, HLA-B*58:01, B*57:02, and B*57:03 alleles are found at relatively high frequencies among blacks, a population in which HLA-B*57:01 carriage and AHR are less frequently observed [61,147] (Figure 21.5). Thus, the epidemiologic data demonstrating that AHR is restricted to the HLA-B*57:01 allotype is explained by the specific association of abacavir with the HLA-B*57:01 molecule, as illustrated by structural studies.

21.5.2 Carbamazepine

Carbamazepine is an aromatic amine anticonvulsant used to treat epilepsy, bipolar disorder, and trigeminal neuralgia. It has been associated with multiple types of DHS, including SJS/TEN, maculopapular exanthema, and DIHS. Carbamazepine-associated ADRs typically manifest approximately 2–8 weeks after initiation of the drug and can include rash, fever, lymphadenopathy, and internal organ involvement [148]. These reactions are estimated to occur in 1–6 of every 10,000 individuals receiving this drug in European populations [92].

However, the prevalence of carbamazepine-associated ADRs in persons of Southeast Asian descent is approximately ten-fold higher than in Europeans [10,78]. In 2004, Chung et al. demonstrated the first association of carbamazepine-induced ADRs with a specific HLA genotype. Remarkably, their study revealed that the HLA-B*15:02 allele was present in 100% of Han Chinese patients with carbamazepine-associated SJS/TEN, as compared to only 3% of carbamazepine-tolerant controls and 8.6% of the general population. Based on these data, the negative predictive value of HLA-B*15:02 for carbamazepine-associated SJS/TEN approximates 100% [78]. Multiple subsequent studies have confirmed the association of the HLA-B*15:02 allotype and carbamazepine-induced SJS/TEN in Chinese, Thai, Malaysian, and Indian populations [79-84,149] (Table 21.2).

In 2009, Chen et al. demonstrated that prospective screening for HLA-B*15:02 positivity among 4855 Han

Chinese patients and subsequent avoidance of carbamazepine in these individuals eliminated cases of carbamazepine-induced SJS/TEN in this group. Based on historical incidence rates, the authors estimated that ten cases of carbamazepine-associated SJS/TEN would have (0.25%) developed in the absence of HLA-B*15:02 screening; thus their report supports a role for pretreatment HLA-B*15:02 genotyping prior to initiation of carbamazepine [150].

The observation that not all HLA-B*15:02 carriers develop hypersensitivity in response to carbamazepine exposure prompted Ko et al. to characterize the TCR repertoire derived from patients with carbamazepine-associated SJS/TEN. These studies demonstrated that a dominant TCR clonotype, VB-11-ISGSY, was present in clinical samples from 84% of HLA-B*15:02–positive patients with active carbamazepine-induced SJS/TEN and 14% of healthy, carbamazepine-naïve controls. Interestingly, this clonotype was absent in all carbamazepine-tolerant controls, including two HLA-B*15:02 carriers. Cell culture experiments demonstrated that T cells derived from individuals who were carbamazepine naive but positive for HLA-B*15:02 and VB-11-ISGSY acquired a cytotoxic phenotype following stimulation with carbamazepine. It was also demonstrated that these responses were blocked with the addition of a VB-11-ISGSY–specific antibody. These studies imply that, in the case of HLA-B*15:02-restricted carbamazepine-SJS/TEN, the presence of both the HLA-B*15:02 allotype and a specific TCR clonotype is predictive of the development of carbamazepine-induced ADR [151]. There are likely other, as yet unknown, contributing factors given that some individuals with a history of carbamazepine SJS/TEN in this study were found to be negative for both HLA-B*15:02 and the VB-11-ISGSY TCR clonotype.

HLA-B*15:02 is carried in <0.1% of the Caucasian population (Figure 21.5). More recently, carriage of the HLA-A*31:01 allele has also been identified as predictive of carbamazepine-induced SCAR in persons of Northern European ancestry [92] (Table 21.2). In a GWAS of 145 patients with carbamazepine-induced hypersensitivity (including SJS/TEN and other DIHSs) and 257 control patients, McCormick et al. demonstrated that the presence of the HLA-A*31:01 allele predicted the development of carbamazepine-induced SCAR with an odds ratio of 9.12 ($p = 1.0 \times 10^{-7}$; test sensitivity 26% and specificity 96%) [92]. This association was also demonstrated in Japanese and Korean patients [93,94,152]. In the Japanese population, it is estimated that HLA-A*31:01 carriage is 60.7% sensitive and 87.5% specific as a predictor of carbamazepine-induced SCAR [94]. It is estimated that the prevalence of HLA-A*31:01 carriage is 2–5% in Northern Europeans, 7% in Han Chinese, 7–12% in Japanese populations, and 5% in persons of Korean ancestry (see www.allelefrequencies.net).

In 2012, Yip et al. published a meta-analysis of 23 studies describing associations between carbamazepine-related cutaneous ADRs and HLA genotypes across multiple populations [153]. The aggregate data included HLA allotype information on 690 patients with carbamazepine-related cutaneous ADRs, 1585 carbamazepine-tolerant controls, and 7056 population controls. Their findings demonstrate that, in persons of Asian descent, carbamazepine-SJS/TEN and HLA-B*15:02 carriage are associated with a pooled odds ratio (OR) of 113.4 (95% $\text{CI} = 51.2 - 251.0$, $p < 1 \times 10^{-5}$). These results imply that HLA-B*15:02 positivity is 96% sensitive and 88% specific as a predictor of carbamazepine-induced SJS/TEN in this population. The calculated positive and negative predictive values were 1.8% and 100%, respectively, and it is therefore estimated that the number needed to screen to prevent one case of carbamazepine-associated SJS/TEN is 461 in persons of Asian ancestry.

Unlike the association of HLA-A*31:01 with multiple phenotypes of carbamazepine-DHS in Caucasians, there has not been a convincing association between carbamazepine-induced HSS or MPE and HLA-B*15:02 carriage in Caucasians and this is likely driven by the fact that the prevalence of HLA-B*15:02 is rare in this population. Yip et al. also confirmed the association between HLA-A*31:01 positivity and carbamazepine-related cutaneous ADRs with a pooled OR of 9.5 (95% $\text{CI} = 16.1 - 13.9$, $p < 1 \times 10^{-5}$) [153]. In subgroup analyses, it was shown that HLA-A*31:01 carriage was 58% sensitive and 87% specific as a predictor of carbamazepine-associated ADRs in the Japanese population, and 26% sensitive and 96% specific in Caucasians.

With regard to the molecular mechanisms underlying carbamazepine-associated ADRs, *in vitro* studies have shown that carbamazepine presentation to T cells in the context of the HLA-B*15:02 protein is independent of intracellular drug or antigen processing, but does require peptide binding to stabilize the class I MHC complex on the cell surface [47]. Interestingly, similar experiments involving APCs that express other members of the HLA-B75 family, which includes HLA-B*15:02, demonstrated T-cell responses in the context of carbamazepine presentation by these related allotypes. This finding suggests that the HLA-B75 serotypes may share a common conformation or TCR that allows for carbamazepine binding [47]. Consistent with this laboratory data, carbamazepine-induced SJS/TEN has been observed in association with HLA-B75 serotypes B*15:08, B*15:11, and B*15:21 in Indian, Japanese, and Korean cohorts [89,90,149] (Table 21.2). The region of carbamazepine association with HLA-B*15:02 maps to the B pocket of the peptide binding groove with a likely primary contact at the Arg62 residue—a conserved amino acid among B75 serotypes. Additional contacts at the Asn63, Ile95, and Leu156 residues also likely participate in carbamazepine-B*15:02 interactions, as mutagenesis studies demonstrate reduced affinity carbamazepine binding in their absence [47]. These findings are consistent with a direct, non-covalent and metabolism-independent mechanism of carbamazepine association with the HLA-B*15:02 molecule.

Analysis of peptides eluted from carbamazepine-treated APCs expressing HLA-B*15:02 demonstrated that 15% of isolated peptides were distinct from those obtained in untreated cells [61]. This finding is similar to that of the abacavir-B*57:01-peptide interaction and suggests that the altered peptide repertoire model may also be etiologic for carbamazepine-induced SJS/TEN. Additional work is needed to precisely define the nature of carbamazepine-HLA-B*15:02–peptide interactions.

Multiple questions remain regarding the genetic mechanisms that contribute to carbamazepine-induced ADRs. For example, a growing body of data suggests that the ADRs associated with carbamazepine exposure in the context of HLA-A*31:01 are phenotypically distinct from those elicited in the context of HLA-B*15:02. HLA-A*31:01 positivity appears to be associated more frequently with DRESS/DIHS/HSS and maculopapular exanthema (MPE), whereas HLA-B*15:02 carriage is associated with more severe cutaneous reactions such as SJS/TEN in Asian populations [92,154]. SJS/TEN, DIHS/DRESS/DHS, and MPE are distinct syndromes, so this may not be surprising; however, the mechanisms underlying this discrepancy are not clear at present. Study design may be important, and, in particular, discrepancies may result from studies that have used GWAS or SNP approaches to identify HLA associations without full high-resolution HLA A B C and DR/DQ typing. These methodologies may miss important associations, particularly those due to the non-specificity of LD within HLA. Further, numerous reports have demonstrated examples of carbamazepine-induced SJS/TEN in HLA-B*15:02–negative patients, which suggests that other HLA class I and particularly HLA-B alleles may be important [153,155,156]. This indicates that additional factors that may be associated with this disease are yet to be identified.

21.5.3 Allopurinol

Allopurinol is a xanthine oxidase inhibitor that is used to treat hyperuricemia and is associated with DIHS and SJS/TEN in some patients. The first report of a potential genetic association between allopurinol administration and observed ADRs occurred in 1989 when it was shown that the AW33 and BW58 loci were prevalent in Southern Chinese patients with cutaneous manifestations of allopurinol hypersensitivity [72]. This observation was followed many years later by a case-controlled GWAS that identified the HLA-B*58:01 genotype as strongly associated with allopurinol-induced SJS/TEN in the Han Chinese population. In this report, the HLA-B*5801 allotype was present in 100% of cases of allopurinol-SJS/TEN/DRESS/DIHS/HSS, 15% of allopurinol-tolerant patients, and 20% of healthy controls [73]. These findings have since been replicated in Japanese, Thai, and Korean populations [74,75,104,157,158] (Table 21.2). However, the association between HLA-B*58:01 carriage and allopurinol-SJS/TEN was found to be less robust in Caucasian populations, a group in which the prevalence of the HLA-B*58:01 allele is much lower (1-6% carriage rate in Caucasians as compared to 15% in Han Chinese) (allele-frequencies.net and Figure 21.5). In a European cohort, only 61% of patients with allopurinol-induced SJS/TEN carried the HLA-B*58:01 gene, suggesting that additional genetic factors might contribute to the development of allopurinol ADRs in this group [101].

In 2011, Genin et al. conducted a GWAS using >500 sera collected from patients enrolled in the RegiSCAR database, a European registry of samples collected from patients with SCARs across the SJS/TEN spectrum. This group included 57 patients with SJS/TEN following allopurinol exposure. A study by Genin et al. identified six SNPs that were significantly associated with allopurinol-induced SJS/TEN, all of which were in LD with the HLA-B loci [76]. Similarly, a 2011 GWAS analysis of Japanese patients with allopurinol-SJS/TEN identified multiple SNPs with strong association to this ADR, some of which were in complete LD with HLA-B*58:01 [105]. Interestingly, both studies identified SNPs found in high prevalence in patients with allopurinol-induced ADRs that overlap genes known to be associated with autoimmune inflammatory conditions (psoriasis, rheumatoid arthritis) and immune function [105,159-161]. Importantly, studies of allopurinol-related ADRs in these European populations show that the association with HLA-B*58:01 is significant but incomplete, which may be due to the lower frequency of HLA-B*58:01 carriage in these groups and/or additional contributing factors that have not been identified [77].

The mechanisms of allopurinol-induced ADR in the context of HLA-B*58:01 expression have not yet been elucidated, and functional studies have been hard to replicate. Unlike carbamazepine and nevirapine, where clinical phenotype and ethnicity seem to be important drivers of the HLA association, HLA-B*58:01 has been associated with both the SJS/TEN and DIHS/DRESS/HSS phenotype across different populations. It is predicted that, as with abacavir and carbamazepine, residues in the antigen binding cleft of the HLA molecule are involved in the HLA-drug interactions. Similar to the exquisite specificity of HLA-B*57:01 for abacavir hypersensitivity and tolerance in patients with closely related B17 serotype alleles such as HLA-B*57:03, B*57-02, B*58:01, HLA-B*58:02, there is a closely related allele that is not associated with allopurinol hypersensitivity and differs from the HLA-B*58:01 allele at six amino acids, three of which are located in the peptide binding groove. Although the F pocket of the peptide binding groove is predicted to be compatible with allopurinol binding, allopurinol is a smaller molecule than the other drugs involved in

DHS. More recent functional studies suggest that it may be allopurinol's metabolite oxypurinol which mediates DHS however the exact mechanisms of this interaction remain to be defined [162].

21.5.4 Nevirapine

Nevirapine (NVP) is a nonnucleoside reverse-transcriptase inhibitor that is part of combination antiretroviral therapy for the treatment of HIV-1 infection. Approximately 5% of patients will develop DHS within the first six weeks following initiation of NVP therapy. Reactions often consist of rash of varying severity (including SJS/TEN), fever and/or hepatitis, and, in rare cases, they can be fatal [163,164]. Observational studies have noted multiple host and environmental factors that influence the likelihood and severity of NVP-induced ADRs. Risk factors for severe disease that have been shown in some include prolonged exposure to any antiretroviral therapy, co-infection with hepatitis B or C viruses, and abnormal serum hepatic transaminase levels at baseline. Interestingly, lower CD4+ T-cell counts prior to initiation of NVP have been shown to be protective against the development of NVP-associated ADRs; however, more recent studies have suggested that this effect may be less important when switching to nevirapine in patients who are virologically suppressed [165-171].

Deciphering the genetic variants that influence risk of NVP-associated ADRs is not straightforward, and the cumulative data indicate that multiple genes associated with immune function and drug metabolism predispose to specific manifestations of NVP hypersensitivity in specific populations. In 2005, it was shown that the combination of higher baseline CD4% (CD4% T cells $\geq$25% of total) and the presence of the HLA-DRB1*01:01 allele is significantly associated with NVP-rash associated hepatitis in an Australian cohort of HIV-infected patients, suggesting that lower CD4% may significantly abrogate specific phenotypes of NVP-DHS [107]. Subsequent studies also demonstrated an association between HLA-DRB1*01:01 carriage and NVP-related hepatic and cutaneous reactions in other Caucasian populations [108,115]. Conversely, the class I MHC allele HLA-Cw8 was identified in Sardinian and Japanese populations in association with NVP-induced hypersensitivity, and the HLA-B*35:05 and HLA-Cw*04 variants were shown to be involved in isolated cutaneous NVP reactions in African Americans, Thais, and Han Chinese [108-112,116,117].

In 2011, Yuan et al. published the results of a large retrospective case-controlled study in which they investigated the genetic variants associated with NVP-related hypersensitivity in 276 cases from 11 countries worldwide. Although their study reported only 2-digit HLA typing, their findings support a relationship between carriage of certain class I MHC alleles—namely, HLA-B*35 and HLA-Cw*04—and the development of cutaneous NVP-related hypersensitivity in Asian populations (Table 21.2). They also found that, among whites, HLA-DRB1*01 positivity is associated with increased prevalence of hepatic and/or systemic NVP-induced DHS but not with isolated cutaneous reactions. There was no association with NVP-DHS and HLA-DRB1*01 carriage among blacks or Asians, two groups in which this allele is infrequently present. However, a subsequent South African case-control study that included high-resolution HLA ABC and DR typing in patients who developed grade 3/4 hepatitis within three months of starting NVP versus those tolerating NVP for at least three months showed an association with HLA-DRB1*01:02, an HLA class II MHC allele with a high degree of structural similarity to HLA-DRB1*01:01 [172].

More recently, a new association was reported between HLA-C*04:01 and NVP-SJS/TEN ($n = 33$) in a case-control study of NVP-treated HIV patients in a Malawi cohort consisting of 117 patients with NVP-DHS and 151 age-, sex-, and gender-matched controls [100]. Interestingly, polymorphisms in CYP2B6, the main cytochrome p450 isoform involved in NVP metabolism that shows genetic variation, was shown to be associated with increased risk of NVP-induced cutaneous ADRs in blacks and whites [108]. Additionally, in a GWAS analysis of 72 Thai patients with NVP-related ADR, it was observed that two SNPs located within the CCHCR1 gene, which regulates keratinocyte proliferation and is known to be associated with psoriasis, are predictive of NVP-induced rash [117].

These findings are similar to those showing a relationship between CCHCR1 and allopurinol hypersensitivity as discussed in the previous section. Because of the high LD between many of these SNPs and HLA-B and C alleles, they should be interpreted with caution because the likely true association is HLA-related. Without mapping the region at risk, it is possible that these associations may be missed. This is similar to the story of the abacavir and HLA-B*57:01 association, where a haplotypic marker in high LD with HLA-B*57:01, HCP5 (rs2395029), is present in most but not all HLA-B*57:01 patients with patch test–confirmed abacavir hypersensitivity; the presence of this tag SNP may vary across the population involved [173]. Taken together, these data indicate that NVP-DHS has complex associations that appear to be specific to phenotype and ethnicity and may result from a complex interplay of immunologic, genetic, and metabolic factors.

21.5.5 Amoxicillin-Clavulanate

The co-formulation of amoxicillin, an aminopenicillin antibiotic, and the beta-lactamase inhibitor clavulanic acid is one of the most frequently prescribed antimicrobials for the treatment of bacterial infections. While the overall side-effect profile of amoxicillin-clavulanate (AC) is favorable, this drug has been identified as a common cause of drug-induced liver injury (DILI) with highly variable clinical manifestations [42,174-176]. Hepatic injury may occur in a cholestatic, hepatocellular, or mixed pattern, and the onset of symptoms has been reported to range between 3 and 59 days following initial drug exposure [175,177]. Rarely, AC-DILI may progress to fulminant hepatic failure requiring liver transplantation or resulting in death. Age and duration of therapy have also been proposed to influence the phenotype of AC-DILI, with advanced age and longer treatment courses favoring the development of cholestatic or mixed patterns of hepatotoxicity [175,178].

Data suggest that both HLA class I and class II genetic variants contribute to AC-induced DILI. A Belgian study published in 1999 reported that the HLA class II haplotype DRB1*15:01-DRB5*01:01-DQB1*06:02 was present in 57% of 35 patients with cholestatic AC-DILI as compared to only 15% in population controls ($p<0.0002$) [119]. In 2000, a similar study performed in a small cohort of Scottish patients confirmed the association of cholestatic AC-DILI and HLA DRB1*15:01. DRB1*15:01 was present in 70% of 20 case patients versus 20% of controls, and it was shown to confer a 9.25 relative risk for the development AC-DILI in this analysis [120]. In concordance with these findings, a UK study published by Donaldson et al. reported that 53% of AC-induced DILI patients carried HLA DRB1*15 alleles compared to 33% of AC-tolerant patients and 30% of population controls ($p=0.002$). Also reported was a potential protective role for the HLA DRB1*07 family of alleles, as these genes were observed at reduced frequencies in AC-DILI patients compared to controls.

These studies were followed in 2011 by a GWAS analysis that included 201 European white, US, and Spanish patients. It was demonstrated that AC-DILI is strongly associated with the SNP rs9274407 that is correlated with the HLA haplotype DRB1*15:01-DQB1*06:02. Additionally, this analysis revealed an independent association with the SNP rs2523822, a known tag for the class I HLA allele A*02:01 among Northwestern Europeans. High-resolution HLA genotyping confirmed these HLA associations in US and Northwestern European populations, but failed to show an association between AC-DILI and HLA-A*02:01 in persons of Spanish descent. These findings likely reflect LD patterns, as it is known that rs2523822 and HLA-A*02:01 exist in strong LD among Northwestern European populations but not among Southern Europeans. Moreover, the associations and haplotypes may also be dependent on ethnicity and subphenotypes [121,178].

Epidemiologic data suggests that the clinical features of amoxicillin-clavulanate-associated DILI may correlate with ethnic background. For example, Lucena et al. demonstrated that 36% of Spanish AC-DILI cases are characterized by hepatocellular injury, 31% by cholestatic damage, and 33% by a mixed hepatocellular/cholestatic pattern [121,175]. This is in contrast to French and Belgian AC-DILI cases, in which a cholestatic pattern of liver injury predominates in 66–74% of cases and hepatocellular damage occurs in only 11–13% of cases [121,175,178]. Stephens et al. postulated that differential HLA associations might underlie this phenotypic variation. To investigate this possibility, they performed class I and class II HLA genotyping for 75 Spanish AC-DILI cases of which 37% were characterized by a hepatocellular toxicity pattern. In this analysis, HLA-A*30:02 and HLA-B*18:01 were associated with hepatocellular liver injury (OR 6.7 and 2.9, respectively), although the latter association did not reach statistical significance. Conversely, carriage of the class II haplotype DRB1*15:01-DQB1*06:02 was significantly associated with cholestatic or mixed AC-DILI in this group with an odds ratio of 3.0 ($p=0.014$). Interestingly, Stephens et al. note that HLA-A*30:02 and HLA-B*18:01 are both present in the MHC haplotype HLA-A*30:02-B*18:01-Cw-05:01-DRB1*03:01-DQB1*02:01, which is the third most common MHC haplotype among Southern Europeans and is less frequently found in Northern European populations [178]. Taken together, these findings suggest that different HLA class I and class II risk alleles and HLA class I/II pairings are associated with phenotypically distinct presentations of AC-DILI, and that the frequencies of allelic carriage among ethnically distinct populations determine the clinical features of AC-DILI in each group.

AC is widely used for short-course treatment, and therefore the clinical application of this body of data is not clear at present. In the 2011 GWAS of AC-DILI cases, Lucena et al. estimated the positive predictive value to be 0.1% for carriage of both HLA-A*02:01 and DQB1*06:02 in Northwestern Europeans and 0.13% for carriage of both HLA-B*18:01 and DQB1*06:02 among Spanish populations. The strongest negative predictive value in this analysis was seen for the absence of HLA-A*02:01 in Northwestern Europeans. Thus, because of the overall rarity of AC-induced DILI, HLA typing based on known associations does not currently meet thresholds to warrant routine screening prior to AC therapy [121].

Of note, some of the HLA associations identified as possible contributors to the pathogenesis of AC-DILI are also associated with other liver diseases of varying etiologies. For example, the DRB1*15:01-DQB1*06:02 haplotype is strongly associated with primary sclerosing cholangitis and weakly associated with primary biliary cirrhosis. This allele might also confer a protective effect in type 1 autoimmune hepatitis. The HLA-DRB1*15 family has also been associated with nitrofurantoin- and halothane-induced hepatitis as well as with allergy to ragweed pollen [179]. More work is needed to determine the exact mechanisms of HLA-DRB1*15 alleles in these diseases as well as in AC-mediated DILI.

21.6 STRATIFIED APPROACHES TO PREVENT DRUG HYPERSENSITIVITY AND THEIR TRANSLATION INTO CLINICAL MEDICINE

In general, diagnostic tests to identify the specific drug cause of an ADR, including DHS, are imprecise. The ability to use stratified approaches to identify patients at risk for any ADR via pharmacogenetic screening prior to drug administration is an attractive concept given the lack of perfect diagnostic tests and the substantial morbidity and cost associated with DHS.

21.6.1 Criteria for Stratified Approaches

The criteria discussed in the following subsections applies to any pharmacogenomic stratified treatment approach; however, there are specific issues with regard to immunogenetics and HLA testing that will be discussed. From a cost and quality assurance standpoint, the increasing availability of accurate and accessible methods with rapid turnaround times (e.g., single allele PCR-based assays) has made these tests accessible to routine diagnostic laboratories. It is advantageous for multiple criteria to be satisfied in order for stratified approaches to be cost-effective and feasible for implementation into routine clinical practice.

21.6.1.1 The DHS Under Investigation Must be Prevalent and Severe so as to Warrant Screening

If the ultimate goal of investigation is the incorporation of specific screening and/or therapeutics into clinical practice, research should be targeted at DHS that result in an unacceptable rate of mortality, morbidity, hospitalization, or therapeutic changes. Minor DHS (e.g., transient mild rash) are not appropriate targets given that the costs associated with research and testing will exceed the cost of current strategies for medical management. In addition, even if a mild rash without systemic symptoms is associated with a specific HLA allele, we know from clinical experience that the vast majority of patients can continue treatment with symptomatic management using antihistamines and/or topical steroids. The disappearance of the rash despite continued treatment in these patients has been presumed to be associated with immunological tolerance.

Other important considerations are that the specific drug under investigation should be widely used and efficacious, and have an overall favorable side-effect profile. Generally, alternative therapies should be limited, less efficacious, associated with negative side effects, or require costly screening or clinical/laboratory monitoring.

21.6.1.2 Clear Diagnostic Criteria Must be Used to Define Putative HLA-Associated ADRs

Our experience with AHR highlights the importance of diagnostic precision. As noted previously, reliance on clinical criteria alone and, in particular, retrospective data to diagnose AHR results in a high rate of false-positive results due to the nonspecific nature of common presenting symptoms. In fact, results from blinded comparative trials to assess the efficacy and safety of antiretroviral therapies that include abacavir-containing regimens show that up to 7% of AHR clinical diagnoses occur in patients who were not receiving abacavir [180–182]. The introduction of epicutaneous patch testing to specifically identify immunologically-mediated cases of AHR substantially reduce diagnostic error and provide a foundation upon which to decipher the immunogenetic correlates of AHR [51,70].

It should be noted that the sensitivity of patch testing for any given drug varies according to clinical phenotype of the DHS and the implicated drug. Generally, the sensitivity of patch testing is less than 70%, although higher sensitivities have been noted for AHR (for which the diagnostic sensitivity as calculated from the PREDICT-1 study is estimated to be 87% [68]. Patch testing has also been associated with a higher sensitivity of carbamazepine-DIHS/DRESS/HSS and AGEP and a lower sensitivity for epidermal diseases such as FDE and SJS/TEN [51,183]. The lower sensitivity of patch testing for drug-induced FDE and SJS/TEN may reflect the presence of resident T cells or the characteristics of the compartment in which these T-cells (epidermal) versus the drug (dermal) reside, as well as the presence or absence of specific drug-metabolizing enzymes in the skin [184].

Additionally, a number of *in vitro* laboratory assays have been employed to complement clinical diagnosis and patch testing in an effort to define immune mechanisms of ADRs. These include lymphocyte transformation assays, in which T cells from hypersensitive patients are collected and induced to proliferate in the presence of the implicated drug, as well as *ex vivo* assays that measure T-cell function following drug exposure, such as enzyme-linked immunospot (ELISpot) and intracellular cytokine release assays (Rive et al. [34]). While these assays are of some collective use in helping to support the diagnosis of an immune-mediated ADR, their sensitivity remains less than 100% and they have no role in pre-therapy screening because they rely on T-cell sensitization to the drug in question prior to testing. Also, because of the severity of the drug reactions involved, a negative diagnostic test is never used as the sole basis for rechallenge to any drug. Given the 55% PPV of HLA-B*57:01 for abacavir hypersensitivity, 45% of patients positive for HLA-B*57:01 are expected to tolerate abacavir. It is of interest, therefore, that abacavir treatment of PBMCs isolated from healthy, abacavir-unexposed healthy blood donors results in a CD8+ T-cell response in 100% of 10–14 day cultures [45]. This is in contrast to abacavir-specific patch test studies, which are consistently negative in HLA-B*57:01 positive, abacavir-naïve patients [185].

21.6.1.3 The Screening Test Must Have Sufficient Predictive Value to Ensure That a Positive (or Negative) Result Accurately Reflects the Likelihood of an ADR

Although multiple HLA alleles have been reported in relation to DHS, only a handful of these reports demonstrate odds ratios that strongly favor association. Importantly, a high negative predictive value (NPV) is critical to ensure drug safety. Additionally, the number needed to test (NNT) to prevent one case of DHS must be appropriately low to allow for cost- and resource-effective screening across a population. For some drug reactions, the combination of a prevalent HLA allele and the low prevalence of the DHS can mean a much lower positive predictive value for the screening test and an impractical number of cases needed to test to prevent one case of DHS (e.g., flucloxacillin-associated DILI).

21.6.1.4 The Screening Test Must Maintain Adequate Predictive Values Across a Defined Population of Patients

A corollary to this criterion is that the HLA allele must be sufficiently prevalent in the population under study. For example, as discussed previously, the presence of HLA-B*15:02 is strongly associated with risk of carbamazepine-induced SJS/TEN in persons of Asian descent, owing to the relatively high prevalence of this allele in this population (10–15% in Han Chinese; NPV 100%, PPV 1–4%, NNT 461 [153]. These results are not, however, generalizable to Caucasian populations in which the rate of HLA-B*15:02 carriage is substantially lower, as shown in Figure 21.5 (allele prevalence <1% in Caucasians; estimated NPV <100%, NNT 10,000) [34,153,186]. Conversely, the HLA-B*57:01 association with abacavir hypersensitivity is sufficiently robust so as to warrant screening of all patients prior to initiation of therapy, regardless of ethnic background (NPV 100%, PPV 55%, NNT 13 across populations) [34,68,69,187].

The question remains as to whether or not HLA-B*57:01 screening is cost-effective in certain populations in Africa and part of Southeast Asia, where the prevalence of HLA-B*57:01 carriage is <1% and there exists little migration or population admixture. Thus, careful definition of the target screening population ensures that the test maintains adequate predictive value in the clinical setting. It should be noted that stratification of patients based on race or reported ethnic background must be approached with some degree of caution given that patient phenotype does not always represent genetics, especially in populations with a high degree of genetic admixture.

21.6.1.5 The Screening Test Must be Available in Clinical Laboratories, Reproducible, Efficient, and Cost-Effective

Currently, high-resolution sequence-based typing is the gold standard for determining an individual HLA genotype. This method, while highly accurate, requires substantial technical infrastructure and expertise; until recently, it was primarily restricted to the research setting and tissue-typing laboratories at organ transplant centers. The demonstration that prospective HLA-B*57:01 screening is effective for the prevention of AHR, along with the subsequent recommendation for universal screening, has increased the market for HLA-typing resources, and multiple commercial laboratories are now performing allele-specific PCR-based tests in the United States and Europe, and a number of rapid and cost-effective assays now exist that deliver results within an acceptable turnaround time for the purposes of initiating antiretroviral therapy. Several technologies have been proposed to improve the cost and efficiency of HLA-B*57:01 identification, many of which have already been applied to HLA typing in other contexts.

HLA-B*57:01 belongs to the B17 family of alleles that also includes HLA-B*58 and at least nine different HLA-B*57 subtypes (HLA-B*57:01 through B*57:09). Within the B17 family, the HLA-B*58:01, HLA-B*57:02, and HLA-B*57:03 alleles are prevalent among diverse populations and share significant homology with HLA-B*57:01, varying only at 1–4 amino acids in the peptide binding groove. Notably, HLA-B*57:01 is the only allotype associated with AHR, and thus HLA screening in this context must discriminate between HLA-B*57:01 and these closely related alleles. In addition to high-resolution genotyping, PCR-based diagnostics have been developed to address this problem. Sequence-specific primer PCR (SSP-PCR) employs primers designed to amplify HLA-B*57:01 sequences but not closely related B17 sequences with high specificity (100%), sensitivity (99.4%), and reproducibility across multiple laboratories [188,189]. These protocols have also been modified to include a melting curve analysis for rapid identification of SSP-PCR products with equivalent accuracy to that of sequence-based assays (100% specificity and sensitivity) [190].

Although these PCR-based protocols currently require DNA extraction from whole blood prior to analysis, it is possible to batch samples in order to decrease costs and turnaround time. Additionally, efforts to optimize PCR parameters for use on whole blood and saliva samples are underway and, if successful, might markedly simplify and standardize these protocols for use in clinical laboratories [191,192].

One strategy to improve the cost and efficiency of PCR-based diagnostics employs serologic screening for any HLA-B*57 or B*58 allele prior to molecular testing. In 2006, Martin et al. demonstrated that flow cytometry using commercially available anti-B17 antibodies and whole blood samples from the HIV clinic accurately identified carriers of B17 alleles with 100% sensitivity. While this method does not differentiate HLA-B*57:01 from other B17 alleles, identification of individuals who do not carry a B17 allele would afford the physician the opportunity to safely start abacavir therapy in a timely manner, and would reduce the number of samples for which HLA tying is indicated. Martin et al. estimated that serologic stratification decreases the number of samples referred for molecular testing to approximately 10% of the total and therefore substantially reduces cost [193]. Similarly, Kostenko et al. developed an anti-B17 monoclonal antibody, 3E12, and demonstrated that labeled 3E12 can be incorporated into multicolor FACS assays that are currently used for the routine assessment of T-cell subsets (CD4+ T-cell count) in HIV patients. This would provide information regarding B17 status without modification of laboratory workflow. Samples that test positive by this method would then undergo HLA genotyping to determine if the patient is positive for HLA-B*57:01 [194].

Alternative proposed strategies for HLA-B*57:01 screening have been investigated. These include identification of SNPs known to be in strong LD with HLA-B*57:01. The HCP5 SNP (rs2395029) was evaluated as a candidate for such analysis, but studies demonstrating incomplete concordance with HLA-B*57:01 across populations raise concerns about the utility of this marker in clinical practice as it would have a <100% negative predictive value [36,195]. Additionally, inspection of HIV-1 viral sequences for mutations associated with selection by HLA-B*57:01 cytotoxic T lymphocytes has also been evaluated as a potential screening tool. However, the strength of these associations was found not to be sufficient for introduction into clinical practice [196,197].

21.6.1.6 A Robust Clinical and Quality Control Infrastructure Must be in Place to Ensure Appropriate Test Administration and Interpretation of Results

Successful application of HLA screening tests that meet the criteria just given requires that the test be administered according to standardized protocols and that clinicians be able to accurately interpret test results to inform clinical decision making. Importantly, if widespread pharmacogenomic screening is to be introduced into clinical practice, consistency among commercially available products and testing facilities will need to be ensured.

21.6.2 Current Recommendations for HLA Screening

Despite numerous reports of HLA-associated drug toxicities, only work involving HLA-B*57:01 screening for AHR has been generally applied in a routine clinical setting based on evidence based medicine and treatment guidelines. It is currently recommended that HLA-B*15:02 screening for carbamazepine SJS/TEN be selectively applied to those populations at higher risk such as South-east Asians; moreover, HLA-B*58:01 screening for allopurinol SJS/TEN and/or DRESS/DIHS/HSS is still under study/consideration in most jurisdictions. The technology exists to create quality-assured low-cost tests with reasonable turnaround times. However, for most drugs there are still many hurdles to overcome prior to their routine testing in clinical practice. The notable success with abacavir—the high prevalence of the DHS, the 100% negative predictive value of HLA-B*57:01 for AHR, the high positive predictive value, the generalizability across ethnicities, and the high prevalence of allele carriage in Caucasian populations combined with convergent clinical and scientific evidence to support the exquisite specificity of HLA-B*57:01 for AHR—has created a roadmap from discovery to translation. Following the PREDICT-1 and SHAPE trials in 2008, both of which demonstrated the efficacy of HLA-B*57:01 screening for the prevention of AHR, the FDA issued a black-box warning against the use of abacavir in patients known to carry the HLA-B*57:01 allele. Multiple groups, including the US FDA and Department of Health and Human Services, the European Medicines Agency, the Clinical Pharmacogenetics Implementation Consortium, and international HIV/AIDS organizations, now recommend universal screening for HLA-B*57:01 carriage in any patient for which abacavir therapy is under consideration, and exclusion of abacavir therapy for any patient with a positive test [187,198-201]. In resource-limited settings where HLA-B*57:01 genotyping is not available and its prevalence in the population is near zero, some groups have advocated for initiation of abacavir therapy with close clinical monitoring for symptoms of AHR and its prompt discontinuation if these symptoms develop [187].

Similarly, the discovery of the HLA-B*15:02 association with carbamazepine-induced SJS/TEN in Asian populations prompted the FDA in 2007 to recommend genetic screening in persons of Asian ancestry prior to initiation of carbamazepine [202]. This recommendation has since been modified to include persons “at risk” of carbamazepine-induced SJS/TEN as determined by the prevalence of HLA-B*15:02 carriage in the population (Figure 21.5). Specifically, screening is recommended for persons of Han Chinese descent and those originating from Vietnam, Cambodia, the Reunion Islands, Thailand, India, Malaysia, and Hong Kong. Further, if a patient is found to carry the HLA-B*15:02 gene, regardless of ancestry, carbamazepine therapy is contraindicated [186]. Additionally, multiple studies have demonstrated that not all carbamazepine-induced SJS/TEN can be attributed to HLA-B*15:02 carriage (Table 21.2) and thus careful clinical monitoring is recommended for all patients treated with carbamazepine regardless of HLA genotype [153,186]. The strong association of allopurinol induced

DRESS/DIHS/HS/SJS/TEN with HLA-B*58:01 is now under consideration by many jurisdictions including the Taiwanese Bureau of National Health Insurance for recommendation for routine HLA-B*58:01 genotyping prior to allopurional prescription. The FDA has currently not made a recommendation for HLA-B*58:01 screening prior to allopurinol prescription. A large Taiwanese clinical trial investigating whether prospective HLA-B*58:01 screening will reduce the incidence of allopurinol-associated ADRs is currently underway [203]. For other drugs (e.g., flucloxacillin) screening appears neither cost-effective nor feasible—almost 14,000 patients would need to be screened to prevent one case of flucloxacillin-induced DILI. Other stratified screening approaches exist, such as HLA-B*57:01 testing in patients who have already developed suspected flucloxacillin-DILI cases in populations with a high prevalence of HLA-B*57:01 carriage (e.g., Caucasians). However, there is no current base of evidence to support this strategy.

21.7 THE FUTURE DIRECTION OF STRATIFIED MEDICINE IN DRUG-INDUCED HYPERSENSITIVITY

The translation of HLA-B*57:01 from its discovery to a routine test for it in HIV clinics to identify persons at risk of AHR and exclude them from abacavir treatment has created a roadmap for successful implementation of pharmacogenomic stratified medicine. Several challenges exist, however, when trying to replicate and fully execute this road map for other HLA-associated drug reactions. In particular the low positive predictive values, the fewer than 100% negative predictive values, and the lack of generalizability across different populations for many HLA-drug associations create concerns not only regarding lack of feasibility and cost-effectiveness, but more broadly in relation to patient safety if screening lead to a false sense of security and lowers clinical vigilance.

It is important that due diligence be applied to the study and interpretation of pharmacogenomic research on drug hypersensitivity. Newer approaches (e.g., GWAS and whole-exome sequencing) are now widely available, but they currently do not provide read lengths long enough to derive high-resolution sequence-based HLA typing. In addition, given LD patterns, caution should be applied when trying to impute an HLA association from a SNP or SNP pattern; moreover, SNP associations in isolation do not give sufficient information about the immunogenetic basis of DHS. For this reason, ancestral haplotype mapping of the region at risk remains the gold standard.

Continuing research promises to further define factors leading to the incomplete positive predictive value of a specific HLA class I or II allele or an HLA class I/II pairing for a drug syndrome. These likely comprise factors outside of the MHC and may lead to further clinical utility for stratified pharmacogenomic screening approaches. More aptly, however, they will provide great insights into the immunopathogenesis of drug hypersensitivity and other inflammatory diseases. The abacavir example has significantly furthered our understanding of the science of drug hypersensitivity and provided proof of concept for the altered peptide model. More recent evidence suggests that this model may extend to phenotypically distinct immunologically mediated adverse drug reactions (e.g., carbamazepine-associated SJS/TEN). Thus, it may be more broadly applicable to immunologically mediated ADRs and in particular T-cell–mediated syndromes where non-covalent interactions between the MHC and the drug are likely. Quite remarkably, it is possible that, through the utilization of currently available structural, biochemical, and functional approaches, the interaction between HLA-B*57:01 and abacavir, as well as the potential for the development of an HLA-B*57:01-restricted CD8+ T-cell–dependent reaction, may have been defined prior to this drug being used in humans. For reasons such as this, exciting future applications of stratified pharmacogenomics will include approaches to pre-clinically define interactions between HLA and drugs using a combination of structural, biochemical, and functional approaches like those recently defined for abacavir. Such approaches might be applied pre-clinically, at the time of initial drug development and design, before the use of drugs in humans as well as at the first sign of any ADR in the pre-marketing or early post-marketing phase of drug development.

Key Concepts in HLA and the Pharmacogenomics of Drug Hypersensitivity

- The HLA genes, in particular HLA-B, are the most polymorphic genes in the human genome. They encode the HLA class I and HLA class II proteins that bind and present peptide antigens to T cells. The interaction of T cells with the HLA-peptide complex elicits a T-cell immune response; thus, the HLA proteins are central to normal immune function. The specificity of HLA-peptide binding is determined by the amino acid composition of the HLA peptide binding groove. A growing body of data shows that HLA-restricted T-cell–mediated immune responses are involved in many adverse drug reactions.
- Multiple models have been proposed to describe the mechanisms of HLA-associated adverse drug reactions. These include:
  - The hapten/prohapten model, which is based on the concept that a drug or drug metabolite may covalently bind to an endogenous peptide and thereby create a neo-antigen that is recognized by T cells to trigger an immune reaction.
  - The p-i model, which hypothesizes that a non-covalent interaction between a drug and the HLA protein can directly activate T cells in a peptide-independent manner.
  - The altered peptide repertoire model, which posits that a drug may non-covalently bind to the peptide binding groove

of an HLA molecule to change the chemistry and shape of the peptide binding cleft. This results in the selection of a different repertoire of endogenous peptides from that selected in the absence of the drug. This altered repertoire includes novel antigens that are recognized by T cells to elicit an immune response. Strong evidence suggests that the altered peptide repertoire model is central to the pathogenesis of phenotypically distinct syndromes (e.g., abacavir hypersensitivity and carbamazepine-associated SJS/TEN).

- The use of high-resolution HLA genotyping is the current gold standard method for determining HLA associations in drug hypersensitivity reactions. Current research suggests that it is the HLA allele that is necessary but not sufficient for the development of hypersensitivity. Alternative methods include identification SNPs that are LD with HLA genes and their use as surrogate markers for HLA carriage. HLA associations defined by this approach, however, must be interpreted with caution in instances where the LD between the tag SNP and the HLA gene of interest is incomplete.
  High-resolution HLA typing with ancestral haplotype mapping is the current gold standard in specifically defining drug-HLA associations.
- Many associations have now been described between various T-cell–mediated DHS and class I and/or class II HLA alleles. In the case of the association of AHR and HLA-B*57:01, this has now been translated from discovery to a routine screening test in clinical practice and has created a roadmap for other drug–HLA associations. Even though most drugs are associated with several innate hurdles that are nonmodifiable, making translation infeasible, they provide many additional valuable insights into the immunopathogenesis of these reactions. For some drugs, such as carbamazepine, regulatory agencies such as the FDA have mandated changes to product labels to recommend risk stratification and screening of select populations at high risk for HLA-B*15:02 carriage prior to carbamazepine prescription. In the future, heightened understanding of the specific structural and functional interactions with drugs and the MHC will be key to developing strategies to preclinically predict drugs at risk for causing severe immunologically mediated ADRs and to inform safer drug development and design.

ACRONYMS

ADR	adverse drug reaction
AGEP	acute generalized exanthematous pustulosis
AHR	abacavir hypersensitivity reaction
DHS	drug hypersensitivity syndrome
DIHS	drug-induced hypersensitivity syndrome
DILI	drug-induced liver injury
DRESS	drug reaction with eosinophilia and systemic symptoms
GWAS	genome-wide association study
HLA	human leukocyte antigen
HSS	hypersensitivity syndrome
LD	linkage disequilibrium
MHCI	major histocompatibility complex class I
MHCII	major histocompatibility complex class II
MPE	maculopapular eruption
NNT	number needed to test/treat
NPV	negative predictive value
NVP	nevirapine
OR	odds ratio
PCR	polymerase chain reaction
PPV	positive predictive value
SCAR	severe cutaneous adverse reaction
SJS	Stevens-Johnson syndrome
SNP	single-nucleotide polymorphism
TCR	T-cell receptor
TEN	toxic epidermal necrolysis

22.1 OVERVIEW

Despite advances in the safety of therapeutic drugs over the past half century, adverse drug reactions (ADRs) remain a major problem in healthcare. ADRs are estimated to be the fourth leading cause of death in the United States [1], associated with more than 100,000 deaths annually, and they are responsible for approximately 7% of hospital admissions [2]. The financial burden associated with ADRs is staggering, with estimates as high as \$177 billion in treatment costs per year, representing up to 10% of gross health expenditures in the United States [3,4].

22.2 EPIDEMIOLOGY AND PUBLIC HEALTH IMPACT

Among ADRs, rare, serious drug-induced adverse events (SAEs) pose significant problems for patients, healthcare providers, payers, and regulators, and are an important element contributing to healthcare cost inflation. Examples of SAEs include hepatotoxicity, severe QT prolongation, rhabdomyolysis, serious skin rashes (e.g., Stevens-Johnson syndrome), acute renal failure, acute hypersensitivity, anemias/neutropenias, visual field loss, and vasculitis, among others. Although such severe adverse events are rare, their severity nonetheless often leads to reduced utilization of the associated drug(s), or their withdrawal from the market. Between 1976 and 2005, 28 drugs were withdrawn from the market, primarily due to rare hepatic, renal, or cardiovascular toxicity that was not anticipated from animal toxicity studies or from phase I–III clinical trials [5]. Thus, in addition to clinical costs, the financial losses caused by SAEs identified after market approval are compounded by the high and rising cost of drug development, currently estimated to be more than \$1.5 billion per approved drug.

Our focus in this chapter is on one of the most important categories of drug-induced severe adverse events. Severe hepatotoxicity, or drug-induced liver injury (DILI), is the most common reason for post-approval drug failures [5]. DILI, excluding acetaminophen associated injury, is estimated to be responsible for approximately 11% of all cases

Handbook of Pharmacogenomics and Stratified Medicine. http://dx.doi.org/10.1016/B978-0-12-386882-4.00022-0

of acute liver failure [6], with an estimated 200 DILI cases in the United States annually [5].

It is unclear how many different drugs are capable of causing DILI, but the most recent estimates are at least in the hundreds [7,8]. Among these, there are several that are the most highly represented: amoxicillin/clavulanate, diclofenac, flucloxacillin, isoniazid, nimesulide, sulfamethoxazole/trimethoprim, tetracyclines, and valproic acid. The fact that these are among the most frequent causes of DILI does not necessarily imply that they are particularly toxic, but it may be that they are very frequently prescribed. Overall estimates of the incidence of DILI range as high as 13.9 per 100,000 patients per year [9], but varies widely depending on the drug. For example, DILI due to valproic acid has been estimated to occur in as many as 1 in 500 patients in certain high-risk groups [10].

22.3 ETIOLOGY

The vast majority of DILI is due to idiosyncratic reactions not predictable from drug dosage/concentration [11], which has led to the suspicion that at least some of the risk for DILI is due to intrinsic genetic risk factors, some of which have already been identified. Many different drugs can cause DILI, with the precise pattern of injury varying among them, and even among patients with liver injury due to the same drug.

Typically, DILI reactions are classified as "hepatocellular" when the injury is believed to be focused on the hepatocyte and "cholestatic" when the damage is believed to occur at the hepatocyte canalicular membrane or further downstream in the biliary tree [12]. The precise mechanisms of either type of reaction are unclear; however, there is emerging evidence that both direct effects of the drug or its metabolites, and immune responses to injury, play a role.

Figure 22.1 shows a general model for how drugs might cause liver toxicity. As discussed in more detail below, it is thought that drug metabolism, or "bioactivation," may be part of the etiology of DILI [13]. Likewise, the ability of drugs to inhibit bile acid efflux from hepatocytes, either at the bile canalicular membrane or at the basolateral membrane, may contribute to bile acid congestion in the liver and lead to liver injury [14]. For at least some drugs, there is evidence that mitochondrial toxicity may be a contributing factor for DILI, perhaps by reducing the rate of hepatocyte regeneration [15]. Finally, there is considerable evidence from human genetic studies that adaptive immune mechanisms contribute to DILI, with both antigen presentation by the liver (through HLA Class I proteins) and recognition of antigen by professional antigen-presenting cells (APCs) implicated in the development of DILI for at least some drugs [16].

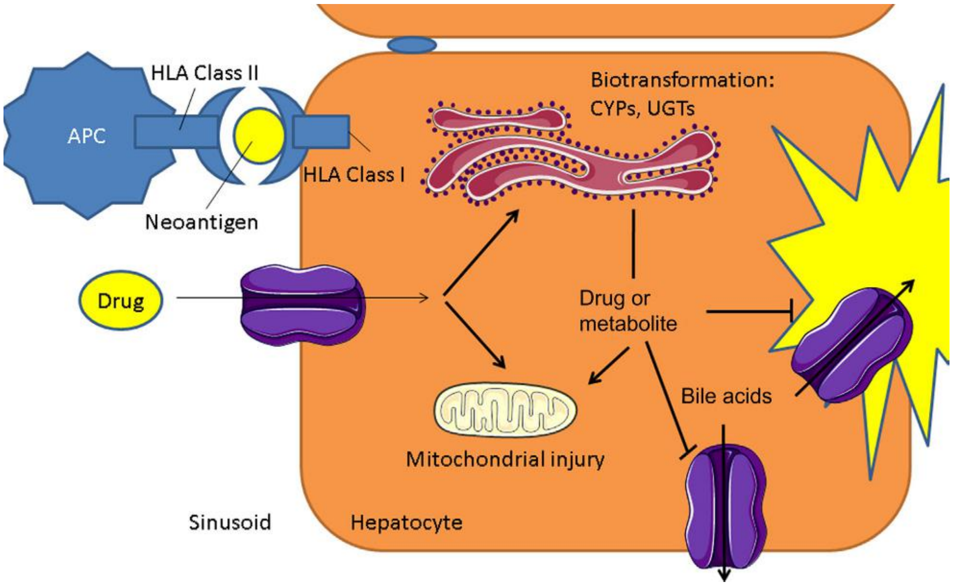

FIGURE 22.1 **Mechanisms for DILI.** It is currently hypothesized that drugs cause stress to hepatocytes, possibly through generation of reactive metabolites. Such stresses may include mitochondrial injury or the accumulation of bile acids in the hepatocyte due to inhibition of bile acid efflux. The magnitude of the stress to the hepatocyte may reflect the balance between production and elimination of the toxic metabolite(s), as well as the ability of the liver to respond or regenerate in the face of injury. Although such stress could lead to hepatocyte death by itself, there is growing evidence that death may involve, or at least be propagated by, both innate and adaptive immune responses, with particular involvement of human leukocyte antigen (HLA) molecules. It is believed that the role for HLA in the development of DILI involves (1) presentation of the neoantigen (possibly the parent drug, a metabolite, or a drug-protein conjugate) on the surface of the hepatocyte by HLA Class I molecules and (2) stimulation of T-cell responses by HLA Class II presentation on antigen-presenting cells (APCs).

22.4 PHARMACOGENOMICS AND STRATIFIED MEDICINE IN DILI

Given the substantial pharmacoeconomic impact of liver toxicity at the drug development stage, this is perhaps the area in which improvements in our knowledge of the mechanisms and genetic determinants of DILI will have the highest value. If there were tools available to reliably screen drug candidates for potential liver toxicity at the preclinical or early clinical development phases, it might be possible to filter out compounds with the potential to cause hepatotoxicity so that the need for clinical predictors would not exist.

22.4.1 Potential Value of Understanding Causes of DILI

Testing for hepatotoxicity in preclinical animal models, particularly in rats, is currently a standard part of toxicity screening in drug development; however, the fact is that many drugs that show hepatotoxicity in humans are not identified as hepatotoxic in rats or other preclinical models, suggesting that the potential for hepatotoxicity is species-dependent or dependent on individual genetic characteristics that are not well represented in animal models [17]. Similarly, the use of primary hepatocytes or hepatocyte-derived cell lines (including HepG2 and more recently HepRG) does not appear to provide a reliably sensitive screen for *in vivo* hepatotoxicity in humans. The reasons for this are numerous, but can be distilled into a single explanation: our current knowledge of the mechanisms for hepatotoxicity, including the contribution of different types of immune cells and their interplay with compromised hepatocytes, is quite incomplete, and thus so is our ability to accurately model this process in cell culture. A better understanding of the mechanisms of hepatotoxicity in humans will allow us to build the appropriate cell culture systems to effectively capture the process and produce a reliable screening tool for liver toxicity.

A prototypical example of this model has recently become a reality for a different type of rare, severe drug toxicity: drug-induced cardiac arrhythmias, including torsades de pointes (TdP). It has been noted that drugs capable of causing TdP tend to prolong the QT interval by inhibition of the human Ether-a-go-go–related protein (hERG), an inward-rectifying potassium channel subunit. Thus, using cell culture models in which the inhibition of hERG can be detected by electrophysiology, for example, provides a highly sensitive screen for drugs with arrhythmogenic potential [18]. Although such methods are not perfect, and must be augmented with early-phase clinical studies that directly measure a drug's effect on QT interval prolongation, they have contributed significantly to reducing the number of arrhythmogenic drugs brought to late-phase clinical trials or to the market [18,19]. Now that liver toxicity appears to have become the major reason for post-approval drug withdrawal, a similarly effective screening method would be tremendously valuable to the pharmaceutical industry, and to patients and health care providers.

22.4.2 Potential Value of Predictive Biomarkers

While eliminating the risk for DILI from newly developed drugs would be a major advance in healthcare, the fact remains that a large number of already approved drugs have the potential to cause DILI and yet are widely used clinically—and are likely to continue to be used routinely until and unless they become supplanted by safer and less expensive alternatives. For this reason, identification of predictive biomarkers (e.g., genetic markers) for DILI would provide a much needed tool for clinicians to test patients prior to prescribing a drug in order to prevent DILI in susceptible patients. Also, without a biomarker, DILI currently is a diagnosis of exclusion.

What would an ideal DILI biomarker look like? For a predictive marker for DILI to be useful in the clinic, it must have certain characteristics, as described in the following subsections.

22.4.2.1 The Biomarker Does Not Change Over Time

For DILI, as for other SAEs, significant investment has been made to identify heritable genetic predictors of susceptibility. There are several reasons that genetic studies of DILI have been favored over other types of research, such as epidemiological studies of environmental DILI risk factors or studies of the role of gene expression in DILI risk, but a major reason is that, unlike environmental triggers or gene expression profiles, genomic DNA sequence variation remains unchanged throughout an individual's lifespan. This means that a reliable genetic test for DILI susceptibility could be performed at birth, or at any point in a patient's medical history, and remain useful for as long as such a test is deemed clinically relevant.

22.4.2.2 The Biomarker is Relevant for a Variety of Drugs

Ideally, a predictive test for DILI susceptibility would indicate whether a particular patient is generally at risk for DILI, as opposed to being at risk for particular causes or types of DILI, or at risk for DILI only in particular environments. Based on the results of genetic studies performed to date, it appears more likely that risk factors for DILI more often than not act in a drug-specific manner [20], or at least are relevant to only a small number of hepatotoxic drugs. Still, there can only be a finite number of biological causes of DILI, and if most of the risk for it can be partitioned into a small number of biological pathways and genetic susceptibility alleles, it may be possible for a "DILI chip" or panel of biomarkers to be developed to give a broad estimate of DILI susceptibility, including drug-specific risk evaluation for an individual patient. The current state of the science suggests that this will not be possible using common SNPs [7], but this does not imply that such markers will not be found using more contemporary methods such as whole-exome or whole-genome sequencing.

22.4.2.3 The Negative Predictive Value is Very High (Especially for Drugs that Cause DILI Relatively Frequently)

One way in which predictive markers for DILI may be useful is in reducing its incidence by finding a common feature among DILI patients that occurs at a reasonably low frequency in the general population. Even if this means depriving a large number of patients of access to a particular drug, if serious toxicity can be minimized or even eliminated, this may still be a useful tool for prescribers, at least in certain contexts. For example, it was shown that in patients of Han Chinese ancestry who developed Stevens-Johnson syndrome (SJS) due to carbamazepine, the carrier frequency of HLA-B*1502 was 100%, compared with only 3% in carbamazepine-tolerant patients and approximately 9% in the general population [21]. Thus, HLA-B*1502 carrier status was shown to be a perfectly sensitive marker for carbamazepine-induced SJS. More recently, this genetic marker was evaluated in a prospective, genotype-guided trial, in which it was shown that SJS could be entirely prevented by genotyping for HLA-B*1502 prior to prescribing carbamazepine [22]. This test is now routinely used in the clinic and is standard practice prior to carbamazepine prescriptions in at least 50 hospitals in Taiwan.

22.4.2.4 The Positive Predictive Value is Very High (Especially for Drugs that Rarely Cause DILI)

Of course, optimally, a predictive test for DILI would tell us exactly which patients are very likely to experience it, especially when the drug being considered is widely prescribed and generally safe (i.e., the incidence of DILI from the drug is very rare). In such cases, a common SNP marker or HLA type may be strongly associated with DILI but not be a clinically useful predictor, merely because the vast majority of patients who are positive for the marker would not be at risk for DILI and would therefore be denied a useful medicine for no real benefit. On the other hand, a rare marker (e.g., a rare genetic variant) that was perfectly correlated with DILI would be rather useful. To date, the study of rare genetic variants in the context of DILI has been limited, but genomic technology has now advanced to the point where such predictors may soon be found, and will be of immediate clinical utility [20].

22.4.2.5 The Biomarker can be Measured Using Easily Accessible Patient Biological Material

Unlike pharmacogenetic/pharmacogenomic studies in cancer, where abundant material from the affected tissue (i.e., the tumor) is often available from diagnostic biopsies or surgical excision of cancerous tissue, it is unusual for clinicians to have access to liver tissue in advance of a clinical indication for biopsy; thus, any predictive test for DILI will almost certainly need to be performed using more accessible tissue, such as blood or saliva, as opposed to "diseased" tissue taken by biopsy or under surgery.

22.4.3 Potential Value of DILI Diagnostics

Given that DILI is currently considered a "diagnosis of exclusion"—in other words, that attributing a particular case of liver injury to a drug primarily relies on ruling out competing causes (e.g., viral hepatitis, autoimmune disease)—it would be of some benefit to clinicians if there were a reliable test that could be given after the occurrence of suspected DILI that would increase confidence in the diagnosis, even if such a test were not sufficiently informative to be used as a predictive marker. As discussed below, one such marker may already exist, with HLA-B*5701 carrier status being a potentially useful diagnostic for DILI due to flucloxacillin [23].

22.5 DIFFICULTIES IN IDENTIFYING BIOMARKERS FOR DILI

Investigation of the risk factors for DILI in humans, whether inherited or acquired, is limited primarily by the available sample sizes of cohorts of patients who have experienced it. Given that DILI is a very rare consequence of most drugs, ascertainment of cases requires a significant amount of diligence and investment.

22.5.1 Acquiring DILI Cases

Over the past decade, a number of national and international registries of DILI patients have been compiled. The US-based Drug Induced Liver Injury Network (DILIN), sponsored by the National Institutes of Health, has been active since 2003 and has enrolled more than 1,400 patients with DILI for the purposes of research into its causes and consequences [8,24]. Several European cohorts of DILI patients have similarly accrued large numbers of cases for research purposes, including DILIGEN [23], EUDRAGENE [25], and the Spanish DILI Registry [26]. Under the auspices of the International Serious Adverse Events Consortium (iSAEC, www.saeconsortium.org/), many of these independent efforts have been coordinated into large, collaborative genetic studies, and have led to a number of significant findings yielding insight into the genetic basis of DILI susceptibility, and continuing efforts promise to provide further discoveries in this area [23,27].

22.5.2 Diagnosis and Phenotyping

The study of drug-induced liver injury is complicated by the lack of specific tests to diagnose it, unlike, for example, viral hepatitis. Thus, causality assessment methods are needed. The most widely used method for causality assessment in DILI is the Roussel Uclaf Causality Assessment Method (RUCAM) [28,29], which is based on a series of objective questions designed to determine the causal relationship between drug initiation and liver injury. Recent efforts have improved on the RUCAM by using an expert panel-based assessment model [30,31]. These methods have likely improved the quality of DILI phenotyping in research studies; however, their implementation may not be practical in all cases, particularly in the clinic. Therefore, it may be that the gold standard for causality assessment includes consensus among experts on the diagnosis, but more practical methods must also be used. There have recently been attempts to standardize definitions and diagnostic approaches that may soon be established as general guidelines for the field [32].

22.5.3 DILI Heterogeneity

In addition to the problem of ambiguous diagnosis in the clinic, there is clearly also a very large degree of heterogeneity in the phenotype. Differences exist among DILI patients in terms of (1) the drug or drugs thought to be responsible for the injury, (2) the clinical presentation (including, for example, liver chemistries, delay between drug initiation and onset of injury, clinical signs and symptoms, and duration of injury), and (3) outcomes from liver injury, ranging from asymptomatic abnormal liver chemistries to reactions requiring liver transplantation or resulting in death [8,26,33].

It seems likely that this variation in DILI presentation from patient to patient may reflect intrinsic differences in the etiology of the injury. As evidence for this, and as described in more detail below, most of the successful genetic studies of DILI to date have been possible because of reasonably large sample sizes of DILI patients whose injury was due to the same drug or drug product, suggesting that at least genetic risk factors for DILI may tend to be drug-specific. On the other hand, it seems reasonable to expect that at least some of the risk factors for DILI are shared across different causal drugs. Thus, if DILI patients could be grouped into "clusters" based on structural similarity among causal drugs, similarities in clinical presentation, or common biological features, this might improve the prospects for discovery of both genetic and nongenetic risk factors by allowing for larger sample sizes of patients falling into these categories, relative to what is available for studies of individual DILI-causing drugs. Currently, however, such information on common mechanisms of DILI remains elusive.

22.5.4 Lack of Adequate Model Systems

As described above, good model systems of DILI, whether *in vitro* or animal models, are currently lacking, and this has significantly limited our ability to understand or to predict DILI. In addition, access to relevant tissues from human subjects is a major difficulty.

22.6 DILI-ASSOCIATED GENETIC VARIANTS

22.6.1 DILI Genetics in the Candidate Gene Era

For much of the history of DILI pharmacogenetics, there was a strong focus on genes or proteins involved in drug metabolism and disposition, with the hypothesis that interindividual variation in the pharmacokinetics of drugs might explain the variable risk of DILI among patients. Although the hypothesis was and remains compelling, the fact is that the recent successful genome-wide association studies (GWAS) have largely ruled out a major role for common variation in so-called "pharmacokinetic genes" in DILI risk. Still, there are many reports of positive associations between pharmacokinetic gene variants and liver injury, and while most of these remain unproven (in the sense of achieving contemporary standards of evidence in human genetic studies), there may be some utility in further studying these genes for their potential role in DILI pathogenesis.

The N-acetyl transferase gene NAT2 has been the most well studied gene in terms of its role in DILI, particularly hepatotoxicity due to isoniazid, which is metabolized by it. Although the results of the many studies on NAT2's role in isoniazid-induced liver injury are conflicting, the consensus is that NAT2 slow acetylators are at increased risk for liver toxicity from isoniazid [34]. It should be noted, however, that most of studies of NAT2 in isoniazid DILI have been performed in East Asian populations. A meta-analysis of NAT2 association studies showed that while NAT2 slow acetylation appears overall to increase risk for isoniazid toxicity, this has not been demonstrated in Caucasian patients [35]. The reasons for this lack of generalizability of the NAT2 results are unknown, but may be related to differences in dosing and monitoring practices in different parts of the world.

Several cytochrome p450 (CYP) genes have been associated with various types of DILI. Most notably, the CYP2E1 gene has been repeatedly implicated in liver toxicity due to isoniazid, with the CYP2E1*5 allele [36,37]. However, this allele was not associated with risk for isoniazid-induced liver injury in other study populations [38,39], and a recent meta-analysis of CYP2E1 studies does not support a role for genetic variation in this gene in isoniazid toxicity [35]. The CYP2C9 gene has been investigated for its potential role in liver injury due to diclofenac, and other drugs, with the results generally not supporting a significant role for genetic CYP2C9 variants [40,41].

The uridinyl diphosphate glucotransferases (UGTs) have also been studied for a role in liver injury, and evidence has been found both for a protective [42] and a deleterious [43] role for UGTs in the development of DILI. However, these results have come from relatively small studies of candidate genes and have not been replicated independently. Similar findings and conclusions have been found for glutathione S-transferase genes (GSTs), including GSTM1 and GSTT1, with the null alleles of these genes being considered risk alleles for DILI due to multiple drugs [44,45]. Again, these results have not been replicated and should be interpreted with caution.

In addition to drug-metabolizing enzymes, there has been a suggestion that certain membrane transporters may be involved in the pathology of DILI. These include genes such as ABCB4 (encoding MDR3), ABCB11 (encoding BSEP), and ABCC2 (encoding MRP2). These transporters are of particular interest in the study of DILI because they are capable of transporting bile acids in addition to their roles as multispecific drug transporters. Since bile acid accumulation in hepatocytes is thought to be one mechanism for the development of DILI, it seems reasonable to suspect that genetic variation in these transporters might be involved either because of their effects on drug disposition or because of the effects of drugs on bile acid handling in the liver. While a number of positive reports exist of genetic variants in these transporter genes relating to DILI risk [43,46,47], none have been confirmed in independent studies [7,48].

22.6.2 Human Leukocyte Antigen Genes and DILI Risk

In addition to genes involved in pharmacokinetics, immune-related genes such as those encoding the human leukocyte antigen (HLA) proteins and several cytokines have been nominally associated with risk for DILI even before the advent of genome-wide association studies (GWAS) [49]. That these genes were considered strong candidates for involvement in DILI reflects a long-standing view that DILI may be at least partly viewed as an immune mediated disease, though perhaps not appreciated until recently was the relative importance of variation in immune-related genes in DILI risk versus genes involved in drug metabolism and disposition.

Perhaps the best example of genetic determinants underlying susceptibility is DILI due to flucloxacillin, in which whole genome association (WGA) has identified the HLA-B*5701 allele as a major determinant of susceptibility. Patients with this allele have an 80-fold increase in susceptibility to DILI when treated with flucloxacillin [23]. Several common variants in the MHC region have been associated with this increase, which is caused by the antibiotic combination amoxicillin/clavulanate; in this case, both HLA Class I and HLA Class II genes are thought to contribute, and possibly interact with one another to modulate DILI risk [27]. Other HLA associations have been observed for lapatinib [50], lumiracoxib [51], and ximelagatran [52]. While it is clear that certain HLA alleles contribute to risk for DILI, it also appears that many of the risk alleles are drug-specific or at least do not contribute generally to this risk [7]. A list of genes in which polymorphisms have been associated with DILI is shown in Table 22.1.

22.6.3 Functional Characterization of DILI-Associated Alleles

While the role of HLA genes in DILI risk has been known or suspected for some time, it has been unclear until very recently how precisely particular HLA alleles cause its development. It has been hypothesized that the drug itself, a drug metabolite, or a protein-drug adduct (hapten) might act as a "neoantigen" and trigger an immune response. Recently, it was shown that carriers of the HLA-B*5701 allele, which has been associated with risk of DILI due to flucloxacillin, have activated CD8+ T cell responses when flucloxacillin is presented by dendritic cells [53]. Further, flucloxacillin was found to bind covalently to albumin, and the degree of binding was positively correlated with T-cell activation, suggesting that flucloxacillin-albumin adducts may be the neoantigen responsible for immune stimulation. This is in contrast to similar studies of the abacavir–HLA-B*5701 interaction [54]. These results give some insight into the processes leading to immune- or HLA-mediated DILI; however, much more work in this area is necessary to give a more complete understanding of the interplay between the liver and the immune system in the DILI's pathophysiology.

22.7 UTILITY OF DILI RISK VARIANTS IN THE CLINIC

Despite the fact that there are now several unequivocal associations between particular genetic variants and risk for DILI, currently there are no predictive tests that are being used clinically. The reasons for this include lack of positive predictive value, a high number needed to treat (NNT), incomplete negative predictive value, and the existence of therapeutic alternatives to drugs that frequently cause DILI.

TABLE 22.1 Genetic Polymorphisms Associated with DILI

Gene	Drug	Type of Study	References
HLA-B*5701	Flucloxacillin	GWAS	[23]
*HLA-DRB1*1501*	Amoxicillin-clavulanate	Candidate gene + GWAS	[27, 63, 51]
	Lumiracoxib	GWAS	
*HLA-DRB1*0701*	Ximelagatran	GWAS	[52, 50]
	Lapatinib	GWAS	
ABCC2 (MRP2)	Multiple drugs	Candidate gene	[43, 46]
ABCB11 (BSEP)	Multiple drugs	Candidate gene	[47]
CYP2E1	Isoniazid	Candidate gene	[36, 37]
GSTM1 and GSTT1 deletions	Multiple drugs	Candidate gene	[44]
NAT2	Isoniazid	Candidate gene	Reviewed in [34, 35]
POLG	Valproic acid	Candidate gene	[64]
SOD2	Multiple	Candidate gene	[65]
UGT1A6	Tolcapone	Candidate gene	[42]
UGT2B7	Diclofenac	Candidate gene	[43]

For most drugs that are currently in clinical use, the rate of DILI is extremely low (less than 1 in 10,000 patients). Thus, if only common alleles (whether SNPs, or HLA types) are known risk factors, then, by definition, most of the individuals carrying the risk allele are not truly susceptible to liver injury. The flucloxacillin-HLA-B*5701 example is once again informative: if all patients being considered for treatment with flucloxacillin were to undergo testing for HLA-B*5701 prior to treatment, it would take more than 10,000 genetic tests to prevent one case of DILI; in the meantime, 7% of patients who are carriers of HLA-B*5701, most of whom are not at risk, would be denied the first drug of choice [55]. In contrast, for a drug like ximelagatran, which causes DILI in up to 8% of patients, knowledge of HLA-DRB1*0701 carrier status might plausibly be used to prevent it: in this case, the NNT (or the number of patients to be genotyped in order to prevent one case of DILI) is a more reasonable 24, and approximately one-third of patients would be denied the drug because they are truly susceptible [55]. When evaluating a potential genetic test for the prevention of DILI, Such considerations of predictive value and NNT of course need to be considered in the clinical environment and in regard to possible therapeutic alternatives. In the case of ximelagatran, its potential benefits over existing anticoagulants might prove to be a reason to reconsider its clinical use if liver toxicity can be prevented by genetic testing.

While the predictive test for DILI remains elusive, several of the HLA associations with certain of its causes have been shown to have very high sensitivity and may in some cases have possible value as tests to aid in diagnosis after a suspected DILI event has occurred. For example, the HLA-B*5701 allele is carried by approximately 7% of individuals of European ancestry, but in roughly 85% of individuals who experienced flucloxacillin-induced liver injury [27]. Thus, in a case of suspected flucloxacillin-DILI, it might be reasonable to test for HLA-B*5701 carrier status: if the patient is found to be HLA-B*5701 positive, this might strengthen the case for a DILI diagnosis. However, since the population frequency of this allele is 7%, and most carriers are not truly at risk, this means that such a test will have roughly a 7% false positive rate—that is, HLA-B*5701 positivity may be entirely coincidental.

22.8 FUTURE DIRECTIONS

While GWASs have so far provided only limited information on the genetic causes of DILI, the continuing rapid advances in genomics and other technologies promise to expand the range of inquiry into its biological determinants of, and they may soon yield additional insight into DILI mechanisms and potentially clinically useful predictive biomarkers.

22.8.1 Expanded-Content Genotyping Arrays

Currently, there is much interest in expanding the GWAS concept, or at least the technology, to include not just a collection of common tagging SNP, but a much larger catalog of human genomic variation including rare variants (i.e., variants with population frequencies less than 1%). In the fall of 2012, several genotyping array manufacturers, in collaboration with a number of human geneticists in academia, developed genotyping platforms intended to cover a large fraction of protein-coding or exonic genetic variation, including variants with frequencies as low as 0.02% in the population (see http://genome.sph.umich.edu/wiki/Exome_Chip_Design). These so-called "exome chips" are currently a much more affordable and efficient approach to studying rare functional genetic variation on a large scale [56–58], and are currently being used to study a broad range of complex human traits, including severe adverse drug reactions (e.g., DILI).

Although their "coverage" of the protein-coding region of the genome is substantial, these arrays should not be considered a substitute for whole-genome or whole-exome sequencing for discovery of DILI risk factors, as any variants that are specific to DILI cases are, by definition, preferentially missing from these chips, whose content is based on genetic variation that is detectable in the general population. Still, it is certainly possible that protein-coding variants in the frequency range of 0.02–1%, which have not previously been interrogated for a role in DILI risk, may prove to contain many useful DILI biomarkers.

22.8.2 Next-Generation Sequencing

For essentially all of the known examples of genetic risk factors for DILI, the penetrance of the associated allele is very low; that is, the vast majority of individuals carrying the risk allele do not experience DILI after treatment with these drugs. Thus, it appears likely that the common risk variants require some modifier (e.g., an environmental trigger) or a rare genetic variant in an unlinked gene to produce DILI.

The advent of massively parallel or "next-generation" sequencing has revolutionized genetic discovery over the past several years. Most notable is the phenomenal pace of discovery of genetic causes of rare Mendelian diseases, with many previously unexplained diseases having been tracked to their genetic cause, often with only a handful of affected patients needed in order to securely implicate a particular gene in the etiology of disease [59]. Given that DILI is typically a rare event, with some drugs resulting in DILI in fewer than 1 in 10,000 patients per prescription, it is possible that, just like many rare diseases, DILI susceptibility may in fact be a Mendelian, monogenic trait. However, even if this were true, it would be unlikely that it would reveal itself clinically: Mendelian diseases are typically recognized on the basis of their segregating into families according to simple Mendelian rules of inheritance, but this is not likely be the case for DILI since it is very rare for entire families to be prescribed the same drug at the same dose concurrently. Thus, such Mendelian patterns of inheritance would be unlikely to emerge. Still, the hope that at least some causes of DILI will turn out to be "cryptic Mendelian traits" is currently fueling efforts to identify rare genetic causes of DILI using whole-exome and/or whole-genome sequencing [20].

One additional advantage to the growing use of whole-exome and whole-genome sequencing in the clinic is that we may soon reach the point at which most, or even all, patients are sequenced routinely and have their genomic sequence available on demand as part of their medical records. Once this happens, there will be many fewer arguments over the costs of predictive genetic testing, or the time between ordering a test and making prescribing decisions, because the test results will be sitting in the medical record to be inspected for any gene and any drug or indication. In such a scenario, the "number needed to treat" will become a largely irrelevant factor in the decision to use genetic information prior to prescribing a particular drug.

22.8.3 Epigenomics

Epigenetic DNA modification, including methylation at CpG dinucleotides, is a major mode of regulating gene expression. Recent technological advances in highly multiplex methylation arrays have allowed for epigenome-wide association studies [60], and have implicated DNA methylation in the pathogenesis of a host of common human diseases, including liver diseases such as nonalcoholic fatty liver disease (NAFLD) [61]. The role of DNA methylation, and other types of DNA modification, in the risk for DILI is as yet unexplored. One reason for this is, as noted above, the particular problem of accessing the relevant tissue because liver biopsies can rarely be obtained for research purposes from DILI patients. It is possible that epigenomic variation in circulating immune cells is responsible in part for DILI susceptibility, so that studies aimed at characterizing the epigenomic profile of peripheral blood leukocytes in DILI patients may reveal risk factors that have so far proven elusive. Additionally, as will be discussed, advances in stem cell technology may soon allow for the faithful reproduction of liver-like cell DILI culture models, which may allow for the use of epigenomic and other "omic" technologies in the absence of primary cells from the liver of DILI patients.

22.8.4 Induced Pluripotent Stem Cells

There has recently been considerable progress with culturing hepatocyte-like cells derived from induced pluripotent stem cells (iPSCs) [62]. In the near future, it is hoped that we will have the capacity to generate faithful cell culture models of DILI that can be used as models for understanding both the pathophysiology of DILI and the role of individual gene variants in DILI pathogenesis, and for screening compounds as potential hepatotoxins. Such models may include coculturing of hepatocytes with immune cells, and perhaps even three-dimensional models of liver incorporating immune cells, so that the relevant biology may be reproducible in the laboratory even without animal models. While this type of work might be done using cells from healthy donors, it may be that the most faithful models will be based on cells taken from those rare individuals who have experienced DILI. Such techniques will provide an immense resource for studying the biology of DILI and preventing the development of hepatotoxic drugs.

22.9 CONCLUSIONS

Drug-induced liver injury remains a major problem in clinical pharmacotherapy and drug development. The accumulating evidence for the role of adaptive immunity in the risk for DILI has provided some insight into the mechanisms underlying DILI, but to date there are no widely-accepted predictive biomarkers for DILI susceptibility. It is hoped that current and future studies that capitalize on the continuing advances in genomic technologies may further aid our understanding of the molecular causes of DILI and provide clinically useful pharmacogenomic tests for DILI risk.

Chapter 23

Hemostasis and Anticoagulants

Matthew R. Wilson and R. Campbell Tait
Department of Haematology, Glasgow Royal Infirmary, UK

Chapter Outline

23.1 Overview 479
23.2 Hemostasis 479
  23.2.1 The "Cascade" Model of Hemostasis 480
  23.2.2 A Contemporary View of Hemostasis 481
  23.2.3 Regulation of Coagulation 481
  23.2.4 Fibrinolysis 482
23.3 Indications for Anticoagulation 482
  23.3.1 Venous Thromboembolism 482
  23.3.2 Stroke Prevention in Atrial Fibrillation 483
23.4 Parenteral Anticoagulants 484
  23.4.1 Unfractionated Heparin 484
  23.4.2 Low Molecular Weight Heparin 486
  23.4.3 Fondaparinux 487
  23.4.4 Danaparoid 487
  23.4.5 Direct Thrombin Inhibitors 487
23.5 Oral Anticoagulants 488
  23.5.1 Vitamin K Antagonists 489
  23.5.2 Direct Thrombin Inhibitors—Dabigatran Etexilate 491
  23.5.3 Factor Xa Inhibitors—Rivaroxaban and Apixaban 493
23.6 Conclusion and Directions for Future Research 494
References 494

23.1 OVERVIEW

The traditional anticoagulants in clinical use for the prevention or treatment of thromboembolic disease are heparin (and its analogs) and warfarin. However, they have major limitations: a narrow therapeutic index, high interindividual variability in a variable dose-response relationship that requires monitoring by laboratory testing, and numerous drug–drug interactions. These limitations have provided not only the impetus for pharmacogenomic studies of efficacy and toxicity for warfarin (described in Chapter 24), but also the development of other antithrombotic agents that target discrete factors in the coagulation cascade. In this chapter, we outline the coagulation cascade and describe the pharmacology of traditional and novel anticoagulants.

23.2 HEMOSTASIS

Blood coagulation and platelet-mediated primary hemostasis are essential physiological defense mechanisms against bleeding, in this way maintaining the integrity of the vascular system. Meanwhile, inherent controlling mechanisms prevent excessive coagulation and thus maintain vascular patency. The biochemistry behind blood coagulation has been carefully studied over the years, and much is known about the sequence of events that results in the formation of fibrin and therefore coagulation.

In normal circumstances, blood flows through the vasculature in a liquid phase until vascular injury occurs, and hemostasis must be initiated to temporarily seal the defect [1]. In the process of resolution of the injury, remodeling occurs with lysis of any excess thrombus. The systems involved are in a delicate physiological balance that, in health, is tipped in favor of an anticoagulant state whereby coagulation occurs only after appropriate stimulation. Factors that favor anticoagulation, thus maintaining the fluidity of blood, include [2]

- The constant flow of blood itself diluting any activated or prothrombotic factors
- A thin layer of plasma preventing platelets from direct exposure to the endothelium
- Expression by healthy endothelial cells of antiplatelet and anticoagulant factors in excess of procoagulant factors
- The requirement for multiple stimuli of platelets for full activation

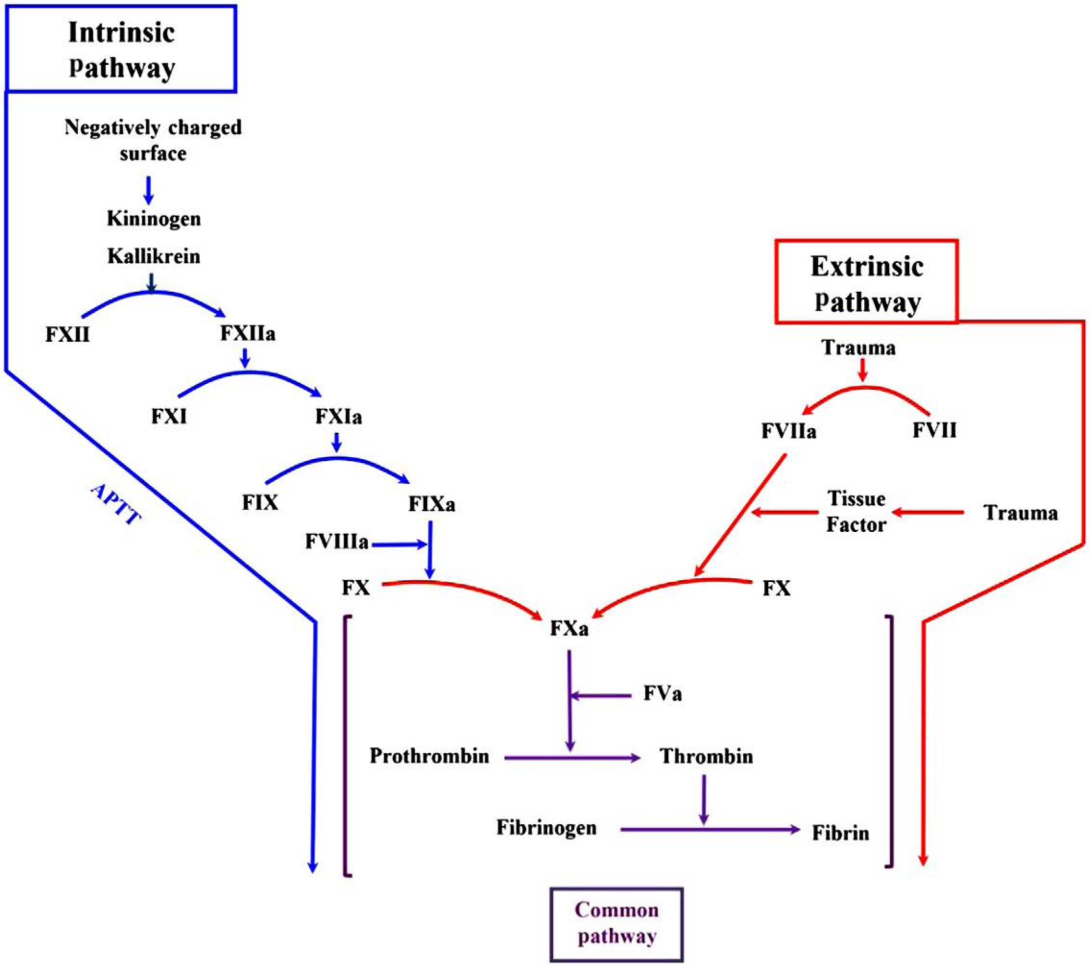

FIGURE 23.1 **Traditional "cascade" model of coagulation.** The extrinsic pathway (red) is initiated following damage to the blood vessel, when tissue factor is exposed and forms an activated complex with factor VIIa, which converts factor X to factor Xa. The intrinsic pathway (blue) is initiated when a negatively charged "foreign" surface is exposed to blood. Factor XII, in a complex with kininogen and kallikriein, becomes activated to form factor XIIa. Factor XIIa converts factor XI to factor XIa, which in turn activates factor IX. Factor IXa forms the "tenase" complex with factor VIIIa, which activates factor X to factor Xa. Both pathways are reflected in laboratory measurements—the prothrombin time (PT) simulates activity of the extrinsic pathway, and the activated partial thromboplastin time (APTT) simulates intrinsic activation. Both pathways converge at factor Xa, which marks the beginning of the common pathway (purple). Factor Xa, catalyzed by factor Va, converts prothrombin to thrombin. Thrombin causes production of fibrin from fibrinogen, which forms the basis of the blood clot. Note: Coagulation factors are denoted by "F" followed by the corresponding roman numeral.

- Circulating coagulation factors that exist as inactive zymogens or are bound to other cells and require activation by proteolysis or other means

23.2.1 The "Cascade" Model of Hemostasis

A comprehensive description of the steps involved in coagulation was first proposed in 1964 [3]. The "MacFarlane cascade"—also known as the waterfall model [4]—defines a stepwise series of enzymatic reactions whereby inactive zymogens are converted to biologically active enzymes (serine proteases). These activated coagulation factors activate each other in a cascade fashion culminating in the conversion of fibrinogen to fibrin, which polymerizes to form a fibrin clot.

According to MacFarlane, there are two distinct pathways that involve different activation stimuli and coagulation factors but eventually converge to a final "common" pathway (see Figure 23.1). Activation of the "intrinsic" pathway (so named because all of the components necessary are present in blood) is dependent on contact activation by a negatively charged surface and involves coagulation factors VIII, IX, XI, and XII. Its activity can be simulated and assessed *in vitro* by the activated partial thromboplastin time (APTT). The "extrinsic" pathway is activated when tissue factor is exposed to the circulation (for example in vascular trauma), and it involves tissue factor and factor VII. Similarly, it can be assessed *in vitro,* using the prothrombin time (PT). Both pathways result in activation of factor X, marking the beginning of the common pathway. Factor

Xa, catalyzed by Factor Va, then converts prothrombin to thrombin, which in turn enzymatically converts fibrinogen to fibrin. Interestingly, the role of platelets is considered unimportant in this model.

23.2.2 A Contemporary View of Hemostasis

In recent years, the "cascade" theory of blood coagulation has been disputed, and a modified cell-based model has been described that is thought to more accurately reflect the real-time events of hemostasis *in vivo* [5]. This new perspective builds on the classic cascade in the following ways [6,7]:

I. The cascade theory implies that clot formation can occur as a result of two independent pathways. It is now known that the interaction between factor VII (FVII) and tissue factor (TF) is the initiator of all coagulation processes (both natural and pathological).

II. The complex formed by TF and factor VII also participates in the activation of factor IX (as well as factor X), implying an element of cross-activation of the intrinsic pathway by the extrinsic system.

III. There is increasing recognition of the role of cells in coagulation. Different cells express varying levels of pro- and anticoagulant proteins and have different complements of receptors for components of hemostasis. It stands to reason, therefore, that cells have an important contribution to make in directing hemostasis *in vivo* [8]. In particular, activated platelets provide the phospholipid surface on which the coagulation factors can assemble—localizing the active coagulation pathway to the site of tissue injury.

IV. There are three consecutive phases to coagulation—initiation, amplification, and propagation. Platelets and thrombin are actively involved in the last two phases.

23.2.2.1 Initiation

It is now well recognized that exposure of blood to cells expressing TF results in the initiation of blood coagulation *in vivo* [1]. TF is a cell-bound transmembrane glycoprotein and a member of the class II cytokine family. It is constitutively expressed at biological boundaries such as skin, organ surfaces, vascular adventitia, and epithelial-mesenchymal surfaces, where it functions as a "hemostatic envelope." This ensures that, following disruption of vascular integrity, blood is immediately exposed to TF and coagulation is initiated. Endothelial cells themselves can express TF—in the healthy state, this is suppressed but upregulated when the endothelial cell is damaged.

Tissue factor forms a catalytic complex with factor VIIa on the phospholipid surface of the cell membrane, which then activates the zymogens factor IX and factor X. The activated factor X (factor Xa) then goes on to generate small amounts of thrombin.

23.2.2.2 Amplification

The levels of thrombin generated from the initiation phase are usually insufficient to generate significant fibrin formation. Thrombin's main function, however, is to activate factors V, VIII, and XI. In the amplification phase, factor XIa activates factor IX, which forms a complex with factor VIIIa. This complex ("tenase") activates sufficient factor Xa to form a complex with factor Va, termed the prothrombinase complex, production of which leads to the explosive generation of thrombin that ultimately leads to generation of a fibrin clot [1].

23.2.2.3 Propagation

The propagation phase relies on recruitment of activated platelets at the site of injury. Platelets provide a phospholipid surface that allows localization of the activated coagulation components for optimum generation of thrombin [2]. These components include the intrinsic tenase complex, the prothrombinase complex, and calcium. The "thrombin burst" brought about by these complexes leads to the generation of fibrin from fibrinogen to produce a stable fibrin clot. Thrombin also activates Factor XIII, which strengthens fibrin cross-linking and thrombin-activatable fibrinolysis inhibitor (TAFI), which protects the clot from plasmin-mediated fibrinolysis. (See Figure 23.2.)

23.2.3 Regulation of Coagulation

Each phase of the hemostatic pathway has associated inhibitory components. Once the TF-Factor VIIa complex stimulates the amplification process, it is rapidly inactivated by tissue factor pathway inhibitor (TFPI), which is released from thrombin-activated platelets found on the surface of endothelial cells [8]. Administration of intravenous heparin or subcutaneous low-molecular-weight heparin (LMWH) results in release of endothelial TFPI.

The most important inhibitor of coagulation is antithrombin, a serine protease inhibitor. It impedes fibrin generation by forming inactive complexes with thrombin and factor Xa (and to a lesser extent factors IXa and XIa). Heparin also greatly enhances the action of antithrombin.

Thrombin also proteolytically activates the anticoagulant protein C pathway. Thrombomodulin, a receptor expressed on endothelial cell surfaces, binds thrombin, resulting in the activation of protein C. Activated protein C, along with protein S as a cofactor, inactivates factors Va and VIIIa, therefore downregulating the amplification phase of coagulation.

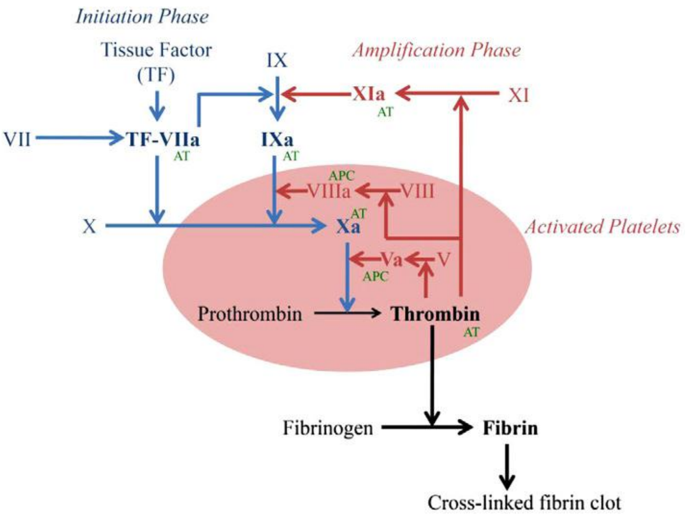

FIGURE 23.2 **Cell-based hemostasis model.** Exposure of blood to tissue factor is the initiating process of coagulation, with tissue factor forming a complex with factor VIIa. This complex activates factors IX and X, and factor Xa then generates small amounts of thrombin. Thrombin initiates a positive feedback network, activating factors V, VIII, and XI. Factors VIIIa and IXa form the "tenase complex," which activates factor X. Factor Xa forms the "prothrombinase complex" with factor Va which causes explosive generation of thrombin. Thrombin converts fibrinogen to fibrin, which forms the basis of the cross-linked blood clot. Activated platelets provide a surface for localization of the tenase-prothrombinase complex and are therefore essential for the "thrombin burst." Coagulation is moderated primarily by AT and APC. AT and APC are denoted in green and are positioned in the figure at the various points where they exhibit their inhibitory effects. Note: TF—tissue factor; AT—antithrombin; APC—activated protein C. Clotting factors are indicated by their respective roman numerals.

23.2.4 Fibrinolysis

Fibrinolysis describes the process of removing (lyzing) the clot formed by activation of hemostatic pathways, either in physiological response to vascular trauma or in pathological thrombosis. Plasmin is the principle mediator of fibrinolysis.

Fibrin itself can bind tissue plasminogen activator (tPA), greatly enhancing its ability to convert plasminogen to plasmin, the active enzyme. Plasmin is formed by proteolytic cleavage of plasminogen by both tPA and urokinase-type plasminogen activator (uPA). A serine protease itself, plasmin acts to dissolve the fibrin clot by splitting the cross-linked fibrin into a variety of small fibrin degradation products.

Regulation of the fibrinolytic system occurs via inhibition of tPA and plasmin by plasminogen activator inhibitor (PAI) and α2-antiplasmin, respectively.

23.3 INDICATIONS FOR ANTICOAGULATION

Anticoagulation, no matter how it is achieved, must only be initiated after careful consideration of its risks and benefits. The specific contraindications for individual anticoagulant agents are covered later in the chapter.

There are many clinical conditions in which anticoagulation has been shown to be beneficial; these are outlined in Table 23.1 [9]. In general terms, however, it is used for either primary or secondary prevention of venous or arterial thrombotic events. Venous thromboembolism and prevention of stroke in atrial fibrillation are the most common indications for anticoagulation. These are discussed in more detail in the following sections.

TABLE 23.1 Clinical Indications for Anticoagulant Treatment

Primary and secondary prevention of venous thromboembolism
Prevention of cardioembolic stroke in the presence of atrial fibrillation (AF) or cardiomyopathy
Cardioversion for arrhythmias such as atrial fibrillation
Valvular heart disease (patients suffering mitral stenosis or regurgitation who have AF or a history of systemic embolism, left atrial thrombus, or an enlarged left atrium)
Mechanical prosthetic heart valves
Bioprosthetic heart valves (conditions apply)
Acute coronary syndromes and ST-elevation myocardial infarction in the acute phase

23.3.1 Venous Thromboembolism

The following subsections discuss the epidemology, pathophysiology, and management of venous thromboembolism.

23.3.1.1 Epidemiology

Venous thromboembolism (VTE), which comprises deep vein thrombosis (DVT) and pulmonary embolism (PE), has a clinical incidence of approximately 1−1.5 per 1000 annually in adult populations [10]. Rates are slightly higher in men than in women. Two-thirds of cases present as DVT and one-third as PE with or without DVT. The major outcomes of venous thrombosis are death, recurrence, post-thrombotic syndrome, pulmonary hypertension, and major bleeding due to anticoagulation. Thrombosis is also associated with impaired quality of life, particularly when post-thrombotic syndrome develops [11]. It is estimated that within one month of an episode of DVT, 6% of patients will die; in the same period after an episode of PE, 10% will die. The mortality rate for PE has been estimated to be as high as 30% in autopsy-based studies, suggesting that PE is often not recognized before death.

VTE is rare before the age of 16, likely because the immature coagulation system is resistant to thrombosis. The risk of VTE then increases exponentially with age; this relationship is thought to relate to the increasing presence of other predisposing illnesses and also to an inherent increased coagulability with aging.

23.3.1.2 Pathophysiology

Virchow was the first to identify stasis of the blood, vessel wall injury, and hypercoagulability of the blood as the pathogenic triad responsible for thrombosis. It is thought that a combination of these factors is usually present. The major risk factors for VTE, and how they relate to Virchow's triad, are outlined in Table 23.2.

TABLE 23.2 **Risk Factors for VTE and Their Relationship to Virchow's Triad**

Virchow's Triad	Risk Factor
Stasis	Immobility
	"Travelers thrombosis"
	Previous VTE
	Surgery
	Trauma
	Obesity
Vessel wall injury	Surgery
	Trauma
Hypercoagulability	Age over 40
	Pregnancy
	Estrogen therapy
	Malignancy, including myeloproliferative neoplasm
	Genetic thrombophilia
	Antiphospholipid antibodies
	Obesity
	Surgery
	Trauma

Hypercoagulability can be either inherited or acquired. The most important inherited disorders associated with VTE result from the following:

- Defects in naturally occurring coagulation inhibitors—antithrombin, protein C, or protein S
- Resistance to activated protein C, usually due to a genetic mutation known as factor V Leiden (*F5* R506Q)

Deficiencies of antithrombin, protein C, and protein S are rare (combined prevalence of <1% in the general population), and so estimates of associated VTE risks are uncertain but have been quoted as creating a 10–40-fold increase in risk [12]. The factor V Leiden mutation is common, with an incidence of 5% in Caucasians, and carries a 5–7-fold increased risk of VTE [13].

23.3.1.3 Management

The mainstay of treatment for VTE is anticoagulation. Traditionally this has been achieved by initially administering low-molecular-weight heparin LMWH, followed by a course of oral anticoagulation. Urgent thrombolytic therapy may be used when the patient has hemodynamic compromise as the result of massive PE.

The optimum duration of anticoagulation in VTE is a contentious issue. Its purpose is to prevent recurrence; however, because this treatment carries a risk of bleeding, it should only continue if the risk of recurrent VTE, or its consequences, outweighs the risk of bleeding [14].

Standard practice has been to give three to six months of treatment for a first VTE, although this may be increased to "lifelong" if the patient is perceived to have a high risk of recurrence following an unprovoked VTE.

23.3.2 Stroke Prevention in Atrial Fibrillation

Atrial fibrillation (AF) is the most common sustained cardiac arrhythmia, increasing in prevalence with age [15]. AF accounts for approximately one-third of hospitalizations for cardiac rhythm disturbances. It has an estimated prevalence of 1.5–2%, but this is estimated to at least double in the next 50 years as the population ages [16].

The rate of ischemic stroke among patients with nonvalvular AF averages 5% per year, which is 2–7 times that for people without AF. This increased risk of stroke and systemic embolism is explained by a combination of pathophysiological mechanisms. The arrhythmia results in "flow abnormalities," as evidenced by blood stasis in the left atrium and in particular in the left atrial appendage. "Endocardial abnormalities" also occur, with progressive atrial dilatation, endocardial denudation, and fibroelastic infiltration of the extracellular matrix. Activation of hemostatic processes and platelets has also been described in AF, as well as inflammation and growth factor abnormalities [17]. These factors, either alone or in combination, result in an increased likelihood of fibrin thrombus formation and therefore embolic stroke [16].

Stroke in AF is often severe and often causes either long-term disability or death, resulting in a sizeable burden on health resources. An individual's predisposition to stroke in AF is related to a number of well-documented clinical and echocardiographic risk factors: age, hypertension, prior stroke or transient ischemic attack (TIA), diabetes, and structural heart disease.

The identification of these risk factors has led to the development of various stroke risk assessment schemes. The most recent and comprehensive of these risk factor stratification algorithms is the CHA_2DS_2-VASc scoring system, which is outlined in Table 23.3.

According to the European Society of Cardiology, if a patient has a score of 2 or more, an oral anticoagulant (OAC) should be prescribed; if the score is 1, either an oral anticoagulant or aspirin can be prescribed (an oral anticoagulant is preferred); if the score is 0, either aspirin can be prescribed or no antithrombotic therapy at all.

It must be remembered that, in considering an OAC, the advantages and disadvantages should be discussed with the patient (along with his or her preferences), and both the risk of bleeding complications and ability to safely sustain chronic stable anticoagulation should be evaluated.

23.4 PARENTERAL ANTICOAGULANTS

In the following sections, the structure and mechanism of action, pharmacokinetics, and other factors relating to unfractionated and low-molecular-weight heparin are discussed.

23.4.1 Unfractionated Heparin

Heparin was first isolated nearly 100 years ago by a second-year medical student, Jay McLean, who was working with the physiologist William Henry Howell at John Hopkins Medical School. McLean had been investigating procoagulant preparations when he came across a fat soluble phosphatide anticoagulant in canine liver tissue (hence the name heparin—"hepar," or "ήπαρ," is Greek for "liver"). Heparin was used in the 1930s as an intravenous anticoagulant in some human trials, and its use became widespread after the Second World War [18]. This original form of heparin is known as unfractionated heparin (UFH), mainly to distinguish it from derivatives that were developed more recently and are described later in the chapter.

23.4.1.1 Structure and Mechanism of Action

Heparin is a highly sulphated glycosaminoglycan, procured from tissues rich in mast cells such as porcine intestine or bovine lung. It is a polymer of repeating disaccharide units, with molecules ranging in molecular weight 3000–30,000 kDa (mean 15,000). Only approximately one-third of heparin molecules possess the unique pentasaccharide sequence that allows binding to the plasma protein antithrombin (AT)—this process is responsible for most of heparin's anticoagulant effect. The remaining two-thirds possess minimal anticoagulant activity at therapeutic concentrations, but at concentrations higher than usually obtained clinically, both high- and low-affinity

TABLE 23.3 The CHA_2DS_2-VASc Risk Factor–Based Scoring System for Stroke Risk in AF

Risk Factor	Condition	Points
C	Congestive heart failure/left ventricular dysfunction	1
H	Hypertension	1
A	Age ≥75	2
D	Diabetes mellitus	1
S	Stroke/TIA/thromboembolism	2
V	Vascular disease	1
A	Age 65–74	1
Sc	Sex category (female)	1

heparin catalyzes the antithrombin effect of a second plasma protein, heparin cofactor II [19].

The aforementioned pentasaccharide sequence binds to positively charged residues on AT, producing a conformational change that converts AT from a slow to a rapid inhibitor of serine proteases [20]. The resultant heparin/AT complex inactivates factor IIa (thrombin) and factor Xa. Binding of heparin to antithrombin occurs at the unique pentasaccharide sequence described above. Binding of this sequence alone is sufficient to generate anti-FXa and anti-thrombin activity. However, longer heparin chains containing at least 18 saccharides, including the pentasaccharide, have the additional capacity to bind thrombin thus localizing it to the activated AT and further enhancing thrombin inhibition. Thrombin inactivation prevents fibrin formation and also inhibits thrombin-induced activation of platelets and factors V, VIII, and XI.

23.4.1.2 Pharmacokinetics

Heparin is not absorbed orally and therefore must be administered parenterally. The two preferred routes of administration of UFH are by continuous IV infusion or subcutaneous (SC) injection.

At typical therapeutic doses, the half-life of intravenous UFH is 45–60 min, demanding continuous IV infusion for a sustained anticoagulant effect. Given subcutaneously, it has a lower bioavailability, with activity starting at 2 h and lasting approximately 10 h. For continued anticoagulation, therefore, subcutaneous dosing must be at least twice daily. If an immediate anticoagulant effect is required and heparin is to be administered subcutaneously, either a higher initial subcutaneous dose, or alternatively an IV bolus in conjunction with the first SC dose, should be given.

In the circulation, heparin binds nonspecifically to a number of plasma and cellular proteins other than AT, resulting in decreased bioavailability and substantial interpatient variability in anticoagulant response. It is for this reason that UFH requires frequent laboratory monitoring to assess the level of anticoagulation, as measured by the activated partial thromboplastin time (APTT) [21]. Clearance of heparin occurs via a rapid saturable and a much slower first-order mechanism combined. The saturable phase is thought to be due to binding to endothelial cell receptors and macrophages, which internalize and depolymerize heparin molecules. The slower, nonsaturable mechanism of clearance is predominantly renal. The complex kinetics of heparin clearance render the anticoagulant response to heparin nonlinear at therapeutic doses, with both intensity and duration of effect rising disproportionately with increasing dose.

23.4.1.3 Monitoring

Because of substantial interpatient variability in anticoagulant response to heparin, it is standard practice to monitor treatment and adjust the heparin dose based on the results of coagulation tests—usually using the APTT.

The evidence for adjusting the dose of heparin to maintain a “therapeutic range” is weak and based on a post hoc subgroup analysis of a descriptive study [20]. This is in stark contrast to the evidence for maintaining an international normalized ratio (INR) within a therapeutic range in patients on warfarin, which has been derived from consistent results of randomized trials and case-control studies.

Nevertheless, current practice uses a therapeutic APTT range of 1.5–2.5 times control for patients on unfractionated heparin, as this was shown to be associated with a reduced risk of VTE in the aforementioned retrospective study [20]. With this in mind, heparin dose adjustment nomograms are frequently used that give dose adjustment advice based on current APTT values. It should also be remembered that the measured response to the APTT varies among laboratory reagents and instruments. Therefore, the therapeutic APTT range at a particular institution should be adapted to the responsiveness of the reagent and coagulometer used [21].

23.4.1.4 Adverse Effects

As well as hemorrhagic complications common to all anticoagulants, heparin has some specific side effects. The most significant are heparin-induced thrombocytopenia (HIT) and osteoporosis. Rarer complications of treatment include skin reactions that can progress to necrosis, hyperkalemia, and hypersensitivity reactions.

Heparin-Induced Thrombocytopenia

One-third of patients have a slight fall in their platelet count (<30% compared with baseline) within the first four days of starting heparin. This is not associated with bleeding or thrombotic complications and does not require cessation of heparin. If the platelet count falls more markedly (>50% compared with baseline), then the possibility of heparin-induced thrombocytopenia (HIT) should be considered.

HIT is a life-threatening disorder that occurs in 0.3–6.5% of those receiving UFH. It is caused by the development of IgG antibodies against platelet factor 4 (PF4) and heparin. Patients with HIT have a thrombotic risk more than 30 times that of control populations. This paradoxical increased risk of thrombosis is explained by the fact that antibodies to PF4 and heparin cause platelet activation as well as depletion.

Thrombotic complications may affect any vascular bed and frequently occur at sites of vascular injury. Venous thromboses predominate in medical and orthopedic patients, whereas arterial and venous thromboses occur at a similar frequency in patients who have undergone cardiac or vascular surgery. Rarer sites of thrombosis include adrenal veins or cerebral venous sinuses.

Platelet counts rarely drop to a level that causes bleeding, and typically recover within 4–14 days after heparin is discontinued [22]. Despite this, the risk of thrombosis remains high for days to weeks after discontinuation of heparin, even if the platelet count has normalized. Atypical manifestations of the condition include heparin-induced skin necrosis, venous gangrene of the limbs, and anaphylactic-type reactions after receipt of an intravenous bolus of heparin.

Diagnosis of HIT is often made clinically, but this can be challenging as there are often other reasons that patients have reduced platelet counts, such as bacterial infection, drugs other than heparin, or bone marrow disease. Another challenging situation is the patient who has recently undergone cardiac surgery. The prevalence of heparin-dependent antibodies is high and thrombocytopenia is common in these patients, who are often on other drugs that could cause thrombocytopenia. The most helpful clinical diagnostic tool is observing a recovery in the platelet count after withdrawing all forms of heparin (including line flushes). Diagnosis can be confirmed in the laboratory using serologic or functional assays or both.

Management of HIT involves immediate cessation of all types of heparin and initiation of an alternative anticoagulant such as danaparoid or argatroban at therapeutic doses. Warfarin is contraindicated until the platelet count has recovered, as there have been reports of warfarin-induced skin necrosis and venous gangrene of the limbs. Platelet transfusion is relatively contraindicated during a HIT episode.

Osteoporosis

Osteoporosis can occur when heparin binds to osteoblasts, causing the release of factors that activate osteoclasts. This effect is normally only seen in prolonged use of UFH—2% of patients receiving treatment-dose UFH for more than nine months developed vertebral fractures [13].

23.4.1.5 Pharmacogenomics

Most pharmacogenetic analyses of heparin have been related to heparin-induced thrombocytopenia (HIT). There is some evidence that a weak genetic predisposition to HIT is related to a His/Arg polymorphism at amino acid 131 of the human FcγIIa receptor. One large study of this relationship found a statistically significant ($p = 0.03$) increase in the frequency of the His$_{131}$ genotype in patients with HIT when compared to healthy individuals [23]. More recently, it has been proposed that a polymorphism of the *GPIIIa* gene may modulate the prothrombotic effects of HIT. However, data on this association is not consistent. Patients with all Fc-receptor genotypes can develop HIT, and the association of these hemostatic polymorphisms with thromboembolic complications is certainly weak.

23.4.1.6 Reversal

Intravenous protamine sulphate can rapidly reverse the anticoagulant effects of heparin. Protamine sulphate is a basic protein derived from fish sperm that binds to heparin to form a stable salt. One milligram of protamine sulphate neutralizes approximately 100 units of heparin. Because the half-life of heparin is 60−90 min when given as an intravenous infusion, the total amount administered over the previous 2−2.5 h should be taken into account when calculating the protamine sulphate dose. However, when heparin has been given subcutaneously (and therefore is cleared with a longer half-life) prolonged or repeated administration of protamine sulphate may be required.

23.4.2 Low Molecular Weight Heparin

The realization that the anticoagulant action of UFH was mostly delivered by short pentasaccharides has led to the use of more efficient fractionation procedures, yielding a number of low-molecular-weight heparin (LMWH) preparations. Like UFH, LMWHs are heterogeneous with respect to molecular size and anticoagulant activity. They have a mean molecular weight of 4000−5000 with a molecular weight distribution of 1000–5000.

LMWHs, formed by chemical or enzymatic depolarization of UFH, have the following characteristics [19]:

- The smaller LMWH fragments have reduced ability to bind and therefore catalyze inhibition of thrombin but retain the ability to catalyze inhibition of factor Xa.
- Reduced nonspecific binding to plasma proteins, resulting in an improvement in the predictability of their dose-response relationship.
- Reduced binding to macrophages and endothelial cells, with a corresponding increase in their plasma half-life.
- Lower incidence of HIT, which is thought to be due to reduced binding to platelets and PF4.
- Weaker association with reduction in bone density, possibly due to reduced binding to osteoblasts.

Examples of LMWHs in clinical use are dalteparin, enoxaparin, and tinzaparin, which are typically administered in fixed or weight-adjusted doses for thromboprophylaxis and in weight-adjusted doses for therapeutic anticoagulation. Like heparin, they produce their major anticoagulant effect by catalyzing AT-mediated inhibition of coagulation factors. Of LMWH chains, 50–75% are too short to efficiently catalyze thrombin inhibition, and therefore their dominant effect is on AT-mediated inactivation of factor Xa.

LMWHs are cleared predominantly by the renal route, and therefore their biological half-life is increased in patients with renal failure. This longer half-life (3–6 h), when compared to UFH, means that a once-daily subcutaneous injection is sufficient for a sustained anticoagulant effect. Intravenous administration of LMWH is rarely used. In the setting of severe renal insufficiency in which therapeutic anticoagulation is required, use of UFH avoids the problems associated with impaired clearance of LMWH preparations.

Coagulation monitoring of LMWH is generally not necessary, but some authorities suggest that it may be appropriate in obese patients and those with renal insufficiency. The APTT is poorly sensitive to LMWH; however, monitoring is achieved by analyzing plasma anti-Xa activity. There is no specific creatinine clearance (CrCl) at which the risk of LMWH accumulation becomes clinically significant, but a value of 30 mL/min has been suggested in the literature [20]. If LMWH is used at CrCl below this level, anti-Xa monitoring and/or dose reduction should be considered.

If reversal of LMWH is required, protamine sulphate is administered in a dose of 1 mg per 100 anti-Xa units of LMWH (for example, 1 mg enoxaparin contains approximately 100 anti-Xa units and so requires 1 mg of protamine sulphate). A second, smaller dose of protamine sulphate can be given if bleeding continues.

To our knowledge, there are no published studies demonstrating a pharmacogenetic effect in LMWHs. However, it has been suggested that interleukin-1 receptor antagonist polymorphisms may be a useful marker to identify patients who benefit from LMWH in non-ST segment elevation acute coronary syndrome (ACS). In particular, carriers of this polymorphism showed a better control of von Willebrand factor increase in a small cohort of ACS patients [24].

23.4.3 Fondaparinux

The discovery that the minimum heparin fragment required for high-affinity binding to AT consists of a pentasaccharide, and that such pentasaccharides can be isolated, paved the way for the development of a relatively specific factor Xa inhibitor called fondaparinux.

23.4.3.1 Structure and Mechanism of Action

Fondaparinux is a synthetic drug consisting of the AT-binding pentasaccharide sequence found in the heparin molecule. It has a molecular weight of 1728 and binds to AT, producing conformational change at the reactive site of AT, resulting in a 300-fold increase in its inhibitory activity on factor Xa. This inhibition of factor Xa is irreversible; however, the interaction between fondaparinux and antithrombin is not, allowing each single molecule of fondaparinux to bind to, and activate, several molecules of antithrombin.

Because there are no additional saccharides to provide the necessary bridging function for thrombin binding, fondaparinux has no activity against thrombin.

23.4.3.2 Pharmacokinetics

Fondaparinux is administered as a subcutaneous injection and is rapidly and completely absorbed. Its half-life after SC injection is longer than that of LMWH (17 and 4 h, respectively). A steady state is reached after the third or fourth once-daily dose, and fondaparinux is excreted unchanged in the urine. It produces a predictable anticoagulant response with minimal nonspecific binding to plasma proteins other than AT.

Based on its long half-life and consistent anticoagulant effect, fondaparinux is administered as a once daily injection and does not require coagulation monitoring. Clearance is exclusively renal; thus, it is contraindicated in patients with a CrCl <30 mL/min.

23.4.3.3 Dosing and Reversal

Fondaparinux has largely replaced LMWH as the anticoagulant of choice in acute coronary syndromes after a study in 2006 [25] showed that it gave similar reduction in ischemic events but caused significantly less major bleeding. For this purpose, it is administered at a dose of 2.5 mg once daily. The same dose is used for thromboprophylaxis in the setting of orthopedic surgery, where it has been shown to be superior to prophylactic doses of enoxaparin in preventing VTE following major hip and knee surgery.

If fondaparinux is to be used for treatment of VTE, it is given at a dose of 7.5 mg for patients with body weight 50–100 kg, 5 mg for patients weighing <50 kg, and 10 mg in those weighing >100 kg.

Protamine sulphate does not bind to fondaparinux, so it cannot be used for reversal in the event of major bleeding.

23.4.3.4 Adverse Effects

Fondaparinux does not bind to platelet factor 4, and therefore has no capacity to cause HIT. Therefore, it can be safely used as an alternative anticoagulant in patients who have developed HIT, although it is unlicensed for this purpose. There is little clinical data available on the effects of fondaparinux on bone metabolism, but *in vitro* studies have suggested that it may not have the same osteoporotic effect as other heparin preparations.

23.4.4 Danaparoid

Danaparoid is a heparinoid that consists of the glycosaminoglycans heparin sulphate, dermatan sulphate, and chondroitin sulphate. It has low cross-reactivity with antibodies induced by heparin and is therefore primarily used as the anticoagulant of choice in patients with HIT. Danaparoid has a long half-life and has no specific antidote, so it can be problematic in patients requiring urgent surgery or those with major bleeding.

23.4.5 Direct Thrombin Inhibitors

Because thrombin is the central effector of coagulation and amplifies its own production, it is a natural target for direct pharmacologic intervention. Direct thrombin inhibitors (DTIs) bind with thrombin to prevent an interaction between the enzyme and substrates. The currently approved parenteral DTIs are bivalirudin and argatroban. Hirudin is no longer available.

The advantages of DTIs include a targeted specificity for thrombin, the ability to inactivate clot-bound thrombin, and an absence of plasma protein and platelet interactions that are responsible for problems with heparin, such as HIT. DTIs exert their anticoagulant effect, independent of antithrombin, by binding directly to thrombin and forming an inactive stoichiometric complex. They do not bind plasma proteins and so have a more predictable anticoagulant effect than heparin [20].

There are no specific antidotes or reversing agents for DTIs; however, their short half-lives mean that such agents should be rarely required. Hemodialysis or hemoperfusion can remove bivalirudin or argatroban.

23.4.5.1 Bivalirudin

Bivalirudin has a smaller molecular weight than the other DTIs and is given intravenously. It has a shorter half-life (25 min), and its elimination is only partially renal. Bivalirudin's mechanism of action is similar to that of other DTIs, the only difference being that the bond it forms with thrombin is reversible. It is licensed as an alternative to heparin in patients undergoing percutaneous interventions for acute coronary syndromes and in patients with HIT.

23.4.5.2 Argatroban

Argatroban is a small-molecule competitive inhibitor of thrombin given intravenously, with a half-life of 40–50 min. It requires anticoagulation monitoring of the APTT. Argatroban is metabolized by the liver cytochrome P450 3A4/5 enzyme system and consequently must be used with caution in patients with hepatic dysfunction. Because it is not renally excreted, it is useful for patients with HIT and severe renal impairment. (See Figure 23.3.)

23.5 ORAL ANTICOAGULANTS

For many decades, the field of oral anticoagulation has been dominated by vitamin K antagonists, specifically warfarin. This section provides an overview of vitamin K antagonists as well as some of the newer anticoagulants that have progressed through clinical trials in the last few years and are now approved for clinical use—dabigatran, rivaroxaban, and apixaban.

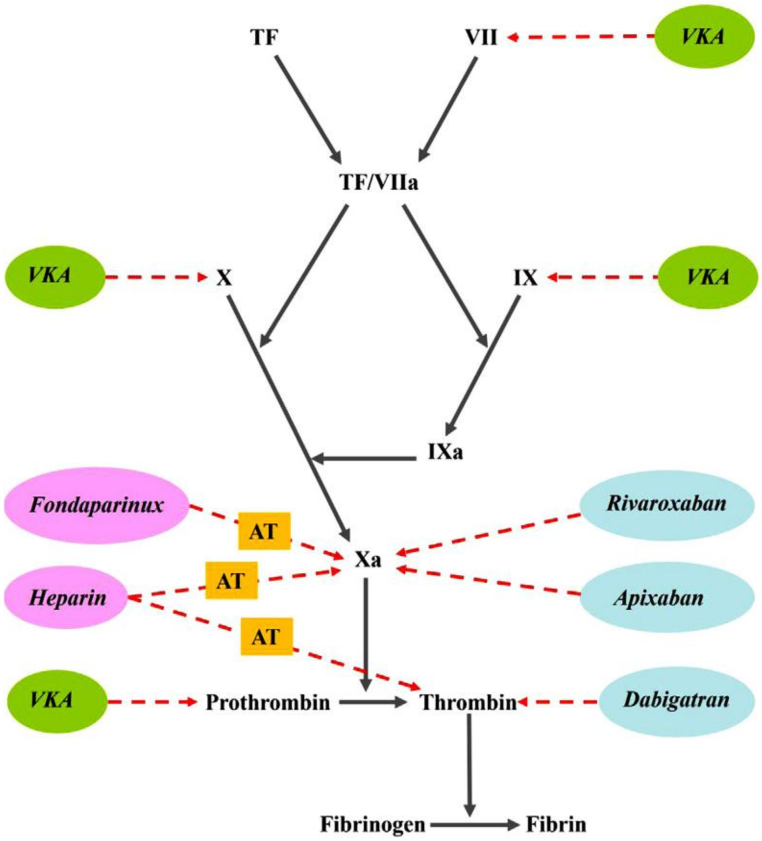

FIGURE 23.3 Anticoagulant drugs and their targets in the coagulation process. Red dotted lines denote inhibition of clotting factors by each anticoagulant. TF—tissue factor; VKA—Vitamin K Antagonist; AT—Antithrombin.

23.5.1 Vitamin K Antagonists

The vitamin K antagonists (VKAs) were first discovered by Karl Paul Link at the University of Wisconsin in the 1930s. Cattle in the Northern United States and Canada had been afflicted by an outbreak of an unusual disease characterized by fatal bleeding either spontaneously or from minor injuries. Investigators discovered that moldy silage made from sweet clover (*Melilotus alba* and *Melilotus officinalis*) was implicated, and that it contained a hemorrhagic factor that reduced the activity of prothrombin. Link, along with his student, Harold Campbell, then discovered that this anticoagulant in sweet clover was 3,3′-methylenebis (4-hydroxycoumarin). In 1948, work by Link led to the synthesis of warfarin, which was initially used as a rodenticide in 1952 but was then approved for human use in 1954. The name *warfarin* is derived from WARF (Wisconsin Alumni Research Foundation) and *arin* from coumarin [26]. The pharmacology of warfarin is briefly discussed here; pharmacogenomics are discussed in detail in Chapter 24.

The effectiveness of VKAs in primary and secondary prevention of venous thromboembolism and in prevention of systemic embolism in patients with prosthetic heart valves or atrial fibrillation has been well established by robust clinical trials. However, their widespread use also presents several challenges in clinical practice.

There are two broad classes of VKA—the coumarins and the indandiones. Warfarin is the most widely used coumarin, other forms being acenocoumarol and phenprocoumon, which have respectively shorter and longer half-lives than warfarin. Examples of indandiones are phenindione and fluindione. Because warfarin is by far the most commonly used VKA worldwide, it is used interchangeably with VKA in this discussion.

23.5.1.1 Mechanism of Action

Warfarin's mechanism of action is covered in more detail in Chapter 24. In summary, it prevents the carboxylation of clotting factors II, VII, IX, and X by inhibiting vitamin K epoxide reductase. These poorly carboxylated clotting factor forms have reduced ability to bind calcium and localize the coagulation process to phospholipid surfaces, and are therefore biologically inactive [13].

Paradoxically, VKAs also inhibit carboxylation of the regulatory anticoagulant proteins C, S, and Z and therefore can cause a transient procoagulant effect when initiated in the acute phase of a thrombotic event. Once the vitamin K–dependent clotting factor levels are reduced, the anticoagulant effect outweighs any procoagulant activity. It is for this reason that, in the treatment of acute VTE, it is advised that an additional anticoagulant (usually heparin) be given for at least five days (and until the INR is ≥2 for at least 24 h), by which time any procoagulant phase will have passed [9].

23.5.1.2 Pharmacokinetics

Warfarin is highly water soluble, is rapidly absorbed from the gastrointestinal tract, and has high bioavailability, reaching maximal blood concentrations within about ≈90 min of oral administration. It circulates bound to plasma proteins, mainly albumin (98–99%), and is metabolized by the hepatic cytochrome P450 enzymatic system [13].

Warfarin is actually a racemic mixture of two optically active isomers, known as the R and S enantiomers. These enantiomers have different anticoagulant potency and are metabolized in slightly different ways. The S enantiomer is 2.7–3.8 times more potent than the R enantiomer and undergoes approximately 90% oxidative metabolism, primarily by the CYP2C9 enzyme of the cytochrome P450 system and, to a lesser extent, by the CYP3A4 enzyme. The R enantiomer undergoes approximately 60% oxidative metabolism by the CYP1A2 and CYP3A4 cytochrome P450 enzymes [27].

23.5.1.3 Interactions

It is well documented that warfarin is susceptible to many interactions with drugs or food, and this constitutes its major disadvantage as a therapeutic agent. Genetic factors also play an important role in warfarin metabolism and therefore can determine an individual's response to the drug. This is discussed in a separate chapter.

The list of drugs that have been shown to interact with warfarin is long and ever expanding. Manufacturer product information for warfarin lists >200 specific agents that may interfere with it. A systematic review of available literature on the topic was carried out in 2005, and warfarin–drug interactions were rated according to interaction direction, clinical severity, and quality of evidence [28]. The investigators listed 72 individual drugs that they deemed as having either a "highly probable" or a "probable" clinically significant interaction with warfarin. Table 23.4 outlines some of the different ways in which warfarin–drug interactions can come about, as well as examples of offending drugs.

Warfarin is also susceptible to interactions with some foods and herbal remedies, which may be problematic for clinicians because patients are less likely to disclose intake of such products. Excessive use of alcohol is also known to affect the metabolism of warfarin and can elevate the INR. Many herbs and spices can interact with warfarin, such as ginger, garlic, ginseng, and ginkgo biloba. St John's Wort, sometimes used in depression, induces hepatic enzymes and therefore has an inhibitory effect on warfarin. In 2003, the UK Committee on Safety of Medicines received several reports of increased INR in patients taking warfarin and cranberry juice [29]. To date, a causal relationship has not actually been proven, but it is generally accepted that warning patients to avoid this combination is advisable.

TABLE 23.4 Mechanisms for Drug Interactions with Vitamin K Antagonists, with Examples

Mechanism	Example
Inhibition	
Reduced absorption due to binding	Cholestyramine
Induction of hepatic metabolism	Barbiturates, rifampicin, azathioprine, carbamazepine
Enhancement of vitamin K pathway	Vitamin K, lipid emulsions
Potentiation	
Inhibition of cytochrome P450 (CYP3A4)	Clarithromycin
Inhibition of cytochrome P450 (CYP2C9), S enantiomer	Sulfinpyrazone, metronidazole
Stereoselective inhibition of hydroxylation, R enantiomer	Cimetidine, omeprazole
Reduced nonstereoselective clearance (R and S enantiomers)	Amiodarone
Inhibition of cyclic interconversion of vitamin K	Second- and third-generation cephalosporin antibiotics
Increased metabolism of coagulation factors	Thyroxine, androgens
Potentiation of warfarin receptor effect	Clofibrate
Inhibition of platelet function	Aspirin, nonsteroidal anti-inflammatory drugs, high-dose penicillin
Increased absorption of warfarin	Acarbose

23.5.1.4 *Monitoring the Anticoagulant Effect of Warfarin*

Monitoring of warfarin's anticoagulant effect is perhaps more important than monitoring any other anticoagulant's effect because of its narrow therapeutic window and unpredictable pharmacokinetics and interactions. Prothrombin time (PT) is the most commonly used test for monitoring VKA therapy. The PT is particularly sensitive to reduced factor VII levels, but is also prolonged by reduced factors II and X. The result (in seconds) for a prothrombin time varies according to the type of analytical system used because of variations between different batches of thromboplastin used in the test reagent. A standardized calibration system called the International Normalized Ratio (INR) was adopted in 1982 [30]. The INR is the ratio of a patient's prothrombin time to a mean normal PT (derived from normal samples), raised to the power of the International Sensitivity Index (ISI) of the analytical system used.

$$\text{INR} = \left(\text{PT}_{\text{patient}}/\text{mean normal PT}\right)^{\text{ISI}}$$

The "target" INR for an individual patient depends on the reason for anticoagulation. For example, the first episodes of VTE should be treated with an INR target of 2.5, as should episodes of AF for prevention of stroke. There are some situations where higher target ranges are used, such as recurrent VTE despite anticoagulation (target 3.5) or mechanical heart valves (target 3 or 3.5 depending on the type of valve used).

Initiation of warfarin is normally guided using dosing nomograms, with higher loading doses adjusted for patient age and subsequent doses adjusted according to the INR. If rapid anticoagulation is not required, a "slow-loading" regimen has been shown to be safe and normally achieves therapeutic anticoagulation at 3–4 weeks [9].

It is a general experience, confirmed by some studies [31], that the quality of anticoagulation control is higher and the rate of bleeding lower when patients are monitored by dedicated anticoagulation clinics. Such clinics have specialized and experienced staff who promote patient education and use computer programs to help optimize anticoagulant therapy.

23.5.1.5 *Management of Bleeding and Reversal*

Bleeding is the most important complication of anticoagulation therapy and, because of the widespread use of warfarin as an oral anticoagulant, it is a fairly common clinical scenario. The annual risk of bleeding on VKAs in prospective studies has been reported to be 0.1–1.0% for fatal episodes, 0.5–6.5% for major episodes, and 6.2–21.8% for minor bleeding. The risk of bleeding increases exponentially as the achieved INR increases beyond 4.5.

There are several strategies for the management of bleeding or overanticoagulation in patients on a VKA. Which is used depends on the degree of overanticoagulation and the severity of the bleeding. Guidelines from the British Committee for Standards in Haematology on this matter are summarized in Table 23.5 [9].

Vitamin K (phytomenadione) works faster when administered intravenously, causing initial reductions in INR at 2 h. Correction of the INR to the normal range is generally achieved at 8–24 h if hepatic function is normal and a sufficient dose is given. Anaphylactoid reactions may occur with IV phytomenadione, especially if large IV doses are administered rapidly. The frequency of this complication is thought to be about 3 per 10,000 doses administered [27].

TABLE 23.5 Management Strategies in the Overanticoagulated or Bleeding Patient on a VKA

Clinical Scenario	Management
INR >5.0 with no bleeding	Withold 1–2 doses of VKA and reduce maintenance dose
INR >8.0 with no bleeding	1–5 mg of oral vitamin K
Major bleeding	25–50 units/kg four-factor prothrombin complex concentrate and 5 mg intravenous vitamin K
Nonmajor bleeding	1–3 mg intravenous vitamin K
Emergency surgery (that can be delayed by 6–12 h)	2–5 mg intravenous vitamin K
Emergency surgery (that cannot be delayed)	25–50 units/kg four-factor prothrombin complex concentrate and 5 mg intravenous vitamin K

Source: From Keeling et al. [9].

Prothrombin complex concentrates consist of the coagulation factors II, VII, IX, and X. They are extremely effective at rapid and complete reversal of anticoagulation in the warfarinized patient. They do not require a cross-match and can be infused over 15–30 min. These plasma products undergo several viral inactivation steps during their manufacture, thus minimizing the risk of viral transmission. The other main potential adverse effect is thrombosis, although this risk is also small.

23.5.1.6 *Nonhaemorrhagic Adverse Effects*

Rare side effects of VKAs are skin necrosis, purple toe syndrome, alopecia, rash, and toxic hepatitis.

23.5.2 Direct Thrombin Inhibitors—Dabigatran Etexilate

The clinical burden of thromboembolic disease and the limitations of current therapies have prompted the development of new anticoagulant agents that directly target a single enzyme in the coagulation cascade. A number of such agents have progressed through clinical development over the last few years, with those first to be licensed including dabigatran, rivaroxaban and apixaban.

Dabigatran is a selective direct thrombin inhibitor given as dabigatran etexilate (an orally absorbable prodrug), as dabigatran itself is not absorbed from the gut. It was first approved for use in VTE prevention after elective total knee or hip arthroplasty [32], but it has now been shown to be superior to warfarin in stroke prevention in nonvalvular AF [33] and noninferior to warfarin in treatment of VTE [34]. Along with the other new oral anticoagulant agents, it represents an alternative to warfarin for long-term anticoagulation with the benefit of fewer interactions and no requirement for monitoring.

23.5.2.1 *Pharmacology*

Dabigatran does not require a cofactor (unlike indirect anticoagulants such as heparin), and it directly inhibits both free and clot-bound thrombin. It is a small synthetic molecule (471.5 d) that prevents access to the active site on thrombin by forming a salt bridge via hydrophobic interactions [35]. Dabigatran also prevents thrombin-induced platelet aggregation.

23.5.2.2 *Pharmacokinetics*

Dabigatran has a predictable pharmacokinetic profile, allowing for a fixed-dose regimen that has been found to be most effective in clinical trials when given twice daily. Systemic bioavailability of oral dabigatran etexilate has been estimated at 6–7% in healthy elderly subjects [36]. The prodrug dabigatran etexilate is rapidly converted (after oral administration and hepatic processing) to dabigatran, with peak plasma dabigatran concentrations recorded approximately 1.5 h after ingestion [37]. After the peak has been reached, levels fall in a biphasic manner consistent with a rapid distribution phase, resulting in a more than 70% decrease 4–6 h after ingestion [36].

Although part of the bioconversion from prodrug to active metabolite occurs in the liver, the cytochrome P450 system is not involved; thus, dabigatran is not susceptible to interference from inducers or inhibitors of these liver enzymes. With repeated dosing, the terminal elimination half-life is 12–17 h and it takes 2–3 days to reach steady-state levels [27]. Of the administered dose, 85% is excreted by renal clearance, almost all as unchanged dabigatran, with the remaining 15% being conjugated to form pharmacologically active compounds. It is for this reason that dabigatran should be avoided in patients with severe renal impairment and that moderate renal impairment be accounted for when choosing the dosing regimen.

23.5.2.3 *Interactions*

Although dabigatran metabolism is not affected by changes in cytochrome P450 enzyme expression, it does display P-glycoprotein (P-gp) efflux transporter–mediated interactions. For example, coadministration with rifampicin (a P-gp inducer) decreases peak dabigatran concentrations and therefore drug efficacy [38]. The strong P-gp inhibitors quinidine and ketoconazole are contraindicated because they markedly increase exposure to dabigatran. There have been reports of interactions with other P-gp inhibitors such as amiodarone and verapamil, but the increase in bleeding risk is thought to be mild and may only be important if combined with old age or reduced creatinine clearance [27].

23.5.2.4 Monitoring the Anticoagulant Effect of Dabigatran

Dabigatran, rivaroxaban, and apixiban have been shown in randomized trials to be effective and safe without monitoring [32–34]. This lack of a need for monitoring is based on the assumed similarity in pharmacokinetic and pharmacodynamic responses between individuals within a relatively wide therapeutic window. It is worth remembering, however, that clinical trials often exclude patients with impaired renal function, children, the very elderly, those with bleeding risk factors, and those at extremes of body weight. It may be that more experience is needed in the use of these drugs in such patient groups before it can be safely assumed that monitoring is not required. There are still instances, however, when rapid measurement of the concentration of an anticoagulant or the degree of anticoagulation is necessary. Examples include hemorrhage, suspected overdose, emergency surgery and compliance assessment.

Traditional anticoagulant tests have limitations for measuring dabigatran effect—the PT is relatively insensitive, the relationship between the APTT and dabigatran concentration is nonlinear, and the usual form of TCT (thrombin clotting time) is oversensitive. It is suggested that each laboratory know the sensitivity of their own APTT reagent to dabigatran and advise on interpretation. Although TCT is oversensitive, a result in the normal range is helpful as it suggests that the level of dabigatran is likely to be very low [39].

Specific chromogenic anti IIa assays are available for the measurement of drugs that inhibit thrombin [40,41]. Ecarin clotting time (ECT) assays can also be used as a direct measure of direct thrombin inhibitors. This test has a linear dose-response relationship throughout the range of dabigatran concentrations expected during prophylaxis or therapeutic doses, but it is not always routinely available [27].

A genome-wide association study of 2944 participants of the Randomized Evaluation of Long-term Anticoagulation Therapy (RE-LY) study [45] identified a single-nucleotide polymorphism (SNP), rs2244613, in the *CES1* gene to be associated with trough concentrations, and the SNPs in *ABCB1* (rs4148738) and *CES1* (rs8192935) to be associated with peak concentrations at genome-wide significance. The carriage of the *CES1* rs2244613 minor allele occurred in 32.8% of patients in RE-LY and was associated with lower exposure to active dabigatran metabolite and with a lower risk of bleeding. This raises the possibility that routine genotyping may enable clinicians to tailor the dose of dabigatran for individual patients and thereby optimize the balance between efficacy and safety.

Bleeding and Reversal of the Anticoagulant Effect of Dabigatran

In the RE-LY trial, which compared dabigatran to warfarin in prevention of stroke for patients with AF, dabigatran showed similar incidences of major bleeding when compared to warfarin and caused fewer intracranial bleeds. It did, however, cause a dose-dependent increase in the incidence of major GI bleeding, which was statistically significantly greater than the risk with warfarin [33].

Perhaps the most significant limitation of the new oral anticoagulant agents is the lack of clinical evidence to guide management when rapid reversal of anticoagulation is required. As yet, dabigatran has no specific antidote, although products are in development. Its relatively short half-life means that, in situations where reversal within 24–48 h is acceptable (for example, prior to surgery), cessation of the drug and allowing it to be cleared may be appropriate. In patients with normal renal function, discontinuation of dabigatran 24 h before surgery decreases plasma levels to approximately 25% of steady-state trough levels, reducing to 5–10% 48 h after discontinuation [42].

In the event of bleeding complications in patients receiving dabigatran, there are a number of potential options for reversal of anticoagulation:

- *Recombinant factor VII*—this procoagulant and general haemostatic agent can initiate hemostasis by directly activating thrombin on the surfaces of platelets in the absence of tissue factor. *In vitro* and animal studies suggest that it can antagonize the effect of a number of anticoagulants, including dabigatran [42]. Clinical data and real-life experience is still lacking, however.
- *Prothrombin complex concentrates (PCCs)*—animal models have shown that PCCs can significantly reduce the effects of dabigatran on bleeding time [43]. A randomized controlled *in vivo* human study in healthy volunteers demonstrated that administration of a PCC resulted in virtually complete correction of coagulation after intake of rivaroxaban, but not after intake of dabigatran. It has been postulated that, because only one dosing regimen of PCC was used in this study, it may be that different doses may show efficacy for dabigatran reversal as well [44].
- *Hemodialysis and hemofiltration*—dabigatran is dialyzable because of its relatively low plasma-protein binding. Hemodialysis is therefore a potential option for rapid reversal of dabigatran's anticoagulant effect, especially in patients with renal impairment. In a study of 12 subjects with end-stage renal failure who received 50 mg of dabigatran, hemodialysis removed 62% of circulating dabigatran within 2 h [42].

Transfusion of fresh frozen plasma (FFP) is thought to have little benefit in dabigatran-associated bleeding. It is of benefit in situations where there is a depletion of clotting factors, but dabigatran causes inhibition rather than depletion of clotting factors, and FFP is unable to overcome this.

23.5.2.5 Nonhaemorrhagic Side Effects

Dyspepsia is the most frequently reported and clinically significant nonhemorrhagic side effect of dabigatran. Approximately 11% of patients experiencing dyspepsia with dabigatran have been reported in large clinical trials, compared to 6% with warfarin [33]. One of the earlier oral direct thrombin inhibitors, ximelegatran, was withdrawn because of severe liver injury. Subsequently, a genome-wide association study identified SNPs in *HLA-DRB1*0701* and *DQA1*0201* to be strongly associated with this, suggesting a possible immune pathogenesis [46]. To date, no dabigatran study has shown liver toxicity to be a clinically significant side effect. One large trial reported a small increased risk of myocardial infarction with dabigatran compared to warfarin (relative risk 1.35) [33], but the explanation for this is unclear.

23.5.3 Factor Xa Inhibitors—Rivaroxaban and Apixaban

Rivaroxaban and apixaban are direct inhibitors of factor Xa that have been evaluated in large, randomized control trials for the prevention and treatment of thromboembolic disease. Both drugs have been found to be either noninferior (rivaroxaban) or superior (apixaban) to warfarin in prevention of stroke in AF, with fewer intracranial bleeding events [47,48]. Similarly, they have been evaluated for treatment and prevention of venous thromboembolism and found to be noninferior to warfarin while causing less bleeding [49,50]. Like dabigatran, these drugs have more predictable pharmacokinetics and fewer interactions than warfarin, and do not require monitoring.

23.5.3.1 Mechanism of Action

Rivaroxaban and apixaban share the same mode of action. They are oral, highly selective, direct competitive inhibitors of factor Xa. Also, they are specific for factor Xa and do not inhibit related serine proteases, including thrombin, plasmin, factor VIIa, factor IXa, or activated protein C [51]. Both drugs reversibly bind to the active site of factor Xa, therefore suppressing the generation of new thrombin molecules. Their mechanism of action differs from indirect factor Xa inhibitors, such as fondaparinux, in that they inhibit both free and fibrin-bound factor Xa and do not rely on the presence of antithrombin [52].

23.5.3.2 Pharmacokinetics

Rivaroxaban and apixaban display similar and predictable pharmacokinetic and pharmacodynamic profiles. They are absorbed rapidly, with maximum plasma concentrations achieved at 4h after administration [53]. Apixaban can be taken without food, but higher doses of rivaroxaban (>15mg) should be taken with food to allow complete absorption. Rivaroxaban is dosed once daily except in treatment of acute VTE, when it is taken twice daily for the first three weeks before reverting to a once-daily regimen. Apixaban is administered twice daily.

Rivaroxaban is partially metabolized by the CYP450 system, specifically through the CYP3A4/5 and CYP2J2 pathways [51]. Apixaban is metabolized via CYP3A4-dependent mechanisms with minor contributions by CYP1A2 and 2J2. Both drugs are substrates of P-glycoprotein. Patients with hepatic dysfunction may have impaired metabolic activation, so rivaroxaban and apixaban should not be used in patients with moderate or severe hepatic disease (Child Pugh B/C).

Rivaroxaban has a half-life of 5–13h and has a dual mode of elimination: one-third is eliminated by the hepatobiliary route in feces; the other two-thirds are excreted in the urine. Rivaroxaban's half-life is prolonged by reduced renal function; therefore, caution is warranted in patients with moderate renal impairment and dose reduction is recommended for those with a CrCl of 15–49mL/min. It is contraindicated in patients with severe renal dysfunction (CrCl <15mL/min). Apixaban also displays a dual mode of elimination, but only 25% is excreted renally and therefore is less susceptible to accumulation in renal dysfunction. Nevertheless, it is still recommended that apixaban is avoided in patients with severe renal impairment [51].

23.5.3.3 Interactions

Both drugs are susceptible to drug interactions as they are metabolized through CYP450 and are P-gp substrates. Concomitant use of strong CYP3A4 inhibitors and P-gp inhibitors, such as the azole antifungals or protease inhibitors, is not recommended as it may lead to over anticoagulation [51]. Less potent inhibitors of these systems may be used without any dose adjustment, but any medication that is known to inhibit both pathways should be evaluated for use. Similarly, coadministration with strong inducers of CYP3A4 and P-gp should be avoided (examples include rifampicin, phenytoin, carbamazepine, St John's Wort).

As with all anticoagulants, vigilance with concurrent use of antiplatelet or other antithrombotics is warranted to avoid potentiation of the anticoagulant effect.

23.5.3.4 Monitoring of Anticoagulant Effect

Rivaroxaban and apixaban have been shown to be safe for use without routine monitoring because of their predictable pharmacokinetic characteristics. Both drugs cause only minor prolongation of the clotting times of APTT and PT assays [39]. Rivaroxaban has a more pronounced effect on APTT and PT than does apixaban, and PT is generally more sensitive to both drugs than is APTT. Again, it is advisable that each individual laboratory know the sensitivity of its PT and APTT assays to factor Xa inhibitors.

Chromogenic assays provide a more reliable measure of plasma concentrations of direct factor Xa inhibitors. The assays used have different dynamic ranges for rivaroxaban and apixaban, so a product-specific calibrator should be used.

23.5.3.5 *Bleeding and Reversal of Anticoagulant Effect*

Significant forms of bleeding have been found to be statistically lower with factor Xa inhibitors than with warfarin. The new oral anticoagulants as a group have shown significantly higher rates of gastrointestinal hemorrhage, but subgroup analyses have suggested that rates are lower in factor Xa inhibitors when compared to dabigatran [54].

At present there is no specific antidote available to antagonize the anticoagulant effects of either rivaroxaban or apixaban; however, such products are in development. In the case of overdose, activated charcoal may be used to reduce absorption.

Unlike dabigatran, renal dialysis is unlikely to be of benefit in enhancing the clearance of rivaroxaban or apixaban due to high plasma-protein binding. Possible alternative strategies include cessation of treatment and supportive management, or administration of prothrombin complex concentrates or recombinant factor VIIa in the case of severe bleeding. Limited data exist to support the use of these products other than some preclinical work in healthy volunteers [44] showing normalization of coagulation tests after their administration.

23.5.3.6 *Nonhemorrhagic Adverse Effects*

The most frequently reported adverse effects in clinical trials evaluating rivaroxaban and apixaban were nausea, vomiting, and constipation. The number of patients with elevated liver enzymes was low, and there were no associated increases in cardiovascular events.

23.6 CONCLUSION AND DIRECTIONS FOR FUTURE RESEARCH

The field of anticoagulation has undergone significant change in recent years, with the advent of new oral anticoagulants believed by many to have the potential to replace warfarin entirely. Warfarin is very well characterized, having had over 50 years of widespread use in healthcare. However, its pharmacology continues to cause clinical problems, with many patients either not receiving optimum anticoagulation or suffering bleeding events as a result of overanticoagulation.

The new, target-specific anticoagulants have a rapid onset of action, low potential for food and drug interactions, and predictable anticoagulant effect with no need for routine monitoring. Although they are more expensive than warfarin, when the cost of monitoring INR and managing complications of VKA treatment is taken into account, they may represent a smaller financial burden. Some pharmacoeconomic studies have already been carried, but this is an area that will require further analysis over the next few years.

It must be remembered that there are still some important limitations to the new oral anticoagulants that need to be addressed. Probably the most important is the lack of a specific antidote or reversal agent. Although the drugs discussed here have significantly shorter half-lives when compared to warfarin, there are situations where immediate reversal may be required. There are some options available for these situations, but clinical experience is lacking and this is certainly an area where further research is required.

That no routine monitoring is required with the new oral anticoagulants is seen by most as a significant advantage, but it should be considered that this may have effects on patient compliance. Lack of compliance may be more difficult to identify or prove and, with the short half-life of these anticoagulants, a missed dose may be more significant than with warfarin. However, it could be argued that, even if this is the case, it hasn't been shown to be clinically significant in large randomized controlled trials.

Despite the many advantages of the new oral anticoagulants, warfarin is still likely to be used widely for many more years, especially in patients with mechanical valves, mitral stenosis, and cardiomyopathy. In time, new agents in these clinical situations may be evaluated, but until then warfarin and its unique clinical challenges will continue to be of relevance in everyday clinical practice.

Chapter 24

Pharmacogenomics of Warfarin

Ann K. Daly
Institute of Cellular Medicine, Newcastle University, UK

Chapter Outline

24.1 Overview 497
24.2 Pharmacology of Warfarin 498
24.3 Nongenetic Factors Affecting Warfarin Dose Requirement 499
24.4 Genes with Major Effects on Warfarin Dose Requirement 500
24.4.1 VKORC1: The Gene Encoding the Warfarin Target 500
24.4.2 CYP2C9: The Main Pharmacogenomic Factor Affecting Warfarin Pharmacokinetics 501
24.5 Additional Pharmacogenomic Factors Affecting Warfarin Dosage 502
24.5.1 CYP4F2 502
24.5.2 Calumenin 502
24.6 Application of Pharmacogenomics to Warfarin Prescription 503
24.7 Conclusion and Future Research Directions 504
References 504

24.1 OVERVIEW

Warfarin is an anticoagulant that was synthesized originally at the University of Wisconsin. Its name was derived from Wisconsin Alumni Research Foundation (*warf*) with *arin* taken from "heparin," another anticoagulant. It was used first as a rat poison but has been prescribed for the treatment of thromboembolic disorders since the 1950s. Warfarin remains one of the most widely prescribed drugs in modern medicine, but, unusually, dosage needs to be individualized for each patient. This normally involves starting with a standard dose, measuring the coagulation rate (international normalized ratio (INR)) after two days and then adjusting the dose by a computer algorithm until the required INR, usually between 2 and 3, is obtained. Overcoagulation places the patient at risk of potentially fatal hemorrhage whereas undercoagulation means that the patient does not benefit from the drug.

For these reasons, improving protocols for initiation of warfarin treatment is important. Most patients are treated successfully with warfarin using current protocols, but some individuals, including around 10% of Europeans and varying numbers from certain other ethnic groups, require a particularly low dose (1.5 mg/day or less). These patients may be at risk of too high a level of anticoagulation that could result in serious bleeding, especially during the initial treatment period [1].

In support of this, several studies have shown that warfarin is frequently linked to emergency hospital admissions relating to adverse drug reactions [2,3]. In addition to some individuals being unusually sensitive to warfarin and needing a low dose, a smaller group of individuals (no more than approximately 1% of the population) are "warfarin resistant." These patients need an unusually high dose of warfarin (more than 15 mg per day) to achieve the required level of anticoagulation; it may be that anticoagulation cannot be achieved at all. Alternatives to warfarin have been developed recently, but warfarin continues to be prescribed widely for newly diagnosed patients suffering from various thromboembolic disorders, including deep vein thrombosis and atrial fibrillation. Large numbers of patients continue to take warfarin on a long-term basis, mostly without serious problems.

Warfarin has a chemical structure homologous to coumarin and is often referred to as a coumarin anticoagulant.

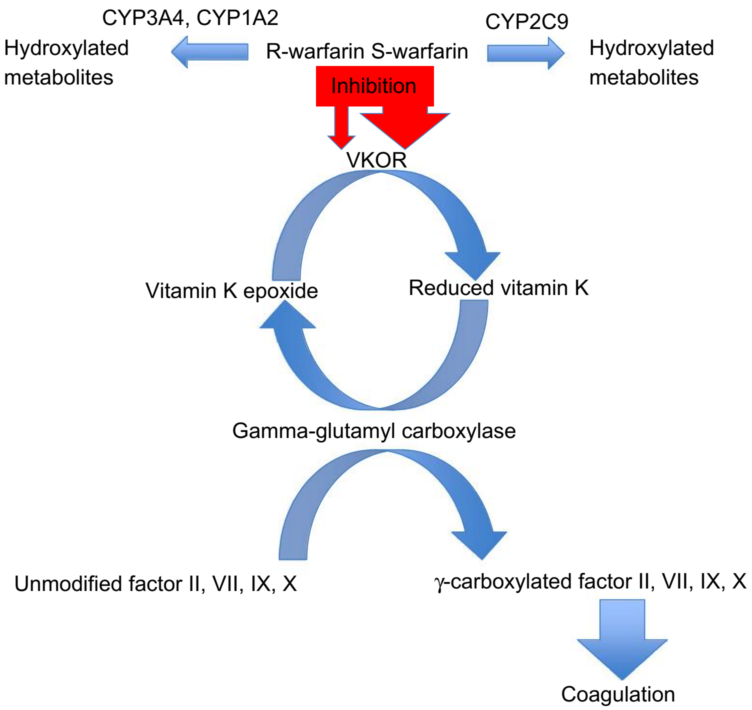

FIGURE 24.1 **The vitamin K cycle.** Warfarin targets VKOR, which regenerates reduced vitamin K after vitamin K epoxide is formed during the gamma carboxylase reaction.

Other coumarin anticoagulants (including acenocoumarol and phenprocoumon) are used as anticoagulants in preference to warfarin in certain European countries. Both drugs have considerable chemical homology to warfarin and overlap with it on pharmacogenomic factors affecting response. The genetic factors discussed in this chapter generally apply equally to these drugs, although there are some minor differences.

It is now very well established from a large number of studies worldwide that pharmacogenomic factors significantly affect individual warfarin dose requirement, although other nongenetic factors are also important. This is one of the best examples of a clinically relevant pharmacogenomic association, and attempts to translate genetic testing to the clinic prior to treatment are still ongoing. This chapter considers in detail a range of genetic polymorphisms in several genes that have been well validated as affecting warfarin dose requirement and also some additional genetic associations where the validation data are less complete, together with nongenetic factors. Progress to clinical translation is also considered.

24.2 PHARMACOLOGY OF WARFARIN

Some background on warfarin pharmacokinetics and pharmacodynamics is helpful in understanding the pharmacogenomic factors affecting response. Warfarin targets the vitamin K pathway, which plays a key role in the blood coagulation cascade. The clotting factors II, VII, IX, and X require post-translational modification of glutamic acid residues by gamma carboxylation prior to activation by proteolysis during the coagulation cascade. In the absence of this modification, the clotting factor is not recognized by the proteolysis complex. The carboxyl group is provided by CO_2 in a vitamin K-dependent reaction by the enzyme gamma-glutamyl carboxylase (see Figure 24.1). During this reaction, reduced vitamin K is converted to its oxidized form, vitamin K epoxide.

For further clotting reactions to occur, it is essential that the vitamin K epoxide is converted back to reduced vitamin K, because the latter is not stored in the body and dietary vitamin K is generally limiting. The enzyme vitamin K epoxide reductase (VKOR) catalyzes the conversion to reduced vitamin K, and warfarin acts by inhibiting VKOR by noncompetitive (also known as mixed) inhibition, whereby the inhibitor interacts with both the enzyme and the enzyme-substrate complex [4]. The gene encoding VKOR, termed vitamin K epoxide reductase complex 1 (VKORC1) was identified more recently than the majority of human genes.

Warfarin is a racemic drug with R and S enantiomers due to an asymmetric carbon at position 9 (see Figure 24.2). The S enantiomer shows a 3–5-fold higher inhibitory effect on VKOR compared with the R enantiomer. However, the

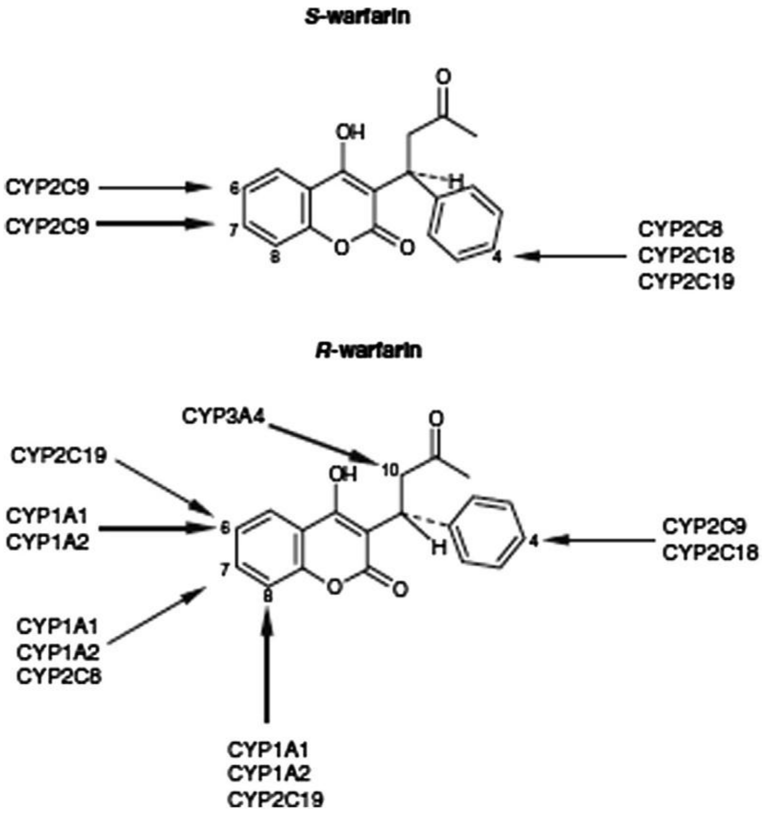

FIGURE 24.2 **S and R warfarin hydroxylation by cytochrome P450 enzymes.** Major metabolic routes are indicated by thick arrows; minor routes by thin arrows. *Source: Reprinted from Kaminsky LS, Zhang ZY*[7]*. Reproduced with permission.*

average plasma concentration of the R enantiomer is approximately two-fold higher than that of the S enantiomer, mainly because of differences in their metabolism [5]. S warfarin appears to account for 60–70% of the overall anticoagulation response, with the R enantiomer accounting for 30–40%. In the case of the S enantiomer, the major oxidative metabolite is the 7-hydroxy form, with some 6-hydroxy and 4′-hydroxy metabolites also formed at approximately equal concentrations. CYP2C9 is the main cytochrome P450 responsible for the 6- and 7-hydroxylation pathways, but at least two additional cytochromes P450, CYP2C8 and CYP2C19, can form the 4′-hydroxy metabolite [6,7]. R warfarin, on the other hand, shows more complex oxidative metabolism. The major metabolites include 6-, 8-, and 10-hydroxylated forms; 7′- and 4′-metabolites can also occur [7]. In the liver, the 6 and 8 metabolites are formed predominantly by CYP1A2. The 10-hydroxy metabolite is formed by CYP3A4—the cytochrome P450 expressed at the highest levels in most human livers. From kinetic data, formation of 10-hydroxy R warfarin by CYP3A4 is likely to be the most important oxidative metabolic route for this enantiomer.

In addition to oxidative metabolism by the cytochromes P450, the ketone group on the R warfarin side chain undergoes reduction by the carbonyl reductase enzyme family. After the phase I pathways of oxidation and reduction, the hydroxylated metabolites undergo further phase II metabolism by several UDP-glucuronosyltransferase isoforms prior to urinary excretion [8].

24.3 NONGENETIC FACTORS AFFECTING WARFARIN DOSE REQUIREMENT

Before considering genetic factors relevant to individual patient dose requirement with warfarin, it is helpful to consider the effect of nongenetic factors that are also important. One of the best studied factors is patient age. It is very well established that increasing age results in a lower dose requirement for warfarin [9]. The underlying mechanism is still not completely clear, but several independent studies suggest that it is not due to decreased warfarin metabolism [10]. Instead, it may be due to decreased hepatic blood flow slowing the delivery of warfarin to the liver [11,12], or it possibly may reflect poorer vitamin K absorption or intake in the elderly [13]. In general, a patient aged 75 years or older needs less than half the daily warfarin dose to achieve the same level of anticoagulation than does a patient aged 35 years or less [14]. When this is translated into the influence of age on warfarin dose, various estimates suggest that around 10% of variability in dose requirement is due to patient age [15,16].

Several studies have shown that parameters concerned with body size—that is, weight, height, or body mass index—also affect the warfarin dose necessary to achieve the required coagulation level [15,17,18]. A higher dose is needed where one or more of these factors is larger than average. The contribution from these parameters to dose variability is typically around 5%, so it is not as large as the variability associated with age.

Since warfarin affects the metabolism of vitamin K within the body, its action can be affected by dietary vitamin K intake. Though the actual contribution of vitamin K levels to individual dose requirements has not been estimated directly and is not taken into account when warfarin treatment is started, several studies have shown that patients who have low dietary vitamin K intake or whose intake varies have more problems maintaining a stable INR when undergoing treatment with warfarin than do patients with a higher intake that does not vary over time [19,20]. The possibility of giving patients vitamin K supplements when taking warfarin is currently under investigation. The warfarin dose needed by patients taking these supplements is higher, but better INR stability may be achieved. Two recent small-scale clinical trials have shown that this approach is feasible and safe, but further investigation in larger studies is needed to fully assess its usefulness [21,22].

Many patients undergoing treatment with warfarin are also taking additional prescribed drugs. These may interact with warfarin and, depending on the precise effect, either lower or raise the dose requirement. Not all prescribed drugs interact with warfarin, but a relatively large number of interactions have been reported [23]. The majority of drug interactions involve inhibition of warfarin metabolism or a decrease in its binding to plasma proteins, resulting in a lowering of dose requirement. Examples of drugs that have this effect include amiodarone, statins, and azole antifungals. However, some drugs are P450 inducers and may cause increased warfarin metabolism, resulting in a need to increase the dose. Examples of inducers include carbamazepine, phenytoin, and rifampicin. In addition to prescribed drugs, herbal medicines such as St. John's wort may also interact with warfarin. St. John's wort is an inducer that increases warfarin metabolism, but other herbal medicines may inhibit it. Tobacco smoking also interacts with warfarin, probably because of the cytochrome P450 CYP1A2, which metabolizes R warfarin being induced by components of tobacco smoke such as polycyclic aromatic hydrocarbons.

An additional factor that is known to affect INR stability is patient nonadherence [24,25]. As with any drug, the patient needs to be advised of the importance of adherence to the prescribed warfarin regimen.

24.4 GENES WITH MAJOR EFFECTS ON WARFARIN DOSE REQUIREMENT

Current data suggest that up to 40% of variability in individual warfarin dose requirements can be explained by genetic polymorphisms. Studies involving both candidate gene approaches and genome-wide association have demonstrated that two genes are particularly important. The VKORC1 and CYP2C9 genotypes together appear to account for the majority of variability, but a few other genes may make a more minor contribution. In addition, there is ethnic variation in the contribution of individual genes and the alleles involved.

24.4.1 VKORC1: The Gene Encoding the Warfarin Target

Until recently, the properties of the VKOR enzyme, especially the human enzyme, were poorly understood. The enzyme had not been purified, and knowledge of its properties was limited. In the original draft of the human genome sequence, no gene coding for this enzyme was shown because the gene had not been cloned and sequenced. However, because warfarin was used widely as a rat poison, data on rat VKOR was available, including the fact that some rats became resistant as a result of altered VKOR.

The genes encoding this protein in rats and mice were localized on the respective genome maps, and genome sequences for these species subsequently became available [26]. In parallel, progress on understanding human VKOR was made by investigations on two families in which several children were affected by bleeding soon after birth. Administration of vitamin K resulted in high levels of vitamin K epoxide, suggesting a defect in VKOR. Linkage analysis enabled the genetic defect to be localized to a region of chromosome 16 within a gene that appeared to code for VKOR and was termed VKORC1 [27].

This initial study also sequenced DNA from warfarin-resistant individuals and found that a majority of these were positive for nonsynonymous mutations in VKORC1. An independent study using siRNA to knock down genes encoding transmembrane proteins apparently associated with warfarin resistance also showed that the gene responsible for this trait was VKORC1 [28].

Subsequent studies on populations of patients undergoing warfarin treatment found that coding region polymorphisms in VKORC1 were rare, but identified upstream and intronic polymorphisms that correlated well with dose requirements. A number of different haplotypes were identified, but the general conclusion was that, in Europeans, the genotype for a single noncoding region polymorphism (either G-1639A or C1173T, which are in complete linkage disequilibrium) accounted for ~25% of variability in warfarin dose requirement, with the minor alleles associated with a lower dose requirement [16,29,30]. This was also the case in East Asians, but the minor allele occurred considerably more frequently than in Europeans, which explains the well-established finding of an average lower anticoagulant dose requirement in this geographic region [31,32].

Current data suggests that G-1639A affects VKOR transcription by the −1639 G allele associating preferentially with active chromatin compared with −1639A [33]. In Africans, the minor allele frequency for G-1639A/C1173T is considerably lower than in Europeans, and there are also differences in the VKORC1 haplotypes seen. The genotype for G-1639A or C1173T also predicts warfarin dose requirement in both Africans and African-Americans, but the proportion of variability in dose requirement in these groups explained by these genotypes is significantly lower (5−10%) compared with Europeans (20−30%), partly because both SNPs are less frequent in Africans.

Genotyping for additional common SNPs to detect a wider range of VKORC1 haplotypes in a study of African-Americans did not lead to an improved ability to predict variation [34]. However, a smaller study of African-Americans suggested that inclusion of a second VKORC1 SNP in addition to G-1639A improved prediction of warfarin dose [35]. Another recent study involving resequencing of VKORC1 in African-Americans found that genotyping for a common novel SNP situated more than 8 kb upstream of the VKORC1 translation start site (associated with an increased dose requirement), in addition to C1173T, increased the ability to predict warfarin dose requirement by greater than 3% [36].

Two additional VKORC1 SNPs, rs7200749 and rs7294, have been shown to be associated with increased warfarin dose requirement in black South Africans [37]. These SNPs were included in the earlier study on African-Americans, where no significant effect on warfarin dose was seen [34], but it is possible that the differences between the studies are due to a higher frequency of these SNPs among black South Africans.

Nonsynonymous mutations in VKORC1 explain many cases of warfarin resistance either where patients require an unusually high dose of the drug to achieve adequate anticoagulation, or it is not possible to achieve the required level of anticoagulation at all. A number of both isolated cases and family cases, where more than one family member was warfarin-resistant, were investigated when VKORC1 was identified [27]; they were found to be positive for such mutations. These findings have been confirmed subsequently by others.

It appears that amino acid substitutions in certain regions of VKOR result in conformational changes that prevent binding of the coumarin anticoagulant. Some of these mutations have been seen only in single patients, but others are more common. For example, Asp36Tyr was found to occur at a frequency of 4% in Ashkenazi Jews and at 15% in Ethiopian Jews [38]. Another mutation, Val66Met, is a relatively common cause of warfarin resistance in Europeans [27,39], but its overall effect at a population level is likely to be negligible.

Overall, current data suggest that genotyping for either G-1639A or C1173T is highly informative for predicting warfarin dose requirement, though the percentage variability depends on allele frequency in the individual population. Genotyping for Asp36Tyr may also be important in predicting dose required in some populations [40].

24.4.2 CYP2C9: The Main Pharmacogenomic Factor Affecting Warfarin Pharmacokinetics

CYP2C9 is a major cytochrome P450 isoform, both based on being a relatively abundant P450 in the liver and in terms of its overall contribution to P450-mediated drug oxidation. Probably the best studied CYP2C9 substrate is S warfarin, which undergoes 7-hydroxylation by CYP2C9. As discussed, S warfarin is also subject to metabolism at other positions by other CYP isoforms [6]. In addition, a different set of P450 isoforms metabolize R warfarin. Though the relatively complex metabolic profile of both warfarin enantiomers might suggest that a range of cytochrome P450 polymorphisms can affect metabolism and therefore be relevant to dose requirement, only the CYP2C9 genotype appears relevant to dose requirement based on a large number of published studies.

Most published studies have focused on the common variant alleles *CYP2C9*2* and **3*. These alleles are associated with amino acid substitutions that affect catalytic activity with S warfarin [41,42]. Initial pharmacogenetic studies showing a significant influence by the CYP2C9 genotype on dose requirement involved studies on patients known to require an unusually low dose of warfarin [1,43], but these findings were later confirmed in several larger studies involving patients of European ethnicity taking a wider range of warfarin doses [44–47]. Genome-wide association studies on European populations have also confirmed that *CYP2C9*2* and **3* are important contributors to warfarin dose requirement [48,49].

The overall contribution of the CYP2C9 genotype to warfarin dose requirement among Europeans has been estimated in a number of studies to be 6–19% [15,44,50]. Recent detailed studies have investigated genetic contributions to a variety of end points relevant to warfarin response in addition to dose requirement. From these, evidence has emerged that points to CYP2C9 as the most important genetic contributor to initial anticoagulant control [51,52], although not to stable anticoagulation.

Despite a large number of studies showing important roles for the *CYP2C9*2* and **3* alleles as determinants of warfarin dose requirement in Europeans, there have been fewer studies on other ethnic groups that show lower frequencies for these alleles but may be positive for other CYP2C9 variants that are also associated with decreased activity. For example, in African populations, the CYP2C9 allele distributions are very different from those described for Europeans. *CYP2C9*2* and **3* are not usually seen, but additional alleles associated with decreased enzyme activity, particularly *CYP2C9*8*, are common [37,53].

Other variant alleles, including *CYP2C9*5*, **6*, and **11*, have also been demonstrated to contribute to warfarin dose requirements in several studies on populations from various African countries. A similar range of CYP2C9 alleles is found among African-Americans from both North and South America, although *CYP2C9*2* and **3* are also relatively common among African-Americans [54]. In addition to the variants in the coding sequence mentioned, an intronic CYP2C9 polymorphism common in African-Americans was reported to be associated with an increased warfarin dose requirement [36], but this has not been confirmed in another independent study [55]. *CYP2C9*2* and *CYP2C9*3* are both detectable in South Asian populations although at frequencies lower than those seen in Europeans. Recent data suggest that *CYP2C9*8* occurs in South Indians [56].

The worldwide findings on the CYP2C9 genotype and warfarin dose requirement suggest that any algorithm for predicting warfarin dose should take account of the genotype for *CYP2C9*8* in addition to that for *CYP2C9*2* and **3*. There is more limited evidence that *CYP2C9*5*, **11* (which is seen at a low frequency among both Europeans and Africans), and **13* should also be considered (see Daly [57]).

24.5 ADDITIONAL PHARMACOGENOMIC FACTORS AFFECTING WARFARIN DOSAGE

The majority of published studies on pharmacogenomic factors affecting warfarin dosage agree that the VKORC1 and CYP2C9 genotypes are the important factors, with only minor contributions from other genes. This issue has been discussed in a recent detailed review article [57]; however, two of the genes, CYP4F2 and calumenin (CALU), appear to have a significant though small effect on warfarin dose requirement based on findings from a number of published studies, so these are discussed in more detail here.

24.5.1 CYP4F2

CYP4F2 is a cytochrome P450 isoform that plays a role in the metabolism of fatty acids and vitamin E [58,59]. A gene chip that genotypes for a large number of polymorphisms relevant to drug disposition, but does not cover the entire genome, provided novel data showing that the CYP4F2 genotype for the nonsynonymous polymorphism Val433Met (*CYP4F2*3* allele) contributes to warfarin dose requirement [60].

*CYP4F2*3* was found to be associated with a higher warfarin dose requirement. After its apparent relevance to warfarin treatment was reported, it was demonstrated that CYP4F2 also contributes to vitamin K1 oxidation, with the nonsynonymous polymorphism resulting in decreased activity *in vitro* [61]. A number of further studies, including several genome-wide association studies, have confirmed a contribution by CYP4F2 to warfarin dose requirement more generally [48,49]. Though the overall contribution of CYP4F2 to dose requirement appears relatively low (1–5%), *CYP4F2*3* is found at a fairly uniform frequency worldwide, so including it in an algorithm to predict warfarin dose may therefore be of value.

24.5.2 Calumenin

Calumenin is a member of the CREC family of Ca^{2+} binding proteins that serve as chaperones in certain secretory pathways [62]. Calumenin is expressed in a range of tissues, including heart, placenta, and skeletal muscle, and at a low level in the liver [63]. The protein is localized in the endoplasmic reticulum. A proposed mechanism of warfarin resistance in rats involves an interaction between VKOR and calumenin, with calumenin binding to VKOR to inhibit warfarin binding. It has also been demonstrated that livers of warfarin-resistant rats overexpress calumenin [64].

A further study on warfarin-resistant rats demonstrated that calumenin also inhibits gamma-carboxylase and therefore placed calumenin centrally in the gamma-carboxylation pathway [65]. There are a few reports on a possible contribution by the CALU genotype to warfarin dose requirement. In a study of the effect of known polymorphisms, in a range of candidate genes, on warfarin dose requirement in an Israeli population, a single patient was homozygous for a G11A allele in calumenin and required an unusually high warfarin dose of 20 mg/day [66]. The prevalence of heterozygotes for G11A in the upper tenth dose percentile was also significantly higher. More recently, a study of African-Americans that included sequencing of the CALU gene found that carriage of a noncoding SNP, which occurred at an allele frequency of 0.14 in this group, was associated with a high dose of warfarin (upper tenth percentile); it also found that this explained 5.7% of dose requirement variation [67].

In addition to CALU's positive associations with warfarin dose, a number of reports indicate no association of these genotypes with warfarin dose requirement or response. Calumenin is a good example of a biologically plausible candidate gene that requires further study to determine if it should be included in a warfarin dose prediction algorithm.

24.6 APPLICATION OF PHARMACOGENOMICS TO WARFARIN PRESCRIPTION

Most studies on genetic factors affecting warfarin response have focused on the relationship between genotype and stable dose requirement. In one of the earliest studies linking genotype and warfarin dose requirement, it was demonstrated that patients on a low, stable dose of warfarin are more likely to develop serious bleeds and high INR levels, which suggests that safety can be improved if genetic information is available at treatment initiation [1]. Subsequent detailed prospective studies have related both the CYP2C9 and the VKORC1 genotype to a range of clinical parameters from the initiation of warfarin treatment [51,52,54,68,69].

All such studies confirmed the significant contributions of CYP2C9 and VKORC1 as predictors of stable warfarin dose requirement. One study found CYP2C9 to be the most important gene determining initial anticoagulant control, and VKORC1 to be important for stable anticoagulation [51]. However, the largest study up to now found that homozygosity for CYP2C9 and VKORC1 variant alleles increased the risk of over-anticoagulation during the initiation period [52]. No effect for CYP2C9 was reported in a recent European study, but homozygosity for the variant VKORC1 allele was associated with both a shorter time to stable INR and a higher number of raised INR values (which increase the risk of bleeding) during the first month [69]. In a study involving both European and African-Americans, VKORC1 was revealed to be a significant predictor of overcoagulation during initiation in Europeans only, with a borderline significant effect for CYP2C9 but no significant effect by genotype on overcoagulation in African-Americans [54]. There is some disagreement between findings, but the various prospective studies indicate that further investigation of genotyping using randomized clinical trials may be worthwhile.

Clinical use of genotyping during warfarin treatment requires the development of suitable dosing algorithms to enable the initiation dose to be calculated. Since, as discussed previously, it is also well established that other factors, including patient age and size, and concurrent drugs affect dose requirement, these factors all need to be considered in the development of personalized dosing. The earliest dosing algorithms incorporating genetic factors were for warfarin in relation to the CYP2C9 genotype [15,44]. Once VKORC1 was also shown to be of relevance to dosing, algorithms incorporating this second genetic factor were developed [16,70–76]. Each of these algorithms was developed and tested on a relatively small patient group, though overall they were quite similar.

To improve prediction of dose requirement and to cover a wider range of ethnicities, a project involving a large number of researchers worldwide—the International Warfarin Pharmacogenetics Consortium (IWPC)—used clinical and genetic data on 4043 patients treated with warfarin to develop a more definitive dosing algorithm, which was then tested on a replication cohort of 1009 patients [18]. This was an important step forward in developing a clinically useful algorithm, but limitations included an overrepresentation of European patients and the fact that the only genotypes considered were those for common variant alleles in CYP2C9 and VKORC1. It was also uncertain exactly how an algorithm predicting a stable dose should be implemented clinically. Further refinements of the IWPC algorithm have subsequently been developed.

One refinement introduces a "dose revision algorithm," which involves initiation of treatment based on the IWPC algorithm-calculated dose followed by use of a new algorithm which incorporates genetic factors, INR value, and clinical factors on day 4 or 5 of treatment [77]. A second uses an "initiation dose" algorithm derived from the IWPC algorithm but introducing an additional term to increase the dose on days 1–3 of treatment [78]. Few currently available warfarin dosing algorithms include genetic factors other than the common CYP2C9 and VKORC1 variants, but a modification of the IWPC algorithm to include CYP4F2 genotype and a range of rarer CYP2C9 alleles was said to improve stable dose prediction [70].

Though the IWPC algorithm was developed to cover a wide range of ethnic groups, there are some recent examples of warfarin dosing algorithms developed specifically for certain ethnic groups [79,80]. Children occasionally require treatment with warfarin. Two recent studies suggest that the algorithms developed for adults are not suitable for use in children, and have developed alternatives [81,82].

A number of small clinical trials of varying designs, including some involving a randomized approach, have examined the value of using genotype and other patient-related factors to set initial warfarin dose [73,83–87]. Most of these report no advantage for a genotype-determined dose, but they may not have had adequate power to detect all genetic effects. One study focused on CYP2C9 genotypes only and did find improved time to stable INR and a higher percentage of time within therapeutic range in the group with the genotype-guided dose compared with controls receiving standard care [83]. Another obtained data showing that provision of information on genotype for both CYP2C9 and VKORC1 to the treating physician resulted in better outcomes for warfarin treatment, although genotype data was provided on average 32 days after the start of treatment, which is a serious limitation [84].

The only large randomized control trial up to the present involved 504 cases treated with a pharmacogenetic-guided dose and 1911 controls given standard dosing [88].

It showed that the pharmacogenetic-guided dosing group had a higher percentage of patients within therapeutic INR range at two time points, and fewer patients showing serious adverse events or very low or high INR values. Further randomized control trials of this type are in progress in Europe, the United States, and Singapore [89–91].

If the large clinical trials currently in progress report positive findings, more widespread translation of genotyping to the initiation of warfarin dosing seems likely. Some guidelines in relation to warfarin treatment genotyping have already been provided [92]. These guidelines are particularly aimed at the U.S. healthcare system, but should be relevant elsewhere. In particular, they emphasize that the likely value of genotyping comes early in the course of therapy, either ideally before the start or, if this is not possible, within the first few days.

Obtaining genotypes rapidly remains challenging, but some progress has been made in developing point-of-care systems. These include methods specifically geared toward use of warfarin [93] and methods to genotype for alternative pharmacogenomic polymorphisms which could be adapted for warfarin [94]. It also seems possible that, in the future, obtaining this type of genetic data might be a routine part of healthcare. Thus, pharmacogenomic information would be already available if needed [95].

24.7 CONCLUSION AND FUTURE RESEARCH DIRECTIONS

As discussed in this chapter, there is widespread agreement on a significant relationship between warfarin dose requirement and CYP2C9 and VKORC1 genotypes. However, there is much less agreement on the value of using genotyping to predict dose requirement. Even if the various clinical trials confirm that a personalized medicine approach involving genotyping leads to improved outcomes in the prescription of warfarin, it is possible that the availability of alternative drugs, including direct thrombin inhibitors such as dabigatran, may make warfarin treatment obsolete and no longer attractive for implementation of personalized medicine.

Some recent modeling data on dabigatran suggests that, if time within target INR can be improved for warfarin by incorporation of genotyping, dabigatran will likely be less cost-effective than continuing warfarin use [96]. Although dabigatran and other similar drugs do not require routine INR monitoring, there is still a risk that bleeding may occur. A recent genome-wide association study on dabigatran pharmacogenomics [97] found decreased bleeding risk in those positive for an intronic SNP in the carboxyesterase gene *CES1*, which encodes an enzyme that metabolizes dabigatran. It was suggested that genotyping for this SNP might be beneficial in individualizing dabigatran dose to increase safety [97]. This slightly unexpected finding may help in demonstrating cost-effectiveness for warfarin prescription combined with genotyping.

Key Concepts

- Warfarin is used widely as an anticoagulant drug and is unusual in that dosage is individualized for each patient by measurement of response.
- The dose required varies widely among patients.
- Factors affecting dose requirement include patient age, size, dietary vitamin K, concomitant drugs, and genotype for several genetic polymorphisms.
- The warfarin target enzyme, vitamin K epoxide reductase, is encoded by VKORC1. Common noncoding polymorphisms in VKORC1 affect warfarin dose requirement significantly and may account for 20–30% of variation in dose requirement.
- The more active warfarin form, S warfarin, is subject to metabolism by the cytochrome P450 CYP2C9. The gene encoding CYP2C9 has two common nonsynonymous polymorphisms that are associated with decreased activity. Patients positive for one or both of these require lower doses of warfarin. The CYP2C9 genotype accounts for 10–20% of variability in dose requirement.
- Other genetic factors may also contribute. The best studied examples are the genotype for CYP4F2 and calumenin, each of which may have a small effect on dose requirement.
- Randomized clinical trials to test the use of a dosing algorithm based on patient age, size, and VKORC1 and CYP2C9 genotypes to determine the initial dose of warfarin are in progress.

25.1 OVERVIEW

Platelets are the smallest elements of the blood; physiologically, they play a crucial role in the hemostatic process. Platelets interact with numerous cells, playing a key role in the development of both atherosclerosis and acute coronary syndrome (ACS). The activation of platelets is the primary mechanism of thrombosis and ischemic events; thus, their inhibition represents an elective therapeutic approach for the treatment of atherothrombotic diseases. Several antiplatelet drugs with different characteristics have demonstrated their efficacy in reducing major adverse cardiovascular events.

25.1.1 Platelets, Atherothrombotic Diseases, and Antiplatelet Therapy

Platelet activation plays a key role in the development of both atherosclerosis and acute coronary syndrome (ACS) [1,2]. It is accepted knowledge that platelets adhere to the damaged walls of blood vessels at sites of endothelial cell activation, contributing to the development of chronic atherosclerotic plaques, and trigger the acute onset of arterial thrombosis in response to atherosclerotic plaque rupture [2].

Platelets are 2–3 μm diameter, disk-shaped cell fragments that derive from fragmentation of megakaryocytes and circulate in the bloodstream of humans for 7–10 days [3]. They play a crucial role in primary hemostasis, where their rapid response to vascular injury prevents excessive blood loss, but they are also a critical factor in the onset of pathological manifestations. In fact, an alteration of platelet number and/or phenotype determines thrombus formation, which is responsible for the clinical manifestations of atherothrombotic disease: ACS (unstable angina, or UA, non-ST-elevation myocardial infarction, or NSTEMI, and

ST elevation myocardial infarction, or STEMI), ischemic stroke, transient ischemic attack (TIA), and symptomatic peripheral arterial disease (PAD). These are the main causes of morbidity and mortality worldwide [3–5].

Platelet activation is a key process in both protective hemostasis and pathological thrombosis through the activation of multiple pathways by the binding of several agonists (e.g., thromboxane A2 (TxA2), adenosine diphosphate (ADP), and thrombin) to their receptors (Figure 25.1). Platelet adhesion to the subendothelium is mediated by direct interaction between the glycoprotein (GP)Ib/V/IX receptor complex on the platelet surface and the von Willebrand factor (vWF). Moreover, the interaction between exposed subendothelial collagen with platelet receptors GPVI and GPIa stimulates the release of platelet agonists ADP and TxA2 from the adherent platelets, as well as activation of the GPIIb/IIIa receptor with high affinity for fibrinogen, which mediates stable adhesion of platelets to the vessel wall, platelet–platelet cross-linking, and contact-dependent signaling within platelet aggregates (Figure 25.1) [1,3–5].

Release of ADP and TxA2 promotes the recruitment of circulating platelets into the growing stable hemostatic plug. Thrombin-mediated cleavage of fibrinogen into fibrin further contributes to the formation of hemostatic plugs.

ADP and TxA2 activate platelets by binding to specific receptors on the platelet-P2Y$_1$ and P2Y$_{12}$ receptors for ADP and prostaglandin G2 and H2 (PGG2 and PGH2) endoperoxide receptors (TPα and TPβ) for TxA2. These bindings result in reduced intracellular cyclic adenosine monophosphate levels and full activation of GPIIb/IIIa. ADP and TxA2 can also potentiate platelet activation induced by other ligands (Figure 25.1). Thrombin activates platelets primarily by binding the protease-activated receptor (PAR)-1 on the platelet surface, cleaving the receptor, and exposing a tethered ligand that binds and activates the receptor (Figure 25.1). Thrombin is the most potent platelet agonist, as it can stimulate platelet activation via the PAR-1 at very low concentrations that are several orders of magnitude lower than those required for the activation of the coagulation cascade. Human platelets also express a secondary receptor for thrombin, PAR-4, which requires higher concentrations of thrombin for activation [1,3–5].

Other factors, such as epinephrine, PGE2, serotonin, and several chemokines play a role in platelet activation, mainly potentiating platelet activation induced by other stimuli. On the other hand, ligand-stimulated platelet activation is inhibited by a number of endothelial-derived factors, nitric oxide, and prostacyclin, which in physiological conditions prevent uncontrolled platelet aggregation and cause an increase in the intracellular levels of cyclic nucleotides (cyclic guanosine monophosphate and cyclic adenosine monophosphate). In addition, the nucleoside adenosine—released as a result of cell damage or by endothelial ectonucleotidase

CD39-mediated conversion of ADP—also inhibits platelet activation via activation of the Gs-coupled adenosine A2A receptor [1,3–5]. Therefore, the perpetuation phase of thrombus formation is mediated by the cell-to-cell contact-dependent mechanisms that lead to changes in platelet morphology, expression of procoagulant and proinflammatory molecules, and platelet aggregation [1,3–5].

Thrombus in acute atherothrombotic events (ACS, ischemic stroke, or symptomatic PAD) can be either partially or completely occlusive—the former composed primarily of platelet aggregates; and the latter of a platelet aggregate core and a superimposed fibrin-rich clot generated by the coagulation cascade [4].

Because the activation of multiple platelet pathways, in particular TxA2 and ADP platelet activation pathways, is the primary mechanism of thrombosis and ischemic events, their comprehensive inhibition is an attractive therapeutic approach for the treatment of atherothrombotic diseases (Figure 25.1). On the other hand, the potential clinical benefits of targeting various platelet activation pathways should be carefully weighed against the likelihood of increased bleeding, as both the TxA2 and ADP platelet activation pathways are also required for hemostasis.

In the last decades, oral antiplatelet agents that inhibit platelet activation by targeting cyclooxygenase 1 (COX-1) inhibition of TxA2 formation (acetyl salicylic acid, ASA, or aspirin) or by targeting the ADP-induced $P2Y_{12}$ receptor pathway (ADP $P2Y_{12}$ receptor inhibitors or thienopyridines, such as clopidogrel, ticlopidine, prasugrel, and ticagrelor) have been deeply studied and have been demonstrated to significantly reduce the incidence of ischemic events in patients with atherothrombotic diseases; also, they are widely used in clinical practice (Figure 25.1) [4,6]. The antiplatelet drugs panel also includes phosphodiesterase inhibitors (cilastozol), GPIIb/IIIa inhibitors (abciximab, eptifibatide, tirofiban), adenosine reuptake inhibitors (dipyridamole), and thromboxane inhibitors (thromboxane synthase inhibitors, thromboxane receptor antagonists) (Figure 25.1).

Antiplatelet drugs are widely used in primary and secondary prevention of thrombotic cardiovascular and cerebrovascular disease, according to current guidelines [2,4,6–8].

In particular, clopidogrel is indicated for prevention of vascular ischemic events in patients with symptomatic atherosclerosis, NSTEMI and STEMI, and it is used along with ASA for the prevention of thrombosis after percutaneous coronary intervention (PCI) with placement of an intracoronary stent. It is also used as an alternative antiplatelet drug for patients who are intolerant of ASA or with a history of gastric ulceration [2,4,6–8].

A large body of evidence exists showing that dual antiplatelet therapy (aspirin and clopidogrel) has a central role in reducing the risk of recurrent cardiovascular events in patients with coronary artery disease (CAD). Dual antiplatelet therapy is the standard of care for acute coronary syndrome (ACS) patients, who are managed either medically or by PCI [4,6]. In particular, clopidogrel treatment has delivered substantial benefits for patients undergoing PCI and stent implantation. Those receiving bare-metal and drug-eluting stents (BMS and DES) are recommended for clopidogrel-maintaining therapy for 1 month and at least 12 months, respectively. Retrospective studies have shown that the discontinuation of clopidogrel after stent implantation is associated with an increased risk of thrombotic events in patients with DES [4,6,9].

However, major adverse cardiovascular events (MACE)—namely, myocardial infarction (MI), cardiovascular death, stent thrombosis (ST), and stroke—can also occur in patients on clopidogrel therapy. Several retrospective and prospective studies have shown that, in patients who suffer MACE, the presence of on-clopidogrel high-platelet reactivity (HPR) might be demonstrated [10–15].

Consistent evidence has been accumulating in the literature on the prognostic role of HPR [16–19]. This has led to the identification of ADP-induced HPR as a marker of vascular risk in an international consensus document [20].

All these data suggest that variable response to clopidogrel is one of the main causes of thrombotic events in high-risk vascular patients. Considering the wide spectrum of alternative antiplatelet drugs, a deep knowledge of genetic and nongenetic determinants of clopidogrel response variability is crucial to the development of a personalized therapeutic strategy that targets individual patient characteristics.

25.1.2 Clopidogrel Metabolism

Different agonists induce platelet aggregation and fibrinogen binding to the subsequently activated GPIIb/IIIa receptor. In this process, ADP is a pivotal actor because it is released by damaged cells and activated platelets, thus enhancing the action of other platelet activators. ADP mediates platelet aggregation through its binding to two G protein-coupled receptors, $P2Y_1$ and $P2Y_{12}$, acting together to achieve complete aggregation. $P2Y_{12}$ also has an important role in amplifying responses to other agonists. In fact, ADP is released from platelet-dense granules regardless of the activating stimulus, be it thrombin, collagen, thromboxane A2, or any other agonist [1,3–5]. Because of the major role of $P2Y_{12}$ in arterial thrombosis and concomitant inflammatory response, the pharmacological targeting of this receptor has become an important pharmacological strategy in cardiovascular diseases. In fact, several antiplatelet drugs of the thienopyridine class have been developed that are capable of selectively binding to and inhibiting platelet $P2Y_{12}$ receptors (ticlopidine, clopidogrel, prasugrel, ticagrelor) (Figure 25.2).

Clopidogrel is a second-generation thienopyridine that has gradually replaced first-generation ticlopidine because

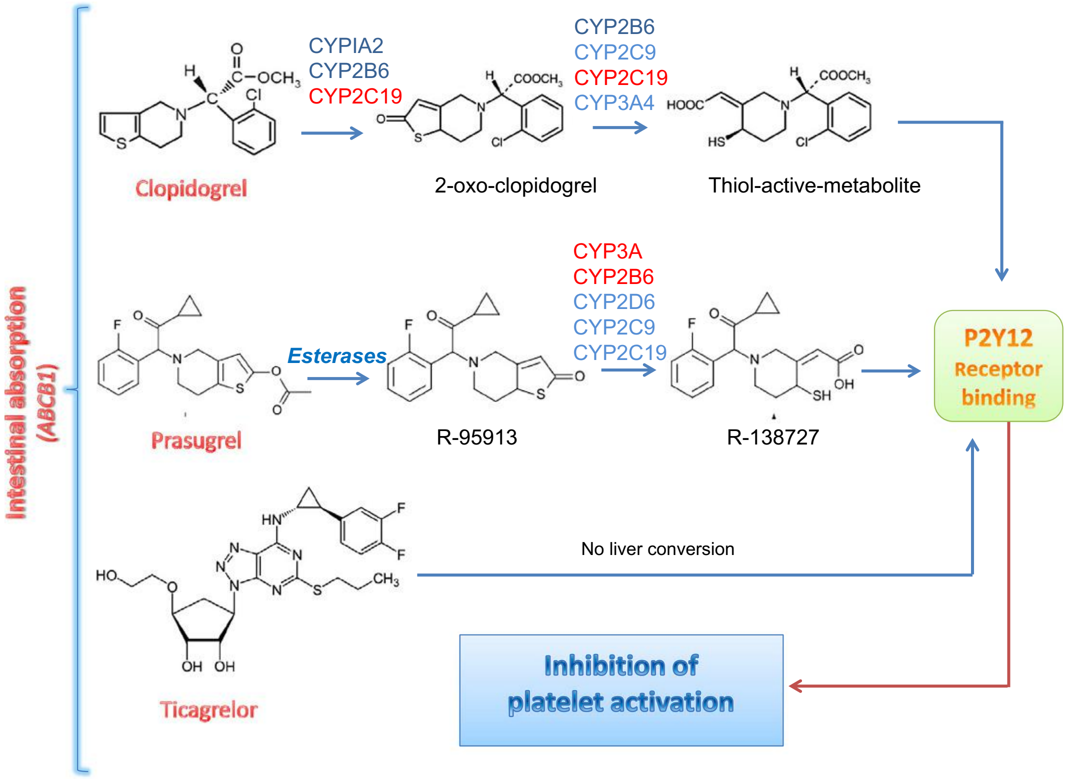

FIGURE 25.2 **Mechanism of action and metabolic pathways for clopidogrel, prasugrel, and ticagrelor.** Clopidogrel and prasugrel irreversibly bind the ADP P2Y$_{12}$ receptor. Ticagrelor reversibly binds the ADP P2Y$_{12}$ receptor.

of its freedom from serious toxicity, such as neutropenia and thrombotic thrombocytopenia purpura. The clinical efficacy of clopidogrel has been demonstrated both as an add-on to aspirin in the clinical setting, particularly for ACS patients undergoing PCI and stent implantation, and as a single antiplatelet therapy for secondary prevention [4,6].

Clopidogrel selectively inhibits the binding of ADP to the P2Y$_{12}$ subtype of the ADP receptor, and consequently inhibits the activation of the GPIIb/IIIa complex mediated by ADP. Therefore, it inhibits platelet aggregation. Because of the irreversible binding, platelets exposed to clopidogrel are affected for the rest of their life (about 7–10 days) and the recovery of platelet function occurs with a normal platelet turnover trend. Even platelet aggregation induced by agonists other than ADP is inhibited by blocking the amplification of platelet activation by released ADP. Platelet inhibition can be demonstrated 2 hours after a single dose of oral clopidogrel, but the onset of action is slow so that a loading dose of 300 or 600 mg is usually administered, followed by a daily maintenance dose of 75 mg [4,6,20].

Clopidogrel is a prodrug requiring hepatic metabolism (oxidation) by cytochrome P450 (CYP450) enzyme isoforms for its conversion to the active thiol metabolite SR26334 (Figures 25.2 and 25.3) [21–23]. It is absorbed in the duodenum, where the P-glycoprotein, coded by the *ABCB1* gene, member 1 of the ATP binding cassette subfamily B (MDR/TAP), is involved in the intestinal transport (Figure 25.3). Only about 15% of the clopidogrel prodrug undergoes metabolism by the CYP450 enzyme system in the liver; the remainder (85%) is hydrolyzed by esterases to an inactive carboxylic acid derivative (Figure 25.3) [23].

Several CYP450 enzyme isoforms, with different contributions, are responsible for the oxidation of the thiophene ring of clopidogrel (Figures 25.2 and 25.3). The first oxidation step to 2-oxo-clopidogrel is mediated by the enzymes CYP1A2 (35.8%), CYP2B6 (19.4%), and CYP2C19 (44.9%), and the intermediate metabolite undergoes further oxidation by the enzymes CYP2B6 (32.9%), CYP2C9 (6.76%), CYP2C19 (20.6%), and CYP3A4 (39.8%). The final product has the opened thiophene ring, resulting in formation of both a carboxyl and a thiol group (Figures 25.2 and 25.3) [9,21,24]. The clopidogrel active metabolite forms a disulfide bridge with the two extracellular cysteine residues located on the ADP P2Y$_{12}$ receptor, and causes an irreversible blockade of ADP binding for the platelet's lifespan [25]. Data on clopidogrel metabolism emphasize that CYP2C19 contributes substantially to

FIGURE 25.3 **Clopidogrel metabolism.** Clopidogrel is absorbed intestinally. In this step, P-glycoprotein, encoded by the *ABCB1* gene, is actively involved. Clopidogrel is mostly hydrolyzed by esterases to an inactive carboxylic acid derivative that accounts for 85% of clopidogrel-related circulating compounds. Several cytochrome P450 (CYP450) enzyme isoforms are responsible for oxidation of the thiophene ring of clopidogrel to 2-oxo-clopidogrel, which is further oxidized by other CYP450 isoforms to cause the opening of the thiophene ring and formation of the carboxyl and thiol groups. The thiol group irreversibly binds to the ADP $P2Y_{12}$ receptor expressed on platelet surfaces and causes irreversible blockade of ADP binding. *ABCB1*—ATP-binding cassette subfamily B (MDR/TAP, member 1 gene coding for the P-glycoprotein involved in clopidogrel intestinal absorption); CYP1A2—cytochrome P450 (family 1, subfamily A, polypeptide 2); CYP2B6—cytochrome P450 (family 2, subfamily B, polypeptide 6); CYP2C19—cytochrome P450 (family 2, subfamily C, polypeptide 19); CYP2C9—cytochrome P450 (family 2, subfamily C, polypeptide 9); CYP3A4—cytochrome P450, family 3, subfamily A, polypeptide 4); P2Y12—purinergic receptor P2Y (G-protein coupled, 12).

both of the oxidative steps required in the formation of the clopidogrel active metabolite (Figures 25.2 and 25.3). Understanding this phenomenon clarifies the significant effect of genetic polymorphisms of the *CYP2C19* gene, which alter the function of this important CYP450 isoform. Indeed, among the different CYP450 isoenzymes involved in clopidogrel metabolism, single-nucleotide polymorphisms (SNPs), such as the *CYP2C19*2* loss-of-function polymorphism, have been associated with the CYP2C19 enzyme's inactivation and with impaired clopidogrel metabolism.

Moreover, the CYP2C19 enzyme is responsible for the metabolism and clearance of numerous drug substrates including proton pump inhibitors (PPIs), diazepam, phenytoin, and cyclophosphamide (http://www.fda.gov/Drugs/ScienceResearch/ResearchAreas/Pharmacogenetics/ucm083378.htm). Therefore, possible drug–drug interactions should be considered in complex patients taking multiple medications.

25.1.3 Alternative Thienopyridine-Class Chemical Compounds

Other chemical compounds of the ADP receptor inhibitors thienopyridine class, prasugrel and ticagrelor, are alternatives to clopidogrel for antiplatelet therapy in the clinical setting of high-risk ACS patients undergoing PCI and stent implantation (Figure 25.2) [6].

25.1.3.1 Prasugrel

Prasugrel, a third-generation thienopyridine, is administered in ACS patients managed with PCI, and requires a loading dose to achieve a rapid, maximal antiplatelet effect. It reduces the aggregation of platelets by binding to the $P2Y_{12}$ ADP receptor. Prasugrel is a prodrug and is rapidly metabolized into a pharmacologically active form. It is hydrolyzed by carboxyesterases to a thiolactone, R-95913, which is subsequently metabolized to the prasugrel-active metabolite, R-138727. Conversion of R-95913 to R-138727 is catalyzed by several CYP450 enzymes, with the greatest contributions from CYP3A and CYP2B6, lesser contributions from CYP2C9 and CYP2C19, and few from CYP2D6. The active metabolite of prasugrel irreversibly binds to the ADP $P2Y_{12}$ receptor (Figure 25.2) [4,6,26,27].

Prasugrel is associated with greater active metabolite generation than is clopidogrel, and its maximum plasma-active metabolite concentration is reached in approximately 30 min [26]. Compared to standard and higher doses of clopidogrel, prasugrel inhibits ADP-induced platelet aggregation more rapidly, more consistently, and to a greater extent in healthy volunteers and in patients with CAD, including those undergoing PCI. Prasugrel is characterized also by less response variability than clopidogrel [4,6,28]. In the TRITON-TIMI 38 study (Trial to Assess Improvement in Therapeutic Outcomes by Optimizing Platelet Inhibition-Thrombolysis in Myocardial Infarction)—randomized, double-blind clinical trial involving 13,608 patients with ACS undergoing PCI—the prevalence of cardiovascular death, nonfatal myocardial infarction, or stroke was lower with prasugrel than with clopidogrel. However, rates of bleeding were higher in the prasugrel group [29].

25.1.3.2 Ticagrelor

Ticagrelor (AZD6140) is the first generation of a new class of reversible $P2Y_{12}$ receptor inhibitors called cyclopentyl-triazolopyrimidines. Like the thienopyridines, prasugrel, clopidogrel, and ticlopidine, ticagrelor blocks the $P2Y_{12}$ ADP receptor, but unlike the other thienopyridines, the block is reversible (Figure 25.2) [6,27,30]. Furthermore, the molecule does not require activation by the liver, which reduces the risk of drug interactions, resulting in rapid onset of action with less interindividual variation. It also inhibits nonplatelet $P2Y_{12}$ receptors present on vascular smooth muscles, where they cause vasoconstriction and increase myocardial perfusion. Ticagrelor binds to an area distinct from the ADP binding site and inhibits ADP-induced receptor activation in a noncompetitive manner. It leaves the receptor intact on dissociation, so inhibition of platelet aggregation is reversible (Figure 25.2) [6,30]. Ticagrelor was evaluated against clopidogrel in patients with ACS in the PLATO (A Study of Platelet Inhibition and Patient Outcomes) trial [31]. It was associated with significant reduction in cardiovascular death, MI, and stroke, with no difference in the overall incidence of major bleeding (defined by PLATO researchers), but with an increase in major bleeding related to non-coronary-artery bypass graft [31].

Moreover, other antiaggregant drugs, such as a PDE3 phosphodiesterase inhibitor (cilostazol), and an additional short-acting competitive $P2Y_{12}$ platelet receptor antagonist (cangrelor) are available and might be considered in the management of high-risk vascular patients.

25.2 CLOPIDOGREL RESPONSE VARIATION

Platelet inhibition by clopidogrel is highly variable, and patients with reduced platelet inhibition have an increased risk for MACE [20]. In fact, a growing number of studies have linked high platelet reactivity despite clopidogrel treatment to an increased risk of MACE, in particular ST [16,17,19,32]. Sofi and co-workers conducted a meta-analysis of the clinical consequences of clopidogrel nonresponsiveness among more than 4500 CAD patients who had undergone a PCI. They followed these patients for a period ranging from 2 weeks to 1 year after a PCI and found poor responders beat increased risk of cardiovascular clinical recurrences as opposed to those with a good response (OR 5.67 (95% CI 2.97–10.84), $p<0.00001$) [16].

Even if a single treatment strategy directed against a specific receptor cannot be expected to overcome all thrombotic events, and clinical treatment failure (e.g., an ischemic event) during clopidogrel treatment is not considered synonymous with clopidogrel resistance [20], an optimal level of platelet inhibition is a sine qua non condition of cardiovascular event prevention without increased bleeding risk. At present, despite numerous papers evaluating this issue, there is no platelet function cut-off that is widely accepted in identifying patients at high risk for ischemic events in different clinical settings [20,32].

25.2.1 High on-Clopidogrel Platelet Reactivity

Platelet function can be evaluated by several laboratory methods. These include the following:

- Light transmission aggregometry on platelet-rich plasma (PRP LTA)
- VerifyNow (Accumetrics, San Diego, CA; formerly known as Ultegra Rapid Platelet Function Assay)
- Platelet Function Analyzer 100 (PFA-100, Dade-Behring, Marburg, Germany)
- Flow cytometry
- Whole-blood aggregometry by multiple electrode platelet aggregometry (Multiplate Analyzer, Dynabyte, Munich, Germany)

Among methods for evaluating on-clopidogrel platelet reactivity, PRP LTA induced by ADP [33,34] is the gold standard. In brief, aggregometry evaluates the complex response of the platelet to ADP stimulation through the function of both $P2Y_1$ and $P2Y_{12}$ receptors. There have been studies on the maximal amplitude of measured platelet aggregation in response to 5, 10, or 20 μM ADP [20]. Despite the wide use of aggregometry, because of the many manual phases involved in the procedure, the LTA is characterized by poor standardization between institutions; thus, at present it may not be the ideal test to monitor the effects of antiplatelet therapy outside of specialized laboratories. Flow cytometry using the vasodilator-stimulator phosphoprotein (VASP) assay detects the availability of the $P2Y_{12}$ receptor and determines the effectiveness of clopidogrel. Among point-of-care tests to be used at the patient bedside or in less specialized laboratories are the following:

- PFA-100, which uses cartridges with epinephrine or ADP to mimic a high-shear state to evaluate platelet function
- The Verify Now assay system, a turbidimetry-based optical device widely used in clinical trials for testing on-clopidogrel platelet aggregation inhibition.

Paniccia and co-workers compared laboratory methods—VerifyNow $P2Y_{12}$, PFA-100, VASP, multiple electrode platelet aggregometry on whole blood, and PRP LTA—and found a significant correlation between the classical PRP LTA and the other platelet function testing platforms [33–36].

POPular was a large study that compared different platelet function methods in relation to their capacity for predicting cardiovascular events. In this study, LTA and VerifyNow were demonstrated to predict cardiovascular events, even with a low positive predictive value [37].

Several studies have been published confirming the association between on-clopidogrel HPR (regardless of the test used for its definition) and enhanced risk of adverse clinical events [16,17,19,32]. In several studies, such as RECLOSE (Low Responsiveness to Clopidogrel and Sirolimus- or Paclitaxel-Eluting Stent Thrombosis) [11,12] and RECLOSE2-ACS [18], on-clopidogrel HPR was defined at 10 μM ADP-induced maximal LTA ≥70%.

Much attention has been focused on clinical validation of point-of-care tests' determination of the cut-off for definition of HPR. For example:

- Price and co-workers conducted a study of 380 patients undergoing PCI with stent implantation. They found that the optimal cut-off for the definition of on-clopidogrel HPR associated with adverse clinical events, at a 6-month follow-up, was ≥235 PRU ($P2Y_{12}$ reaction unit) [13], as measured by the VerifyNow$P2Y_{12}$ assay.
- In the ARMYDA-PRO study (Antiplatelet Therapy for Reduction of Myocardial Damage during Angioplasty—Platelet Reactivity Predicts Outcome), and in the Marcucci and co-workers study, both using VerifyNow, the cut-off was ≥240 PRU associated with: (1) 30-day MACE on 160 patients undergoing PCI cardiovascular death; and (2) nonfatal MI at 12-month follow-up on 683 ACS patients, respectively [14,38].
- In the GRAVITAS trial (formally, Gauging Responsiveness with A VerifyNow Assay—Impact on Thrombosis and Safety), which followed 2214 patients, Price and co-workers defined on-clopidogrel HPR at ≥230 PRU [39].

25.2.2 Nonpharmacogenetic Mechanisms of High on-Clopidogrel Platelet Reactivity

Failure of clopidogrel response is due to multiple chronic or transient mechanisms. Chronic mechanisms include inadequate drug compliance, drug–drug interactions, age, diabetes mellitus, elevated body mass index (BMI), and reduced left ventricular ejection fraction (LVEF) (Figure 25.4). Transient mechanisms include inflammation, accelerated platelet turnover, reticulated platelets (RPs), erythrocyte deformability, and the activity of a disintegrin and metalloproteinase with thrombosporin motif-13(ADAMTS13) (Figure 25.4) [23]. All of these mechanisms could interact with genetic predisposition in determining inadequate response to clopidogrel and consequently increased risk of MACE, including ST, in high-risk vascular patients.

25.2.2.1 Compliance

Clopidogrel noncompliance may represent a critical issue. In a cohort of patients after stroke, discontinuation of clopidogrel therapy was observed in ~15% (within 30 days) of patients with CAD [40], in 18.4% (at 3 months), and in 38.4% (at 1 year) [41]. Whereas noncompliance represents a minor issue in short-term studies, it may have a significant impact on longer follow-up studies. In CAD and post-ischemic stroke patients, therapy with clopidogrel was associated with double-digit underestimated risks for noncompliance, especially in stroke survivors. This supports the hypothesis that lack of inhibition of platelet aggregation and clopidogrel resistance are attributed to hidden noncompliance [42]. Much evidence tells us that discontinuation of clopidogrel is associated with a significantly higher risk of ischemic events—first of all, ST [43,44]. Recently, a study assessing the risk associated with temporary (median: 7 days) discontinuation of double antiplatelet therapy, during the first year after DES implantation in 1622 consecutive patients, showed that 10.6% interrupted at least one antiplatelet drug during the first year after DES implantation (only one during the first month). Discontinuation was followed by ACS in 4.1% of patients—a rate of major cardiac

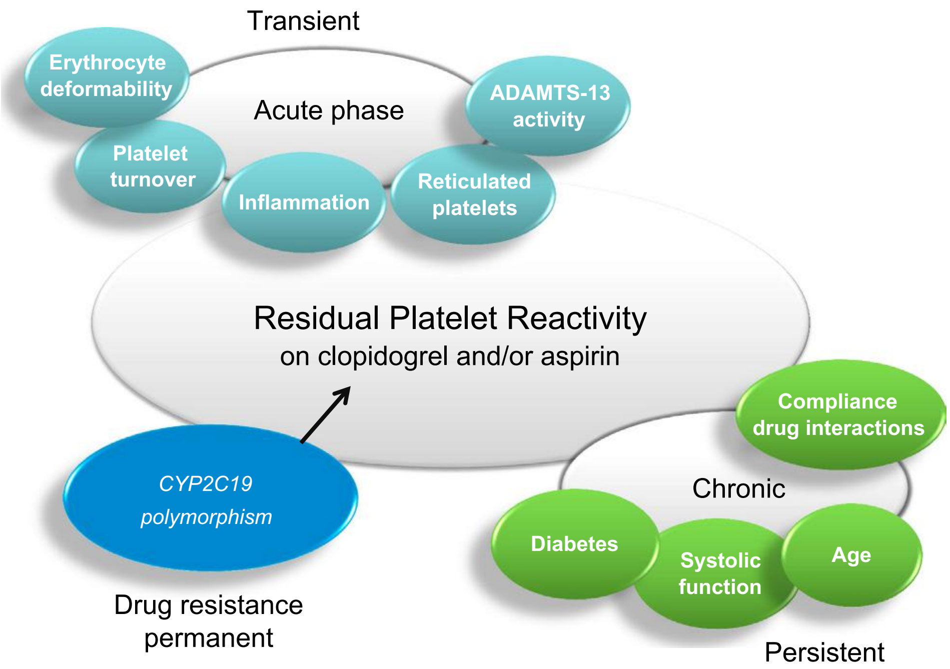

FIGURE 25.4 Mechanisms of clopidogrel response variability.

events similar to that in patients without antiplatelet therapy discontinuation (5.5%). Thus, the researchers observed that antiplatelet therapy discontinuation for a few days was not independently associated with 1-year major cardiac events (hazard ratio: 1.32 (95% CI 0.56–3.12)) [45].

25.2.2.2 Clopidogrel Interaction with Other Drugs

Other drugs taken at the same time may interfere with clopidogrel inhibition of platelet reactivity. This phenomenon may derive from high doses of calcium-channel blockers and angiotensin-converting enzyme inhibitors [9]. The lipophilic statin atorvastatin is frequently studied in clopidogrel trials because it has a high affinity for the CYP3A4 isoenzyme. Studies evaluating clopidogrel–atorvastatin interaction have not given consistent results. Some reported that atorvastatin promoted clopidogrel resistance. On the other hand, pravastatin or rosuvastatin, characterized by a nonCYP3A4 metabolism, did not seem to significantly affect clopidogrel platelet inhibition. In fact, in PCI-treated patients with HPR during co-administration of clopidogrel and atorvastatin, switching to a nonCYP3A4-metabolized statin can significantly decrease platelet reactivity and the prevalence of HRP. This effect appears similar irrespective of the type of nonCYP3A4-metabolized statin [46].

More recent studies, however, did not confirm this interaction. Post hoc analysis of several important trials—for example, CREDO (Clopidogrel for the Reduction of Events During Observation), PRONTO (Plavix Reduction of New Thrombus Occurrence), and MITRAPLUS (Maximal Individual Therapy in Acute Myocardial Infarction Plus—have not revealed a significant interaction between statins (i.e., atorvastatin, fluvastatin, lovastatin, pravastatin, simvastatin) and clopidogrel in terms of platelet inhibition [9].

The results of a recent prospective pharmacodynamic randomized study known as ACHIDO (Atorvastatin and Clopidogrel High Dose) that was conducted on stable patients with residual high platelet activity showed that treatment with high-dose atorvastatin (80 mg) associated with double-dose clopidogrel (150 mg) reduces platelet reactivity significantly more than does double-dose clopidogrel alone in statin-naïve patients with stable CAD and HPR before PCI in both diabetes mellitus and nondiabetes mellitus [47,48]. This datum suggests a possible role for statins in decreasing platelet reactivity through its anti-inflammatory effect independently of the hepatic pathway of metabolization. In particular, the antiplatelet effects of high-dose atorvastatin occur early and persist over time; they are additive to those of clopidogrel and do not correlate with the degree of lipid reduction observed during the study period [48].

There is a growing body of evidence on the interaction between the proton pump inhibitors (PPIs) and clopidogrel in influencing platelet reactivity and adverse outcomes [49–51]. It is estimated that ~15% of an absorbed clopidogrel dose is converted to an active thiol metabolite, mainly by the hepatic CYP450 isoenzymes [22]. One of these isoenzymes, the CYP2C19 isoform, is involved in the metabolism of many PPIs, which are also, to varying degrees, CYP2C19 isoenzyme inhibitors. The ability of PPIs to inhibit CYP2C19 activity reduces the active metabolite of clopidogrel generation and causes a diminished platelet response to clopidogrel. In addition, PPIs may influence antiplatelet clopidogrel response through the variability of intestinal clopidogrel absorption [9]. PPIs are substrates and inhibitors of the intestinal efflux transporter P-glycoprotein, a key factor in intestinal absorption of clopidogrel. Alterations in P-glycoprotein activity can potentially affect plasma concentrations of clopidogrel, and hence the concentration of active metabolite [9].

Gilard and co-workers documented for the first time that the contemporary administration of clopidogrel and omeprazole is associated with reduced platelet inhibition related to the $P2Y_{12}$ receptor in CAD patients. Those undergoing stent implantation on dual antiplatelet treatment in the OCLA (Omeprazole Clopidogrel Aspirin) trial were randomized to receive omeprazole 20 g/day or placebo for 7 days. This treatment significantly decreased the effect of clopidogrel on platelet reactivity as tested by platelet vasodilator-stimulated phosphoprotein (VASP) phosphorylation assay [52]. The influence of pantoprazole and esomeprazole on clopidogrel antiplatelet response was assessed in different studies, which reported that the intake of these two drugs was not able to impair platelet inhibition by clopidogrel [9]. The effect of pantoprazole and omeprazole on inhibition by clopidogrel was evaluated in 104 non-ST-segment elevation (NSTE) ACS patients. This study found, after 1 month of treatment, a significantly reduced platelet inhibition by omeprazole but not by pantoprazole [53].

Contrasting data about the capability of PPI administration to affect the risk of clinical events are also available [49–51]. In 13,636 patients with ACS treated with clopidogrel, the use of PPIs was associated with an increased risk of acute MI [54]. However, the use of pantoprazole did not significantly affect the risk of acute MI, whereas the other PPIs were associated with an increased risk of about 40%. In a retrospective study of 8205 patients with ACS, the use of clopidogrel plus PPIs (at discharge, during follow-up, or both) was associated with an increased risk of death or rehospitalization for ACS compared with the use of clopidogrel without PPIs. By analyzing the different PPIs in relation to adverse outcomes, the earlier mentioned study failed to demonstrate a significant difference between omeprazole and raboprazole [55].

The PRINCIPLE-TIMI 44 study (formally, Prasugrel in Comparison to Clopidogrel for Inhibition of Platelet Activation and Aggregation—Thrombolysis in Myocardial Infarction 44) and the TRITON-TIMI 38 study (formally, the Trial to Assess Improvement in Therapeutic Outcomes by Optimizing Platelet Inhibition—Thrombolysis in Myocardial Infarction 38) retrospectively analyzed data in order to verify the possible interactions between the use of PPIs, platelet function, and adverse cardiovascular events in relation to both clopidogrel and prasugrel. In both studies, the use of PPIs was not significantly associated with an increased risk of ischemic events in patients treated with clopidogrel and prasugrel; this was confirmed in the subgroup analysis with the single PPI (omeprazole, pantoprazole, esomeprazole, and lansoprazole) in both sets of patients [56]. Recently, Parri and co-workers published the first documentation in a randomized trial showing that, after correction for the bias of *CYP2C19*2* polymorphism, pantoprazole increases the ADP-maximal aggregation in patients treated with dual antiplatelet therapy [57]. In addition, the PLATO study retrospectively evaluated the possible influence of PPIs on the clopidogrel and ticagrelor arm. Surprisingly, they found a significantly higher risk of CV events associated with both drugs. Thus, the association of PPIs and adverse events may be due to confounding factors—namely, that patients administered PPIs have a higher morbidity—and so PPIs might be more a marker than a cause of higher rates of cardiovascular events [58].

25.2.2.3 Age

The available evidence demonstrates that advanced age is associated with a significantly high percentage of on-clopidogrel HPR. One of the causes may be the fact that the conversion of clopidogrel to its active metabolite is impaired in older patients [9]. In a prospective study that evaluated 191 patients who underwent PCI, it was shown that ADP-inducible platelet reactivity increased linearly with age after adjustment for cardiovascular risk factors, type of intervention, medication, C-reactive protein, and renal function [59]. At variance, the study by Price and co-workers evaluating various confounding factors in patients on continuous clopidogrel therapy demonstrated no effect on ADP-inducible platelet reactivity due to age (≥75 years) [60]. This discrepancy may be attributable to the duration of clopidogrel therapy. Most patients in the study by Gremmel and co-workers received a loading dose of clopidogrel prior to angioplasty, while the Price study assessed platelet aggregation mainly in patients on continuous clopidogrel therapy [59,60]. Therefore, the attenuation of clopidogrel-mediated platelet inhibition at an advanced age may be a phenomenon of the initial phase of antiplatelet therapy.

The SENIOR-Platelet study compared platelet function in 1331 elderly patients (>75) on thienopyridine (clopidogrel 75/150 mg/prasugrel 10 mg), versus that in younger patients (<75 years). It found that elderly patients present an impaired response to clopidogrel with a high rate of HPR. Clopidogrel 150 mg or prasugrel 10 mg blunted but did not eliminate the difference in response observed in old and young patients [61].

25.2.2.4 Diabetes Mellitus

Diabetes mellitus is a clinical condition characterized by enhanced platelet reactivity that exposes diabetic patients to an increased risk of atherothrombotic events. In diabetics, platelets are more frequently activated by subthreshold stimuli and consumed more rapidly, thus contributing to accelerated thrombopoiesis compared to platelets of nondiabetic individuals [62]. It has been documented that on-clopidogrel HPR is more prevalent in diabetic than in nondiabetic patients. In particular, type 2 diabetic patients undergoing elective PCI have approximately a four-fold increase in nonresponse at 24 hours following a standard loading dose. Moreover, platelet reactivity is persistently elevated in diabetic patients even in the maintenance phase of clopidogrel and is highest among those requiring insulin therapy [9,62].

25.2.2.5 Inflammation

Recent studies have documented a significant and independent association between platelet hyper-reactivity and both inflammatory markers (such as erythrocyte sedimentation rate and leukocyte number) and unbalanced proinflammatory/anti-inflammatory cytokine levels [63]. In ACS patients on dual antiplatelet treatment, during the acute phase of the disease, proinflammatory cytokine levels not sufficiently compensated by anti-inflammatory cytokines are able to modulate platelet hyper-reactivity [64]. Interestingly, Antonino and co-workers demonstrated that patients who underwent elective PCI treated with long-term clopidogrel and aspirin dual therapy had less inflammation, as indicated by specific biomarkers (C-reactive protein and other proinflammatory cytokines), compared with clopidogrel-naïve patients, suggesting that long-term clopidogrel therapy is associated with an anti-inflammatory effect [65].

25.2.2.6 Platelet Turnover and Reticulated Platelets

An elevated turnover of the circulating platelet pool yields a larger population of young platelets that are more reactive than older platelets. It has been shown that younger platelets have increased mean volume and a greater number of dense granules than do older circulating platelets [66]. In both healthy subjects and patients with stable CAD, it has been demonstrated that an increased platelet turnover, as reported by the proportion of circulating RPs, is associated with a significantly increased aggregation and activation of platelets even after dual antiplatelet therapy [9,66]. In 372 ACS patients on dual antiplatelet therapy, the number with suboptimal or “low” response to aspirin, clopidogrel, or both was clustered among patients with a high proportion of circulating RPs [67]. Moreover, RPs have been found to be independent predictors of cardiovascular death and may be useful per se in improving risk stratification in ACS patients [68].

25.2.2.7 The von Willebrand Factor and ADAMTS-13

The adhesion and activation of platelets at sites of vascular injury is mediated by the von Willebrand factor (vWF), which is released from storage sites or secreted by endothelial cells as ultralarge vWF (ULvWF) and rapidly cleaved through intravascular proteolysis by ADAMTS-13. In the acute phase of CAD and after the vascular injury induced by a PCI, endothelial cells are activated and high amounts of ULvWF are released. ULvWF forms are able to bind the GPIb–IX complex to aggregate platelets. In physiological conditions, the large multimeric forms are rapidly cleaved by ADAMTS-13 on the surface of the endothelium, resulting in the normal multimeric vWF pattern. When ADAMTS-13 activity is reduced, the ULvWFs accumulate and can induce platelet aggregation [9]. On-clopidogrel HPR is associated with lower ADAMTS-13 activity accompanied by elevated vWF levels [69], suggesting a modulatory effect of the interplay between ADAMTS-13 and vWF on antiplatelet therapy response in patients with marked endothelial activation, such as those with ACS who have undergone PCI.

25.2.2.8 Red Blood Cells and Leukocytes

Red blood cells and leukocytes are significantly implicated into the pathogenesis of arterial thrombosis. Platelet–leukocyte interactions play an important role in both adhesion and activation of platelets, but red blood cells are also involved in the interactions between platelets and the vessel wall. In patients with ACS, the inhibition of platelets induced by antiplatelet therapy is modulated not only by direct action on platelets, but also by erythrocyte deformability and white blood cell count [70]. This suggests that all blood components, including red blood cells, should be taken into account.

Some hemorheologic variables are also associated with on-treatment HPR in patients with ACS on dual antiplatelet therapy. In particular, decreased erythrocyte deformability is significantly associated with increased platelet aggregation induced by ADP [71]. A possible explanation for this association is that erythrocytes with decreased deformability tend to release a larger amount of ADP into the circulation compared to those without decreased deformability; the ADP released can compete against clopidogrel for purinergic receptors present on the platelet surface [72].

25.3 GENETIC DISSECTION OF CLOPIDOGREL RESPONSE

25.3.1 Genetic Determinants of Clopidogrel Response Variability

Among mechanisms responsible for the on-clopidogrel HPR, the individual susceptibility conferred by genetic variants in different genes coding platelet components (glycoprotein (Gp)Ia (*ITGA2*), GpIIIa (*ITGB3*), GpIb alpha (*GP1BA*), GpVI (*GP6*), ADP receptor $P2Y_{12}$ (*P2Y12*) and $P2Y_1$ (*P2Y1*), P-selectin (*SELP*), cyclooxygenase-1 (*COX1*), and cyclooxygenase-2 (*COX2*), endothelial nitric oxide synthase (*eNOS*)), or genes coding for several CYP450 enzyme isoforms involved in clopidogrel metabolism, has been hypothesized, studied and in some cases consistently demonstrated [73–76].

In particular, several polymorphisms in genes coding different isoforms of CYP450 (*CYP3A4*, *CYP3A5*, *CYP1A2*, *CYP2B6*, *CYP2C9*, *CYP2C19*) or the glycoprotein P involved in clopidogrel intestinal absorption (*ABCB1*) have been studied as determinants of on-clopidogrel HPR. For the majority of the investigated genetic variants results are negative or inconsistent.

On the contrary, consistent data are available concerning loss- and gain-of-function genetic variants in the gene *CYP2C19* on chromosome 10, and in particular the CYP2C19*2 polymorphisms. Several *CYP2C19* variant alleles have been identified and exhibit functional impairment which phenotypically categorized subjects as poor metabolizers [76,77].

The power of the evidence on the genetic contribution of genetic variants in the gene coding for one of the enzyme isoforms of CYP450, *CYP2C19*, were so consistent that in March 2010, the U.S. FDA (Food and Drug Administration) added a boxed warning to the clopidogrel label to alert clinicians to the impact of the CYP2C19 genetic profile on the drug's efficiency, thereby leaving the decision to use genetic testing to the discretion of physicians (see for details http://www.fda.gov/NewsEvents/ Newsroom/ PressAnnouncements/ ucm204253.htm and http://www.fda.gov/Drugs/DrugSafety/ PostmarketDrugSafetyInformation forPatientsandProviders/ucm203888.htm).

The *CYP2C19*2* loss-of-function polymorphism (rs4244285) is a G681A nucleotide substitution in the junction of intron 4 and exon 5, which introduces a splicing defect, resulting in a truncated, nonfunctional protein, responsible for the poor metabolizer phenotype [76,78,79]. The *CYP2C19*2* variant allele has different minor allele frequencies in Caucasian (15%), Asian (30%) and African-American (17%) populations [76,78–80].

The *CYP2C19*3* polymorphism (rs4986893) is a G636A nucleotide substitution in exon 4 that creates a premature stop codon at amino acid position 212 resulting in a truncated, metabolically inactive protein and poor metabolizer phenotype [76,78,79]. The *CYP2C19*3* polymorphism is less frequent in Asian (5%) and rare in both Caucasian (0.04%) and African-American (0.4%) populations [76,78–80]. Other rare variant alleles contribute to determine the poor metabolizer phenotype, such as *CYP2C19*4* (rs28399504, A-to-G substitution in the initiation codon, resulting in a Met1Val amino acidic substitution) and *CYP2C19*5* (rs56337013, C1297T nucleotide substitution in exon 9, resulting in an Arg433Trp amino acidic substitution) [76]. A further allelic variant, *CYP2C19*17* (rs12248560) in the *CYP2C19* gene has been discovered which results in an increased enzyme function due to a nucleotide substitution (-806C/T) in the 5′-flanking region of the gene that causes increased transcription of *CYP2C19* [76,78,79].

In 2010, Sibbing and co-workers conducted a study of 1524 patients undergoing PCI after pretreatment with 600 mg clopidogrel with a 30 day follow-up. They showed that *CYP2C19*17* carrier status is significantly associated with enhanced response to clopidogrel, as evaluated by whole-blood ADP-induced (6.4 μM) platelet aggregation (β coefficient = −32.3, SE 9.5, p = 0.0006 in the multivariable linear regression model), and an increased risk of bleeding (OR = 1.85, 95% CI 1.19−2.86, p = 0.006 in the multivariable logistic regression model) [81]. No significant influence of the *CYP2C19*17* polymorphism on ST was observed in this study [81]. However, the association was confirmed by further evidence, suggesting the need for *CYP2C19*17* in the diagnostic panel of clopidogrel pharmacogenetic variants [76–79]. Table 25.1 lists the *CYP2C19* genetic variants with known enzymatic activity alteration, and their characteristics [81–92].

25.3.2 Association of *CYP2C19*2* with High on-Clopidogrel Platelet Reactivity in Healthy Subjects

Several studies have evaluated the impact of the *CYP2C19*2* polymorphism on clopidogrel pharmacokinetics and pharmacodynamics in healthy volunteers (Table 25.2). Hulot and colleagues showed that the *CYP2C19* loss-of-function allele is associated with a marked decrease in platelet responsiveness to clopidogrel in 28 young healthy male subjects treated for 7 days with clopidogrel 75 mg/day (Table 25.2) [93]. Fontana and colleagues replicated the evidence of this association in 94 healthy subjects by assessing ADP-induced platelet aggregation after one week of clopidogrel administration (300 mg the first day; 75 mg/day maintenance dose). They too showed that *CYP2C19*2* explained 10% of the variability in clopidogrel responsiveness when the analysis was adjusted for age, platelet count, hematocrit, collagen lag time, fibrinogen, and vWF levels (Table 25.2) [94]. Brandt and co-workers genotyped healthy subjects for genetic variants in several genes involved in clopidogrel metabolism (*CYP1A2*, *CYP2B6*, *CYP2C19*, *CYP2C9*, *CYP3A4*, and *CYP3A5*). These subjects were participating in studies evaluating pharmacokinetic and pharmacodynamic response to prasugrel (60 mg, n = 71) or clopidogrel (300 mg, n = 74) [95]. In subjects treated with clopidogrel, the presence of the *CYP2C19*2* polymorphism was significantly associated with lower exposure to the clopidogrel active metabolite, lower inhibition of platelet aggregation

at 4 hours, and poor responder status (Table 25.2) [95]. Similarly, loss-of-function variants in another gene coding a different CYP450 isoenzyme—*CYP2C9*2* (rs1799853) and *CYP2C9*3* (rs1057910)—were significantly associated with lower exposure to the clopidogrel active metabolite, lower inhibition of platelet aggregation at 4 hours, and poor responder status. Concerning prasugrel, the authors did not observe a relationship between the *CYP2C19* or *CYP2C9* polymorphisms and exposure to either the active metabolite of prasugrel or pharmacodynamic response [95]. The association of clopidogrel response variability with the genetic variants of the *CYP2C9* gene was not demonstrated in other studies of healthy subjects or studies of CAD patients on clopidogrel therapy [77,96,97].

In 162 healthy subjects treated with a 300 mg loading dose of clopidogrel, Mega and co-workers reported that

TABLE 25.2 Association of *CYP2C19*2* Loss-of-Function Polymorphisms with Clopidogrel Response Variability in Healthy Subjects

Study	Number of Subjects	Treatment	Functional Evaluation	*CYP2C19*2* Carriers (%)	Association
Hulot et al. [93]	28 Caucasian males	75 mg/day for 7 days	10 μM ADP-induced PA	28.6	Yes
Fontana et al. [94]	94 Caucasians	300 mg + 75 mg/day for 7 days	20 μM ADP-induced PA	27.7	Yes
Brandt et al. [95]	74 Caucasians (57 male/17 female)	300 mg	20 μM ADP-induced PA; active metabolite by LC + MS	25.8	Yes
Mega et al. [96]	162 (130 male/32 female)	300–600 mg + 75 mg/day for 7 days	20 μM ADP-induced PA; active metabolite by LC + MS	34.0	Yes
Kim et al. [98]	24 Koreans	300 mg + 75 mg/day for 7 days	5 μM ADP-induced PA; PCC by LC + MS	66.6 (selected)	Yes
Umemura et al. [99]	47 Japanese	300 mg	20 μM ADP-induced PA; VASPph; active metabolite by LC + MS	61.7	Yes
Shouldiner et al. [97]	429 Amish (214 male/215 female)	300 mg + 75 mg/day for 6 days	20 μM) ADP-induced PA	32.9	Yes

LC + MS—liquid chromatography with tandem mass spectrometry; PA—platelet aggregation; PCC—clopidogrel plasma concentrations; VASPph—vasodilator-stimulated phosphoprotein phosphorylation state of whole blood performed by dual color flow cytometric assay.

carriers of at least one *CYP2C19* loss-of-function allele (30% of the study population) had a relative reduction of 32.4% in plasma exposure to the active metabolite of clopidogrel, as compared with noncarriers (Table 25.2) [96]. Carriers also had an absolute reduction in maximal platelet aggregation in response to clopidogrel that was 9% less than that seen in noncarriers [96].

Kim and co-workers divided 24 Korean subjects into three groups on the basis of their *CYP2C19* genotype: homozygous extensive metabolizers (homoEMs, n = 8), heterozygous EMs (heteroEMs, n = 8), and poor metabolizers (PMs, n = 8) (Table 25.2) [98]. After a single 300 mg loading dose of clopidogrel on day 1, followed by a 75 mg daily maintenance dose on days 2–7, the investigators measured the plasma levels of clopidogrel and assessed the antiplatelet effect. The mean clopidogrel area under the curve (AUC) for PMs was 1.8 and 2.9 times higher than that for heteroEMs and homoEMs, respectively. The mean peak plasma concentration in PMs was 1.8 and 4.7 times higher than that of heteroEMs and homoEMs, respectively. PMs exhibited a significantly lower antiplatelet effect than heteroEMs or homoEMs [98].

In 47 Japanese healthy subjects, Umemura and colleagues determined plasma concentrations of the active metabolite before and at 0.25, 0.5, 1, 2, 4, and 8 hours after treatment with 300 mg clopidogrel (Table 25.2) [99]. Moreover, before and at 1, 4, and 6 hours and after 24 hours, they measured inhibition of platelet aggregation to ADP and VASP, confirming that the *CYP2C19*2* polymorphism is a determinant for active metabolite formation and demonstrating that the pharmacokinetic parameters of the active metabolite (area under the plasma concentration–time curves (AUC); peak concentration (C_{max})) were well correlated with the platelet reactivity index by VASP and inhibition of platelet aggregation by ADP. Their findings suggest that low or no responsiveness to clopidogrel is mainly caused by the lower metabolic formation of the metabolite, but not because of the poor sensitivity of the platelet $P2Y_{12}$ receptor [99].

In an elegant study published in the 2009, known as PAPI (Pharmacogenomics of Antiplatelet Intervention, Shuldiner and colleagues administered clopidogrel—300 mg oral loading dose followed by 75 mg per day for 7 days—to 429 healthy Amish individuals and measured response by *ex vivo* platelet aggregometry (baseline platelet aggregation and 1 hour following the last dose of clopidogrel) (Table 25.2) [97]. They then performed a genome-wide association study (GWAS) followed by the genotyping of the *CYP2C19*2* polymorphism. The presence of relatives in the population allowed the investigators to observe that platelet response to clopidogrel was highly heritable ($h2 = 0.73$; $p < 0.001$). They identified 13 polymorphisms on chromosome 10q24 in the *CYP2C18-CYP2C19-CYP2C9-CYP2C8* cluster associated with diminished clopidogrel response. All of these polymorphisms were in strong linkage disequilibrium with the genetic variant rs12777823, the most significantly associated polymorphism ($p = 1.5 \times 10^{-13}$ at the additive model). rs12777823 was in strong linkage disequilibrium with the *CYP2C19*2* variant, accounting for 12% of the variation in platelet aggregation to ADP ($p = 4.3 \times 10^{-11}$). No other genomic region revealed association signals that met or exceeded genome-wide significance ($p < 1.0 \times 10^{-7}$) [97]. These data suggest that, in this population of healthy subjects, the common loss-of-function *CYP2C19*2* variant may account for most of the association signal detected in the GWAS. Because of the high heritability of platelet response to clopidogrel, other common SNPs not present on the chip, other types of variants (e.g., copy number variants, insertions/deletions), or rare variants with large effect sizes not tagged by the genotyped SNPs may play an important role in determining clopidogrel response variability.

25.3.3 Association of *CYP2C19*2* with High on-Clopidogrel Platelet Reactivity in High-Risk Vascular Patients

In 2007, Giusti and co-workers were the first to study the effect of the *CYP2C19*2* loss-of-function allele on platelet function modulation in ACS patients who had undergone PCI and stent implantation on dual antiplatelet treatment (Table 25.3) [100]. They demonstrated that *CYP2C19*2* is associated with higher platelet aggregability and HPR in 1419 high-risk vascular patients on dual antiplatelet treatment. Carriers of the *CYP2C19*2* allele had significantly higher platelet aggregation values than noncarriers after 2 μM and 10 μM ADP, and after arachidonic acid (AA) stimuli. In particular, homozygous subjects for the *CYP2C19*2* allele had significantly higher platelet aggregation after ADP stimulus (2 μM and 10 μM) than heterozygous carriers. The genotype distribution of *CYP2C19*2* significantly differed between patients with and without HPR evaluated by 10 μM ADP-induced platelet aggregation ≥70%. The prevalence of carriers of the minor allele was higher in patients with HPR by ADP than in patients without HPR by ADP. Similar results were also observed in patients with HPR by AA compared with patients without HPR by AA.

In the multivariate linear regression model—with ADP 2 μM or ADP 10 μM or log(AA) platelet aggregation as the dependent variable and age, gender, hypertension, diabetes mellitus, dyslipidemia, and smoking habit as the independent variables—age, diabetes, and *CYP2C19*2* remained significant and independent risk factors for antiplatelet treatment variability [100]. In that study, Guisti et al. also found no influence on clopidogrel platelet aggregability in ACS patients of previously suspected and studied polymorphisms: the +12G/A IVS10 (rs2242480) polymorphism of the *CYP3A4* gene and the T744C (rs2046934) polymorphism of the *P2Y12* gene [100].

Several other studies confirm that the **2* allele of the *CYP2C19* gene is associated with higher platelet aggregability and HPR in similar and different clinical settings. Table 25.3 lists selected representative studies from the literature on the association of *CYP2C19*2* with on-clopidogrel HPR in high-risk vascular patients.

In 603 patients with non ST-elevation ACS, Frere and colleagues demonstrated that *CYP2C19*2* influences post-treatment platelet reactivity and clopidogrel response assessed by ADP-induced platelet aggregation, VASP phosphorylation index, and ADP-induced P-selectin expression (Table 25.3) [101].

Trenk and colleagues studied and followed 797 patients undergoing elective coronary stent implantation; they showed an association between *CYP2C19*2* and platelet function phenotype of high (>14%) ADP residual platelet aggregation on clopidogrel (Table 25.3) [102].

Geisler and co-workers studied 237 symptomatic CAD patients (both stable angina and ACS). They observed that *CYP2C19*2* carriers showed significantly increased residual platelet aggregation compared with noncarriers (Table 25.3) [103].

In the randomized PRINC (Plavix Response in Coronary Intervention) trial involving 60 patients undergoing elective PCI, Gladding and co-workers measured platelet function using the VerifyNow $P2Y_{12}$ analyzer after a 600 mg or split 1200 mg loading dose and after a 75 or 150 mg daily maintenance dose (Table 25.3) [104]. *CYP2C19 *1*1* homozygotes had greater platelet inhibition 2 hours after a 600 mg dose, compared with platelet inhibition in *CYP2C19*2* or *CYP2C19*4* and *CYP2C19*17* carriers. *CYP2C19*2* or *CYP2C19*4* carriers had greater platelet inhibition with the higher loading dose than with the lower dose at 4 hours, and they responded better to the higher maintenance dose regimen.

The association of the *CYP2C19*2* polymorphism with HPR was observed in Japanese patients by Jinnai and co-workers. They found a higher prevalence of *CYP2C19*2* carriers (56%) compared to patients in Western countries (30%) (Table 25.3) [105].

In 2012, Price and co-workers sought to evaluate the influence of SNPs on the pharmacodynamic effect of high- or standard-dose clopidogrel after PCI. In the GIFT (Genotype Information and Functional Testing) study, the GRAVITAS trial screened patients with platelet function testing (VerifyNow $P2Y_{12}$) after PCI at 12–24 hours, and randomly assigned those with high on-treatment HPR to either a high (150 mg) or a standard (75 mg) dose of clopidogrel [106]. A cohort of patients without HPR was also

TABLE 25.3 Association of *CYP2C19*2* Loss-of-Function Polymorphisms with Clopidogrel Response Variability in High-Risk Vascular Patients

Study	Number of Subjects	Treatment	Functional Evaluation	*CYP2C19*2* Carriers (%)	Association
Giusti et al. [100]	1419 PCI + stent	600 mg LD + 75 mg/day maintaining	10 μM ADP-induced PA	31.4	Yes
Frere et al. [101]	603NSTE	600 mg LD	10 μM ADP-induced PA; VASPph; ADP-induced P-selectin	27.6	Yes

Price et al. [106]	1028 PCI + stent	600 mg LD + 75/150 mg/day maintaining	VerifyNow P2Y$_{12}$	36.4	Yes

GPIIa/IIIb—glycoprotein IIa/IIIb (PAC-1); GPIIb—glycoprotein IIb; LD—loading dose; NSTE—non-ST elevation; PA—platelet aggregation; PCI—percutaneous coronary intervention; VASPph—vasodilator-stimulated phosphoprotein phosphorylation state of whole blood performed by dual color flow cytometric assay.

followed. The researchers obtained DNA samples from 1028 patients, who were genotyped for 41 SNPs in 17 genes related to platelet reactivity. They found that *CYP2C19*2* was significantly associated with HPR at 12–24 hours, 30 days, and 6 months after PCI, whereas other candidate SNPs (e.g., *PON1*, *ABCB1*) were not. Carriers of one and two reduced-function *CYP2C19* alleles were significantly more likely to display persistently high HPR at 30 days and 6 months, irrespective of treatment assignment. The portion of the risk of persistently high HPR at 30 days that was attributable to reduced-function *CYP2C19* allele carriage was 5.2% in patients randomly assigned to high-dose clopidogrel. The investigators concluded that CYP2C19, but not PON1 or ABCB1, is a significant determinant of the pharmacodynamic effects of clopidogrel, both early and late after PCI. In patients with high HPR identified by platelet function testing, the *CYP2C19* genotype provides limited incremental information regarding the risk of persistently high reactivity with 150 mg clopidogrel maintenance dosing [106].

25.3.4 Association of *CYP2C19*2* with Major Adverse Cardiovascular Events

In 2009, several groups simultaneously demonstrated, in different clinical settings and at different follow-up times, that the *CYP2C19*2* polymorphism is a significant and independent determinant of MACE and, in particular, of ST (Table 25.4) [96,107–110].

A study conducted in 2008 failed to demonstrate the role of the *CYP2C19*2* loss-of-function polymorphism in the occurrence of MACE or ST. In fact, Trenk and co-workers did not demonstrate a relationship between *CYP2C19*2* polymorphism and increased occurrence of adverse 1-year clinical outcome (death from any cause and MI) of elective PCI with DES or BMS [102]. They showed an association

TABLE 25.4 Association of *CYP2C19*2* Loss-of-Function Polymorphisms with MACE

Study	Number of Subjects	Treatment	Outcome (Follow-up)	CYP2C19 Alleles	Association
Simon et al. [107]	2208 AMI with or without PCI 1535/2208 PCI	300 mg mean LD + 75 mg/day maintaining	Death + nonfatal stroke	Any two **2, *3, *4, *5*	Yes (HR=1.98)
			MI (1 year)		Yes (HR=3.58)
Mega et al. [96]	1477 ACS	300 mg LD + 75 mg/day maintaining	Cardiovascular death + MI + stroke (15 months)	**2*	Yes (HR=3.09)
			ST (15 months)		Yes (HR=1.53)
Collet et al. [108]	259 MI (<45 yrs)	600 mg LD + 75 mg/day maintaining	Death + MI + coronary revascularization (6 months)	**2*	Yes (HR=6.02)
			ST + ischemic events		Yes (HR=3.69)
Giusti et al. [109]	772 PCI + DES	600 mg LD + 75 mg/day maintaining	Cardiovascular death + ST (6 months)	**2*	Yes (OR=2.70)
			ST (6 months)		Yes (OR=3.43)
Sibbing et al. [110]	2485 PCI + stent	600 mg LD + 75 mg/day maintaining	ST (30 days)	**2*	Yes (HR=3.81)

Note: Study results published in 2009. LD—loading dose; PCI—percutaneous coronary intervention; MI—myocardial infarction; AMI—acute myocardial infarction; ACS—acute coronary syndrome; ST—intrastent thrombosis; DES—drug-eluting stent; HR—hazard ratio; OR—odds ratio.

of *CYP2C19*2* with platelet function phenotype, as well as an association of on-clopidogrel HPR with poor clinical outcomes. On the other hand, in their patient population only 280 patients out of 797 had at least one DES. In that group, the percentage of patients with an event was 3.3% (3 out of 90) among carriers of the *CYP2C19*2* allele versus 2.1% (4 out of 190) among wild-type homozygotes [102].

In a study of 2208 patients with acute MI on clopidogrel therapy, Simon and co-workers assessed the association of several allelic variants of genes modulating clopidogrel absorption (*ABCB1*), metabolic activation (*CYP3A5* and *CYP2C19*), and biological activity (*P2Y12* and *ITGB3*) with the risk of death from any cause, nonfatal stroke or MI during 1 year of follow-up [107]. None of the selected polymorphisms in the *CYP3A5*, *P2Y12*, or *ITGB3* genes were associated with the risk of adverse outcomes. Patients with two variant alleles of *ABCB1* (TT genotype) had a higher rate of cardiovascular events at 1 year than those with the *ABCB1* wild-type genotype (CC) (15.5% versus 10.7%; adjusted HR = 1.72, 95% CI 1.20–2.47). Moreover, they demonstrated that patients carrying *CYP2C19* loss-of-function alleles (**2, *3, *4,* or **5*) had a higher rate of subsequent cardiovascular events during 1 year of follow-up (HR 1.98, 95% CI 1.10–3.58) than those who were not. The presence of two variant alleles of *CYP2C19*, but not *ABCB1*, was found to be associated with an increase by a factor of 3.58 (95% CI 1.71–7.51) in the rate of cardiovascular events among the 1535 patients who had undergone PCI during hospitalization, as compared with those who had not (Table 25.4) [107].

Mega and co-workers tested the association of functional genetic variants in CYP genes (*CYP2C19*, *CYP2C9*, *CYP2B6*, *CYP3A5*, *CYP3A4*, and *CYP1A2*), plasma concentrations of active drug metabolites, and platelet inhibition in response to clopidogrel in 162 healthy subjects [96]. Furthermore, they examined the association between these genetic variants and cardiovascular outcomes in a separate cohort of 1477 subjects with ACS who were treated with clopidogrel in the TRITON TIMI 38 trial [96].

In the cohort of 1477 ACS patients who were treated with clopidogrel, Mega and co-workers demonstrated that *CYP2C19*2* carriers had significantly lower levels of the active metabolite of clopidogrel, diminished platelet inhibition, and a higher rate of MACE at 15 months (death from cardiovascular causes, MI, or stroke; HR 1.53, 95% CI1.07–2.19) and an increase (by a factor of 3) in ST risk (HR 3.09, 95% CI 1.19–8.00) [96].

In 259 young patients (<45 years) who had survived a first MI and had been exposed to clopidogrel treatment for at least 1 month, Collet and co-workers assessed whether *CYP2C19*2* affected long-term prognosis in those chronically treated with clopidogrel [108]. They chose as a primary end point a composite of cardiovascular death, nonfatal MI, and urgent revascularization during exposure to clopidogrel. ST was the secondary end point. In this cohort of premature MI patients, the primary end point occurred more frequently in carriers than in noncarriers (15 versus 11 events; HR = 3.69, 95% CI 1.69–8.05, p = 0.0005). Similar results were obtained for the secondary end point; the researchers observed an increase in the risk of ST by a factor of 6 (8 versus 4 events; HR = 6.02, 95% CI 1.81–20.04, p = 0.0009). After multivariable stepwise Cox regression analysis, considering all of the baseline characteristics in the model, if they were significant at p = 0.20 in the univariate model, especially those known to be associated with recurrent acute coronary thrombosis and poor response to clopidogrel (body mass index, smoking status, diabetes mellitus, stent implantation, initial ST-segment elevation MI, and use of PPIs), the *CYP2C19*2* genetic variant was the only independent predictor of cardiovascular events (HR = 4.04, 95% CI 1.81–9.02, p = 0.0006) [108].

Giusti and co-workers studied 772 patients undergoing PCI and stent implantation, who were receiving dual antiplatelet treatment as part of the RECLOSE trial. They evaluated the role of *CYP2C19*2* in drug-eluting ST (primary end point) and the composite feature of cardiac mortality and drug-eluting ST (secondary end point) at 6-month follow-up (Table 25.4) [109]. Patients with ST or the composite of cardiac mortality and ST showed a higher prevalence of *CYP2C19*2* carriers (54.1% versus 31.3%, p = 0.025; 51.7% versus 31.2%; p = 0.020, respectively). In this clinical setting of high-risk vascular patients, the researchers demonstrated that *CYP2C19*2* was an independent risk factor for ST when its effect was evaluated in a model adjusted for on-clopidogrel HPR evaluated by ADP-induced platelet aggregation (ADP-HPR), traditional cardiovascular risk factors, and clinical and procedural risk factors for ST (e.g., total chronic occlusion, multivessel disease, bifurcation lesion, acute MI, previous MI, total stent length, left ventricular ejection fraction) (OR = 3.43, 95% CI 1.01–12.78). Moreover, subjects with contemporaneous *CYP2C19*2* and ADP HPR showed a strong risk of ST or ST and cardiac mortality (OR = 5.79, 95% CI 1.04–39.01 and OR = 11.45, 95% CI 1.84–71.27, respectively) [109].

Sibbing and co-workers investigated the role of the *CYP2C19*2* loss-of-function polymorphism on ST following PCI performed after pretreatment with clopidogrel. The primary end point of the study was the incidence of definite ST within 30 days following PCI. A total of 2485 patients with CAD undergoing PCI were enrolled in this study (Table 25.4) [110].The cumulative 30-day incidence of ST was significantly higher in *CYP2C19*2* allele carriers (*1/*2 heterozygotes or *2/*2 homozygotes) versus *CYP2C19* wild-type homozygotes (*1/*1) (1.5% in *CYP2C19*2* allele carriers versus 0.4% in *CYP2C19* wild-type homozygotes, HR = 3.81, 95% CI 1.45–10.02, p = 0.006, after adjustment for confounding variables). The risk of ST was highest (2.1%) in patients with the *CYP2C19* *2/*2 genotype (p = 0.002) [110].

In contrast to the findings of previous studies, Paré and co-workers showed that, in patients with ACS from the CURE study (formally, Clopidogrel in Unstable Angina to Prevent Recurrent Events) and in those with atrial fibrillation from the ACTIVE A study (formally Fibrillation Clopidogrel Trial with Irbesartan for Prevention of Vascular Events A) *CYP2C19*2* was not associated with an increased risk of MACE [111]. One possible explanation for the discrepancy between these data and previous data can be found in the rate of PCI with stenting. Whereas previous evidence was obtained in cohorts of which the totality, or at least a large proportion, had undergone PCI with or without stenting, only 18% of the patients from CURE had undergone PCI, and only 14.5% had undergone PCI with stent implantation.

Several meta-analyses of clopidogrel pharmacogenetics available in the literature discuss apparently different responses to a similar interrogation [50,112–114]. These apparent discrepancies are used to support doubts about the usefulness of clopidogrel pharmacogenetics. Sofi and co-workers [112] performed a meta-analysis using data available for 7950 patients from six cohort prospective studies who were followed for a time ranging from 6 months to 8.4 years [96,102,107–110]. Their results reinforced the observation that *CYP2C19*2* is associated with increased risk of MACE and, in particular, ST. The summary risk ratios (RR) for included cohort prospective studies showed a significant association between *CYP2C19*2* and increased risk of MACE in the follow-up (RR = 1.80, 95% CI 1.02–3.19, p = 0.04). When studies evaluating ST (n = 4), for a total of 4975 patients were considered, *CYP2C19*2* was associated with an increased risk of ST (RR = 2.82, 95% CI 1.43–5.56, p = 0.0001).

In two larger meta-analyses, one by Hulot and co-workers and the other by Mega and co-workers, it was further demonstrated that the status of carriers of just one loss-of-function *CYP2C19*2* allele is associated with significantly increased risk of MACE, particularly ST [50,113]. With these findings, the *CYP2C19* genetic identifies approximately 30% of the population who may be less likely to gain protection from recurrent ischemic events after PCI, despite treatment with standard doses of clopidogrel.

A further systematic review and meta-analysis of 32 studies by Holmes and colleagues came to different conclusions [114]. By including all studies in which clopidogrel pharmacogenetics were tested relative to cardiovascular events—independently of the fact that they studied high-risk patients undergoing PCI or lower-risk vascular patients—the researchers concluded that CYP2C19*2 carrier status was not clinically relevant for cardiovascular outcomes, with the possible exception of ST [114].

The hazard of drawing conclusions to apply in clinical practice by acquiring data from systematic reviews or meta-analyses—including and considering similar patients with greatly different risks of cardiovascular events and therefore with different benefits gained from clopidogrel treatment—should be underlined [76]. Indeed, Holmes and co-workers paid particular attention to comparator trials of clopidogrel treatment response in which both treatment and comparator group were genotyped (CLARITY-TIMI 28, CURE, ACTIVE-A, CHARISMA) [114]. In these studies, populations consisted of patients who, in large part, had substantial differences in cardiovascular risk in comparison to populations in studies considered in previous meta-analyses: patients receiving fibrinolytic therapy. Of these patients, 50% also had PCI (CLARITY-TIMI 28) with NSTEMI, and 18% had PCI (CURE) with atrial fibrillation (ACTIVE-A). The benefit of clopidogrel in terms of risk reduction for these patients was 11%; for those with documented cardiovascular disease, or risk thereof, clopidogrel showed no benefit over placebo (CHARISMA) [114].

25.3.5 Other Investigated Genetic Variants

Other polymorphisms were studied, but at present clear evidence on their role has not been attainable. In the same issue of the *Lancet*, Mega and co-workers [115] (in a TRITON-TIMI 38 cohort of patients) and Wallentin and co-workers [116] (in a PLATO cohort of patients) evaluated the effect of *CYP2C19*2* and C3435T *ABCB1* (rs1045642) (a synonymous polymorphism in exon 26 substitutes itself for isoleucine at position 1145 in the protein) on antiaggregant treatment efficacy. The two studies confirmed the independent role of *CYP2C19*2* as a determinant of MACE in patients with ACS receiving clopidogrel [115,116], even if a lower impact of the loss-of-function alleles was observed in PLATO compared with TRITON-TIMI 38 or the meta-analyses [50,112,113]. Neither study showed any association between the *CYP2C19* genetic variants and MACE in patients receiving prasugrel or ticagrelor [115,116].

The most interesting novel data from these two studies were those obtained on the C3435T *ABCB1* polymorphism. The Mega and Wallentin articles presented conflicting results here, even though both investigated relatively large populations [115,116]. Mega and co-workers found that patients receiving clopidogrel who had the *ABCB1* 3435 TT genotype were at increased risk of recurrent ischemic events compared with those who had the CT or CC genotypes. The researchers posited that this was most likely because of reduced platelet inhibition in these patients, according to their observations in healthy individuals [115]. In contrast, Wallentin and co-workers observed a higher composite end point of death from cardiovascular-related causes, MI, and stroke in those who had the *ABCB1* 3435 CC genotype (high predicted P-GP expression) and were receiving clopidogrel [116].

When interpreting the results of these two studies, we should consider that several important differences were present, for example, in a clinical setting (only two-thirds of patients were managed invasively in the PLATO cohort), severity of disease, available clinical information, geographic origin, and proportion of platelets naïve to antiplatelet treatment. However, few and contrasting data are available on the potential effect of the *ABCB1* 3435 CT polymorphism on P-GP expression or activity, or on the absorption or metabolism of clopidogrel [27]. In CAD patients who had undergone stent implantation, Bouman and co-workers investigated the clinical relevance of the Q192R (rs662) polymorphism of the gene coding paraoxonase-1 (*PON1*), an enzyme involved in clopidogrel bioactivation [117]. Homozygous *PON1*192 QQ patients showed a considerably higher risk of ST than did homozygous 192 RR patients, reduced PON1 plasma activity, lower plasma concentration of the active metabolite of clopidogrel, and reduced platelet inhibition [117]. Cayla and co-workers performed a sequential analysis of clinical, angiographic, and genetic factors associated with definite early ST [118]. They observed that among the 23 genetic variants investigated in 15 different genes, the significant determinants of early ST were CYP2C19 metabolic status (*CYP2C19*2*, and *CYP2C19*17*) (adjusted OR = 1.99, 95% CI 1.47–2.69), *ABCB1* 3435 TT genotype (adjusted OR = 2.16, 95% CI 1.21–3.88), and *ITGB3 PLA2* carriage (adjusted OR = 0.52, 95% CI 0.28–0.95) [118]. Interestingly, these researchers demonstrated that the combined clinical and genetic model led to a statistically significant increase in the model's discriminatory power compared with the clinical-only model (area under the curve = 0.78 (95% CI 0.73–0.83) versus 0.73 (95% CI 0.67–0.78); $p = .004$) [118].

Recently, Lewis and colleagues measured *ex vivo* platelet aggregation before and after dual antiplatelet therapy in individuals ($n = 565$) from the PAPI study, and conducted a GWAS of drug response [119]. Significant findings were replicated by examining genotype and cardiovascular outcomes in 2 independent aspirin-treated cohorts: 227 PCI patients and 1000 patients in the International Verapamil SR/Trandolapril Study (INVEST) Genetic Substudy (INVEST-GENES). Lewis and colleagues showed that a common polymorphism in the platelet endothelial aggregation receptor-1 (*PEAR1*) gene is a determinant of platelet response and cardiovascular events in patients on aspirin alone or in combination with clopidogrel. In fact, results from the GWAS revealed an association between SNPs on chromosome 1q23 and post-dual antiplatelet therapy platelet aggregation. Further genotyping revealed rs12041331 in *PEAR1* to be most strongly associated with dual antiplatelet therapy response ($p = 7.66 \times 10^{-9}$). Among patients undergoing PCI, A-allele carriers of rs12041331 were more likely to experience a cardiovascular event or death compared with GG homozygotes (HR = 2.62; 95% CI 0.96–7.10, p = 0.059; and HR, 3.97; 95% CI 1.10–14.31, p = 0.035, respectively). In aspirin-treated INVEST-GENES patients, rs12041331 A-allele carriers had significantly increased risk of MI compared with GG homozygotes (OR = 2.03; 95% CI 1.01–4.09, p = 0.048) [119].

25.4 CURRENT STATUS

A large, consistent body of evidence exists on clopidogrel response variability, pharmacogenetics, and alternative therapeutic strategies in high-risk vascular patients. The development of personalized medicine is a concrete opportunity in this clinical setting. The definition of when to perform the genetic test, how many and which genetic variants to include in the diagnostic panel, and what diagnostic tests are available for routine purposes according to the specific context in which the test is carried out are, at present, widely discussed by the scientific community.

25.4.1 Screening, Stratification, and Personalization

In May 2013, the "Clinical Pharmacogenetics Implementation Consortium (CPIC) Guidelines for Cytochrome P450-2C19 (CYP2C19) Genotype and Clopidogrel Therapy: 2013 Update" was published [77]. This update on the clinical use of *CYP2C19* genotype test results for patients requiring antiplatelet therapy includes the appropriate indication for *CYP2C19* genotype-directed antiplatelet therapy, recommendations for specific *CYP2C19* alleles, and additional evidence from an expanded literature review (available at www.pharmgkb.org). In the near future, as a result of the growing ease and availability of genetic testing and other sequencing programs, an increasing number of patients may already know their CYP2C19 genotype status at the time of treatment. Thus, the CPIC guidelines provide guidance on the clinical management of subjects for whom the genotype is available, or for whom the clinician chooses to order a CYP2C19 genotyping test [77].

In July 2013, investigators conducted a prospective randomized controlled trial on antiplatelet therapy tailored on the basis of the CYP2C19 genotype. To the best of our knowledge, clinical outcomes have yet to be reported; therefore, the May 2013 CPIC recommendations are based on the evaluation of evidence available up to that point. Moreover, it is necessary to point out, as do the authors of the guidelines, that therapeutic recommendations are more focused on patients with ACS undergoing PCI. Indeed, the strong evidence for the importance of clopidogrel pharmacogenetics was obtained in clinical settings of high-risk vascular patients. However, this is the clinical setting in which patients draw major benefits—more so than those in other clinical settings—from clopidogrel therapy. Even if, in the clinical setting of ACS patients undergoing PCI and stent implantation, prasugrel and ticagrelor are strongly recommended according to the CPIC update guidelines [6], an optimal individualized antiplatelet treatment should maximize its benefit by reducing the risk of recurrent cardiovascular events while minimizing adverse effects such as bleeding, especially in specific subgroups (e.g., the elderly, women, and those with history of TIA, stroke, or intracranial bleeding). Hence, genotype-directed therapy can identify patients who benefit most from alternative antiplatelet therapy.

In Table 25.5 lists the classifications of subjects' metabolizer status according to the presence of common and rare CYP2C19 polymorphisms.

Concerning treatment with clopidogrel, Table 25.6 summarizes the therapeutic recommendations for antiplatelet therapy based on *CYP2C19* status according to CPIC guidelines: standard dosing of clopidogrel as recommended in the product insert is warranted for patients with ACS and

TABLE 25.5 Metabolizer Status According to CYP2C19 Polymorphisms

Gene	PM	IM	EM	URM
CYP2C19	Subject homozygous/heterozygous compound for **2, *3, *4, *5, *6, *7, *8, *9, *10* loss-of-function alleles	Subject heterozygous for **2, *3, *4, *5, *6, *7, *8, *9, *10* loss-of-function alleles	Subject carrying 2 functional **1* alleles	Subject homozygous/heterozygous for **17* allele

Note: The *CYP2C19*17* allele could balance the effect of the loss-of-function alleles. PM—poor metabolizer; IM—intermediate metabolizer; EM—extensive metabolizer; URM—ultrarapid metabolizer.

TABLE 25.6 **Likely Metabolizer Status (phenotype) Based on CYP2C19 Genotypes and Antiplatelet Therapy Recommendations for ACS/PCI Patients According to CPIC Guidelines**

Phenotype	PM[a]	IM[b]	EM[c]	URM[d]
Genotypes	Subject carrying 2 loss-of-function alleles (**2–*8*) (e.g., **2/*2, *2/*3, *3/*3*)	Subject carrying 1 functional allele **1* and one loss-of-function allele (**2–*8*) or one loss-of-function allele (**2–*8*) and 1 increased-activity allele (**17*) (e.g., **1/*2, *1/*3, *2/*17*)	Subject carrying 2 functional **1* alleles (**1/*1*)	Subject carrying 2 increased-activity alleles (**17/*17*) or 1 functional allele and 1 increased activity allele (**1/*17*)
Implication for clopidogrel	Significantly reduced platelet inhibition; increased RPA; increased risk of MACE	Reduced platelet inhibition; increased RPA; increased risk of MACE	Normal (EM) or increased (URM) platelet inhibition; normal (EM) or decreased (URM) RPA[e]	
Therapeutic recommendations	Alternative antiplatelet therapy (if no contraindication)—e.g., prasugrel, ticagrelor	Alternative antiplatelet therapy (if no contraindication)—e.g., prasugrel, ticagrelor	Clopidogrel label recommended dosage and administration	
Classification of recommendations	Strong	Moderate	Strong	

[a]*PM (poor metabolizer): homozygous variant, mutant, low, or deficient activity (∼2–15% of patients).* [b]*IM (intermediate metabolizer): heterozygote or intermediate activity (∼18–45% of patients).* [c]*EM (extensive metabolizer): homozygous wild-type or normal activity (∼35–50% of patients).* [d]*URM (ultrarapid metabolizer): normal or increased activity (∼5–30% of patients).* [e]*The CYP2C19*17 allele may be associated with increased bleeding risk [81]; RPA—residual platelet aggregation; MACE—major adverse cardiovascular events.*

Source: Scott et al. [77].

PCI who are predicted *CYP2C19* extensive metabolizers (EMs) or ultrarapid metabolizers (UM) (i.e., **1/*1, *1/*17,* and **17/*17*). If genotyping from a CLIA-certified laboratory (i.e., a Clinical Laboratory Improvement Amendments laboratory) identifies a patient as a CYP2C19 PM (i.e., **2/*2*), current literature supports the use of an alternative antiplatelet agent (e.g., prasugrel, ticagrelor) when not clinically contraindicated. The most challenging patients are CYP2C19 intermediate metabolizers (IMs) (e.g., **1/*2,*1/*3, *2/*17*) because they have higher on-treatment HPR on average compared to EMs. ACS and PCI *CYP2C19*2* heterozygotes treated with clopidogrel have increased risks for MACE, including ST. These data support switching to an alternative antiplatelet agent for IMs when not contraindicated. However, given the wide interindividual variability in HPR observed among clopidogrel-treated IMs, clinical judgment should also take into account other factors that may place an IM at increased risk of a cardiovascular (or adverse bleeding) event to most effectively individualize therapy [77].

In addition, although the CPIC guidelines focus on *CYP2C19*2* and *CYP2C19*3*, many clinical genotyping platforms include other variant alleles (**4–*8, *17*) that can alter the interpretation of a patient's predicted metabolizer phenotype [77]. The **4–*8* alleles show strong *in vitro* evidence for complete loss-of-function of the CYP2C19 enzyme. Therefore, when these alleles are identified among patients with ACS and PCI being treated with clopidogrel, they should be considered as influencing both clopidogrel metabolism and clinical outcomes consistent with the **2* loss-of-function allele [77].

Several studies evaluated the effect of increasing clopidogrel loading or maintenance dosing in both healthy subjects and ACS patients. They consistently indicated an improved platelet inhibition among *CYP2C19*2* heterozygotes (IMs) based on *ex vivo* platelet aggregation, but not significant improvement among homozygotes (PMs) [104,106,120–127].

On the other hand, large clinical trials investigating the effect of higher-dose clopidogrel in ACS patients undergoing PCI with on-clopidogrel HPR concluded that adjusting the dosage based on platelet function monitoring alone does not reduce the incidence of death from cardiovascular causes, MI, or ST [18,39,128]. Although we should keep the results of these clinical trials in mind when discussing this issue, we also need to observe that these trials mainly doubled the clopidogrel maintenance dose, which may not be sufficient based on recent studies suggesting that higher clopidogrel doses may be required to achieve adequate platelet inhibition among *CYP2C19*2* heterozygotes [127].

On the basis of this evidence, and because few clinical studies have investigated the eventual improvement of clinical outcomes according to clopidogrel dose adjustment based on CYP2C19 status alone, it is premature to support an increased dosing strategy based on *CYP2C19* genotype at this time. We should wait for future guidelines incorporating results from ongoing clinical trials that are investigating pharmacogenetics or from those that are evaluating the clinical management of antiplatelet therapy for ACS patients undergoing PCI, including platelet function monitoring as well as genetic and nongenetic determinants of clopidogrel response variability.

As can be seen from the available evidence, *CYP2C19* genetic testing has the potential for allowing clinicians to better evaluate and choose the best antiplatelet therapy when considering treatment of patients with ACS undergoing PCI whose genotypes confer a higher risk of MACE. However, at present the lack of randomized clinical trial evidence that *CYP2C19* genotyping improves outcomes must be acknowledged. Furthermore, although *CYP2C19* genotyping is straightforward and reliable when performed in qualified laboratories, as with any laboratory test an additional possible risk to the patient may be caused by an error in genotyping. Because genotypes are lifelong, any such error may have adverse health implications for the patient. On the other hand, commercial tests and tests approved by the CEIVD (European Communities *In Vitro* Diagnostic) or the FDA are available. Some of these can provide genotyping results in a few hours and have point-of-care features that do not require specialized personnel.

25.4.2 Pharmacogenetic Testing

Because *CYP2C19* genetic variants are implicated in inadequate clopidogrel response, the FDA added a box warning on clopidogrel's label about the diminished effectiveness of the drug in patients whose ability to convert it into its active form is impaired because of unfavorable genotypes (Tables 25.5 and 25.6). Besides indicating that some patients may be poor clopidogrel metabolizers because of genetically determined low CYP2C19 activity, the box reports that genetic testing is available to identify patients with the implicated genetic variants and that, in poor metabolizers of the drug, alternative treatment strategies should be considered (see http://www.fda.gov/Drugs/DrugSafety/PostmarketDrugSafetyInformationforPatientsandProviders/ucm203888). In fact, because it is important to identify high-risk individuals and to improve patient risk stratification, there is growing interest in genetic testing to identify *CYP2C19* genetic variants and other gene polymorphisms related to clopidogrel pharmacogenetics.

The introduction of pharmacogenetic testing in addition to platelet function testing is another tool for clinicians to use in managing differentiated therapeutic strategies and in tailoring antiplatelet therapy to the characteristics of individual patients, thus amplifying the concept of "personalized medicine."

Beside the fact that the clinical benefits of tailored antiaggregant therapies have been demonstrated in prospective clinical trials, the introduction of clopidogrel pharmacogenetic tests into clinical practice may highlight both the need for the rapid availability of results and the need to consider the costs associated with genetic tests [129]. In fact, clopidogrel pharmacogenetic testing results must be available in a very short time before or during the management of ACS patients in the catheterization laboratory in order to improve clinicians' decisions in the early high-risk phase of ACS and its treatment. Moreover, a pharmacogenetic test must be simple to use, fast, and inexpensive. In particular, it must be performed in the catheterization laboratory or at the bedside (point-of-care) to have a real-time effect.

Clopidogrel pharmacogenetic testing is already available in clinical laboratories. However, it can be technically demanding, time-consuming, and expensive, thus limiting its use in the acute clinical care setting. Indeed, in the clinical setting of ACS patients undergoing PCI, it is fundamental that testing be available as early as possible from a nearby specialized clinical laboratory or from a rapid point-of-care platform.

Classical methods of genotyping, such as TaqMan, need experienced staff (molecular biologist/biotechnologist/technician); thus, they are suitable for research purposes but inadequate for providing diagnostic responses in situations of urgency. New, rapid genotyping methods must necessarily be easy to use by unskilled personnel and must provide a rapid turnaround of results at a reasonable cost. Most especially, they must be executable at the patient bedside in order to allow cardiologist to obtain a rapid genetic profile of patients under treatment and to combine this information in an accurate predictive algorithm to achieve truly antiplatelet-personalized care.

Table 25.7 lists CYP2C19 standard and rapid genotyping technologies/assays that are commercially available for clopidogrel pharmacogenetics.

25.4.2.1 Rapid FDA/CEIVD-Approved Clopidogrel Pharmacogenetic Testing

Verigene®

The Verigene system (Nanosphere, Northbrook, IL) is a molecular diagnostics platform for genotyping variants via an automated blood sample-to-results approach. It employs gold nanoparticle technology for genomic detection, making current genomic DNA amplification by polymerase chain reaction (PCR) unnecessary. The specific cartridge for clopidogrel pharmacogenetics testing, the *CYP2C19* Nucleic Acid Test, allows analysis of *CYP2C19*2*, *CYP2C19*3*, and *CYP2C19*17*. As the starting material for the test, fresh

TABLE 25.7 Commercially Available Clopidogrel Pharmacogenetics Genotyping Technologies

Test	Company	FDA/ CEIVD-approved	Time Analysis	Sample Type	CYP2C19 Alleles Investigated	Laboratory Expertise	Test Type
Standard Genotyping							
TaqMan	Life Technologies	Yes	DNA extraction + 1–2 hours	DNA	_*2, *3, *4, *5, *6, *7, *8, *9, *11, *12, *13, *14, *15, *17_	Excellent	RT-PCR TaqMan probes

i-densy	Arkray	—	90 minutes	Whole blood, oral swabs, purified DNA	_*2/*3_	Very good	QP (quenching Probe)
INFINITI CYP2C19 Assay	Auto-Genomics	Yes	8 hours	Whole blood	_*2/*3/*17_	Very Good	Microarray (ASPE)
eSensor Technology	GenMark Diagnostics	No	DNA extraction + 3–4 hours	DNA	_*2, *3, *4, *5, *6, *7, *8, *9, *10, *13, *17_	Very good	Microarray
Encompass Platform/ Rheonix CARDCon-sumable (IVD)	Rheonix	No	—	Fresh and fixed tissue; whole blood; serum-saliva-urine	_*2/*3_	Very good	—
HyBeacons	Evogen	No	DNA extraction + 35–40 minutes	Saliva; urine, swabs; whole blood	User choice	Excellent	PCR
Tag-It Mutation Detection	Luminex	No	8 hours	DNA	_2, *3, *4, *5, *6, *7, *8_	Excellent	ASPE via bead array
Invader	ThirdWave Technologies	—	3 hours	DNA	User choice	Very good	Enzymatic
ParagonDX/ SmartCycler	Cepheid	Yes	DNA extraction + 20–40 minutes	DNA	User choice	Excellent	RT-PCR

(not frozen) whole venous peripheral blood anticoagulated in ethylenediaminetetraacetic acid (EDTA) is required. The Verigene system comprises two different instruments, the reader (control unit) and the processor (extractor, hybridization, and scanner unit).

The touch-screen interface and barcode scanner in the reader unit allow the user to track samples, monitor test processing, analyze data obtained from the processor unit, and generate reports. The processor performs automated "hands-off" sample preparation, nucleic acid extraction, sonication, and target hybridization on the specific cartridge.

The cartridge (Figure 25.5) is a laboratory consumable holding prepackaged reagents and the microarray slide (a solid substrate). It contains fluidic compartments with reagents ready to use: hybridization, wash solutions, detection probes, gold nanoparticles, and detection reagents (all of which are automatically transferred to the microarray slide while the cartridge is in the processor). The identification of polymorphisms takes place on the cartridge. In order to trace samples, the cartridge is labeled with a barcode identification number. The extraction tray and the tip holder—a single-use plastic holder containing pipette tips and a rubber plug—are placed in the processor, and transfer the sample and reagents during extraction and subsequently the DNA sample to the test cartridge.

Verigene's technology uses gold nanoparticles (Figure 25.5): after DNA extraction and sonication, the genetic sequences of interest are hybridized on the cartridge microarray slide to complementary fixed sequences. Afterwards, the hybridized sequences fixed on the array are incubated, with the gold nanoparticles functionalized with complementary probes to the sequences of interest. Then the unbound nanoparticles are washed and the bound nanoparticles are amplified by a reduction reaction with silver nitrate to produce a visible spot on the array. The reader captures the image of post-silver amplification, and the spot signal intensities are used by the software to genotype samples and to generate the analysis report.

Verigene's workflow is very simple and takes 3 hours. Moreover, the system can be used by operators with modest understanding of molecular biology and genetic diagnostics. Indeed, after the addition of 1 ml of venous peripheral blood anticoagulated in EDTA by the vacutainer tube and loading onto the processor of consumables (cartridge,

FIGURE 25.5 Microarray and gold nanoparticles used in the Verigene system. The upper drawing represents the structure of the cartridge; the lower part, the technology and the post-silver amplification spots as captured by the analyzer and used by the software for the genotype call. *Source: from Saracini et al.* [129].

extraction tray, and tip holder), the operator can move away and return to move the cartridge in the reader after the 3 hours are up [129].

The accuracy of the Verigene system in identifying *CYP2C19*2* and *CYP2C19*3* was evaluated by Buchan and co-workers [130] using 1286 samples and sequencing validation. The Verigene assay accurately identified homozygous and heterozygous *CYP2C19*2* and *CYP2C19*3* genotypes with a specificity of 100% and a final call rate of 99.7% [130].

Another fundamental feature of rapid genetic testing in clinical practice, besides accuracy and turnaround time, is cost. Saracini and colleagues compared the rapid point-of-care Verigene system with TaqMan, a standard genotyping method [131]. Using both Verigene and TaqMan, they genotyped for *CYP2C19*2*, *CYP2C19*3*, *CYP2C19*4*, *CYP2C19*5*, and *CYP2C19*17* genetic variants in 100 ACS patients, and observed a 100% concordance between the two technologies for all five analyzed polymorphisms. Saracini and colleagues showed that Verigene has a shorter turnaround time than TaqMan; however, they found the cost of its reagents to be higher. Still, staff involvement and relative cost resulted in a higher total cost for TaqMan than for Verigene [131].

Spartan RX

The Spartan RX system (Spartan Biosciences, Ottawa, ON) is a CEIVD-approved portable point-of-care test for fast and accurate analysis of *CYP2C19*2*, *CYP2C19*3*, and *CYP2C19*17*. It is very rapid, with results available in 1 hour, because genomic DNA extraction is not required; instead, DNA is obtained by lysis from cells of the buccal mucosa.

Spartan RX consists of an analyzer, a thermocycler for real-time PCR (with two optical detection channels for analysis of fluorescence emission relative to the specific probes for the two alleles of each polymorphism), and disposable plastic materials and reagents for genotyping (Figure 25.6). The system is connected to a computer with dedicated software for data analysis and management (e.g., sample identification, report preparation).

Spartan RX's consumables are dedicated and are prepackaged in the Sample Collection Kit. Each kit includes two swabs to collect buccal cells and two 0.2 ml tubes filled with all necessary reagents for real-time PCR and allelic discrimination (Figure 25.6). Swab sticks consist of a cap buffer mounted at one end. Cell samples are collected directly on the cap, the swab sticks are then placed in the tube and the tube is inserted in the PCR instrument (Figure 25.6). The Spartan system does not require complex procedures or experienced staff.

Roberts and co-workers performed a prospective randomized, proof-of-concept trial, called RAPID GENE, to assess pharmacogenetic approaches to dual tailored antiplatelet treatment after PCI in ACS patients. Two hundred patients undergoing PCI for ACS or stable angina were *CYP2C19*2*-genotyped by Spartan RX and then randomly assigned according to genotype to a tailored treatment or to a standard treatment (75 mg/day of clopidogrel) [132]. Carriers of the *CYP2C19*2* allele in the tailored branch were treated with 10 mg/day of prasugrel, while noncarriers were treated with 75 mg/day of clopidogrel. Seven days after PCI, the carriers of *CYP2C19*2* treated with prasugrel showed a significantly lower rate of on-treatment HPR compared with *CYP2C19*2* carriers in the standard treatment group. At follow-up, 23 of 91 patients (25%) in the genotype-tailored group and 23 of 96 patients (24%) in the standard treatment group were carriers of at least one *CYP2C19*2* allele. While no *CYP2C19*2* carriers treated with prasugrel showed HPR (defined as $PRU > 234$), 7 of those in the arm treated with 75 mg/day of clopidogrel did show HPR. The study revealed the Spartan RX system's sensitivity to be 100% with a specificity of 99.3% [132].

Saracini and co-workers compared Spartan RX with the classical TaqMan (Life Technologies, Carlsbad, CA) genotyping technology [129]. The aim of their study was to evaluate this commercially available system in terms of accuracy, turnaround time, cost, and management in a diagnostic laboratory. Genotyping was performed for *CYP2C19*2* with the two technologies on 100 ACS patients undergoing PCI. The results obtained by Spartan RX and TaqMan showed a 100% concordance. The study also compared both Verigene and Spartan RX against TaqMan [129]. Spartan RX provided results more quickly (60 minutes); however, its cost was higher and it could genotype only a limited number of polymorphisms contemporaneously. Although the system is potentially upgradable with additional polymorphisms, at present it seems numerically limited.

Verigene is more expensive than TaqMan, but it can be considerably extended (~80 polymorphisms) to a number of additional genetic variants that can be tested at the same time and in the same analysis session. Apparently, TaqMan does not have a relatively longer total turnaround than the other two technologies (292 minutes for Taqman; 71 minutes for Spartan RX; 206 minutes for Verigene). However, compared to Verigene and Spartan RX, Taqman's time to complete depends on how long the operator takes to conduct the analysis. In sum, even if TaqMan's reagent costs are lower compared to the other systems, its manual operator involvement and related costs are higher (Table 25.8) [129].

Extraction and genotyping with real-time PCR and TaqMan can be automated and organized so that pharmacogenetic results are rapidly made available (a few minutes to a few hours) in a molecular biology laboratory equipped for analysis of diagnostic and prognostic genetic factors. However, it is fundamental to have a work platform

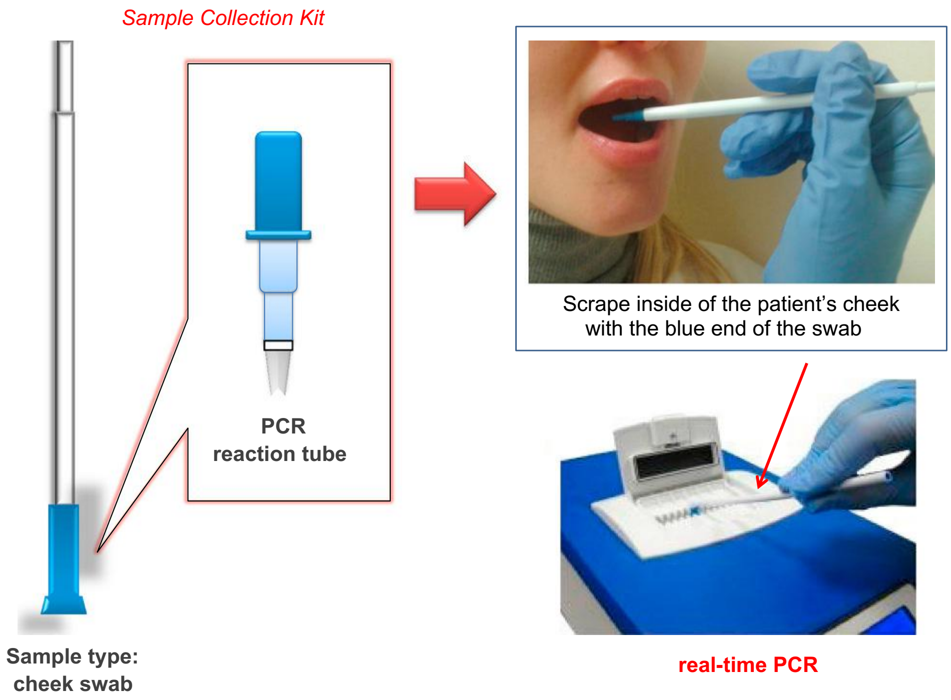

FIGURE 25.6 Real-time PCR-based Spartan RX system.

(for extraction and genotyping) on which the genotyping session can be started at any time of the day without waiting for completion of analyses begun previously. This need for ad hoc work sessions for individual patients makes TaqMan's costs quite high, which is why Taqman is used primarily for research purposes. Verigene and Spartan RX seem to be more compatible with tests carried out by operators unskilled in molecular biology techniques. Moreover, given their characteristics and dimensions, these systems are particularly suitable for genetic testing directly at the patient's bedside—in a catheterization room, for example—for immediate management of therapy for the patient even in situations where a molecular biology/genetics laboratory is not available in the immediate vicinity [129].

TABLE 25.8 Comparative Times and Costs of Genotyping: TaqMan, Verigene, and Spartan RX

	TaqMan	Verigene	Spartan RX
Informatic work plan	3 min	3 min	3 min
Reagents/sample preparation	35 min	20 min	5 min
DNA extraction	200 min	180 min	60 min
DNA quantification	5 min		
Genotyping	10 min + 30 min		
Data analysis	9 min	3 min	3 min
Operator manipulations	Many	Few	Few
Total time per 3 SNPs	62 min + 230 min	6 min + 200 min	6 min + 65 min
Biologist/scientific laboratory technician	€52	€5 biologist/scientific laboratory technician	€5 biologist/scientific laboratory technician
Materials costs	€30	€90	~€100
Total cost	€82	€95	~€105

25.4.2.2 *Other CYP2C19 Genotyping Technologies*

AmpliChip® CYP450

The AmpliChip® CYP450 Test (Roche Molecular Systems, Basel, Switzerland) is the first microarray-based *in vitro* diagnostic test that is FDA approved for clinical use. It allows the detection in the *CYP2D6* and *CYP2C19* genes (Table 25.7) of up to 33 *CYP2D6* alleles and 3 *CYP2C19* alleles (*CYP2C19*1*, *CYP2C19*2*, *CYP2C19*3*).

The AmpliChip test runs on the Affymetrix GeneChip Microarray Instrumentation System (Affymetrix, Santa Clara, CA). Data analysis is performed by the GeneChip Operating Software (GCOS). The main criticisms of this test involve cost (of the order of hundreds of dollars) and time (for DNA extraction and the test itself), and the lack of dedicated high-throughput technology that requires a specialized genetics laboratory and personnel.

Luminex® 100/200™ System and xTAG™

The Luminex 100/200 assay and xTAG P450-2C19 assay (Luminex Molecular Diagnostics, Toronto, ON) are designed to analyze 7 allelic variants: *CYP2C19*2*–*CYP2C19*8* (Table 25.7). They are not currently approved by the FDA. Luminex 100/200 combines multiplex PCR, allele-specific primer extension (ASPE) bead hybridization, and fluorescent detection. It requires manual expertise and is completed in about 8 hours.

INFINITI® CYP2C19

The INFINITI CYP2C19 assay (Autogenomics, Vista, CA) is a CEIVD-approved test for analysis of *CYP2C19*2*, *CYP2C19*3*, and *CYP2C19*17* (Table 25.7). It utilizes the CYP450 2C19+ Intellipac™, the CYP450 2C19+ Amp Mix, and the CYP 450 2C19+ BioFilmChip™ microarray. INFINITI requires the extraction of genomic DNA from whole blood. It is based on allele ASPE technology and quantification of generated fluorescent signals. After DNA extraction, all of INFINITIs other steps can be automated by the INFINITI Analyzer (Autogenomics, Vista, CA). Gladding and co-workers used INFINITI in their dose-escalation study to suggest that increasing the dose of clopidogrel in patients with nonresponder polymorphisms increases antiplatelet response [121].

I-Densy™ IS-5320

A novel rapid platform for polymorphism analysis is i-densy IS-5320 (Arkray, Kyoto, Japan), which in a single system combines sample pretreatment, amplification, and signal detection (Table 25.7), allowing results to be obtained in about 90 minutes. i-densy does not require DNA extraction and is suitable for genotyping from whole blood, purified nucleic acids, and oral swabs. The system and its reagents (Compact Reagent Packs) are commercially available for analysis and allow genotyping of *CYP2C19*2* and *CYP2C19*3*. The technique is based on a quenching-probe (QP) system as the principle tool of SNP detection.

eSensor®

The eSensor 2C19 Genotyping Test (Genmark, Carlsbad, CA) is a DNA microarray system based on electrochemical and hybridization detection of genotypes, designed for multiplex testing of the *CYP2C19*2*–**10*, *CYP2C19*13*, and *CYP2C19*17* polymorphisms (Table 25.7). It is commercially available but has not been cleared or approved for marketing by the FDA. eSensor's results are available in ≈3–4 hours after DNA extraction, and the assay requires a very small amount of DNA concentration (0.05 ng/μl). DNA extraction and PCR are necessary prior to genotyping; the assay can process the sample in 3 hours, requiring 40 minutes of hands-on time.

Encompass MDx™ and Rheonix CARD®

The Encompass MDx™ platform (Rheonix®, New York, NY) is an open system for research only and has not been approved by the FDA for IVD use (Table 25.7). It is fully automated and must be used with Rheonix CARD® consumables. Rheonix Plavix PGx CARD was designed to detect *CYP2C19*2* and *CYP2C19*3*, starting from different sample types such as fresh tissue, formalin-fixed tissue, whole blood, serum, saliva, and swabs. DNA is subjected to multiplex PCR; amplicons are then denatured and delivered to the primer extension reactor, and annealing occurs between the denatured amplicon strands and the immobilized "primers." Solid-phase primer extension is initiated, resulting in incorporation of biotinylated dUTP in the extended "primer" strand on the surface. Primer-extended products are detected via incubation with streptavidin-conjugated HRP and substrate.

25.4.2.3 *Other Genotyping Technologies*

Other available genotyping technologies include Invader® Assay (Third Wave Technologies, Madison, WI), HyBeacons® Assay (Evogen, Kansas City, MO), and ParagonDX/SmartCycler (Chepeid, Sunnyvale, CA) (Table 25.7). Invader is a proprietary system for genetic analysis that is similar to PCR. HyBeacons High Definition PCR (HD PCR) utilizes fluorophore-labeled oligonucleotides to detect and identify specific nucleotide sequences post-amplification. Hybeacon's probes can be used in combination with direct analysis of biological samples of different types and thermal cyclers, such as LightCycler (Roche Molecular Systems, Basel, Switzerland), to perform genotyping of SNPs for many samples in 35–40 minutes. Smart Cycler performs sample analysis in 20–40 minutes after DNA extraction. It is based on real-time PCR amplification of target genomic DNA and simultaneous detection of SNPs.

25.5 CONCLUSIONS AND FUTURE DIRECTIONS

Even though guidelines for clopidogrel pharmacogenetics, as well as on-clopidogrel platelet function evaluation, have been the subject of much research [20,77], still unresolved is the personalization of antiplatelet therapeutic strategies aimed at reducing ischemic events without increasing bleeding risk.

We believe that a clear definition of clopidogrel pharmacogenetics' usefulness (e.g., regarding clinical setting(s); polymorphisms to be included in the genetic profile; length of testing; use of genetic profiling alone or with algorithms for other nongenetic determinants) is particularly important in the current clinical context, where alternative drugs with different characteristics and costs are available. Indeed, a generic version of clopidogrel is now available; the patent for prasugrel expired in 2012; and the patent for ticagrelor will expire in 2018. The opportunity to choose the most efficient and economic pharmacologic strategy is crucial for all patients, of course, but it is particularly important in healthcare systems in which expenditures are totally borne by the patient [76]. Indeed, prasugrel and ticagrelor have been shown to be more potent platelet inhibitors and to have a favorable benefit-to-risk ratio compared with clopidogrel in high-risk patients, but this comes at the expense of shifting the balance toward an increased bleeding risk especially in some patient categories (the elderly, women, and those with history of TIA, stroke, or intracranial bleeding) [6,29,31,76]. Moreover, other antiaggregant drugs such as cilostazol and cangrelor are available and might be considered in the management of high-risk vascular patients.

A large body of evidence highlights an urgent need for prospective studies to clarify whether personalized therapeutic strategies will improve outcomes in high-risk patients with vascular disease. It may not be the best strategy to choose the "superior" drug solely on the basis of the results of large clinical trials in which patients with different risk profiles are considered equal. The challenge for the present and for the near future is to choose not the lesser evil, but the greater good. Overcoming this challenge will be possible only by identifying the antiplatelet therapeutic approach that warrants the higher benefit/risk ratio taking into consideration individual patient characteristics [27].

Prospective studies that evaluate antiplatelet treatments tailored to individual patient characteristics—genetic profile, residual platelet reactivity, drug–drug interactions, and traditional and procedural risk factors—are urgently needed. The results of these studies may allow development of algorithms that take into account and weigh genetic or acquired risk factors for cardiovascular complications, and that help clinicians to better identify therapeutic strategies that will provide the greatest benefit for each patient.

On the other hand, evidence from the literature underlines the need for continuing investigation of as yet unidentified genetic and nongenetic factors that contribute to clopidogrel variability, on-treatment HPR, and ultimately poor outcomes [133,134]. Indeed, Marcucci and co-workers showed that on-clopidogrel HPR by ADP is an independent determinant of MACE in good clopidogrel metabolizers (i.e., noncarriers of *CYP2C19*2*). This suggests that both phenotype and genotype are clinically relevant in evaluation of clopidogrel's antiplatelet effect and in the prognostic stratification of ACS patients. It also suggests that additional factors may be implicated [133]. Recently, Frelinger and co-workers found that clopidogrel pharmacokinetics and pharmacodynamics vary widely in healthy subjects, despite rigorous exclusion or control of known disease, polymorphisms (*CYP2C19*, *CYP3A5*, *ABCB1*, *PON1*), noncompliance, co-medications, diet, smoking, alcohol, demographics, and pretreatment platelet hyper-reactivity. As yet unidentified factors also contribute to on-treatment HPR [134].

In general, the pharmacogenetics of clopidogrel in the treatment of cardiovascular disease and that of other drugs in the treatment of noncardiovascular disease represent an important model for identifying strategies and solutions that will improve healthcare. Consider the following:

- Information is available and consistent regarding the impact of pharmacogenetics, particularly on the inadequate efficacy of clopidogrel.
- Available information is consistent regarding *CYP2C19*2*'s association with poor outcomes in the clinical setting of ACS patients undergoing PCI and stent implantation.
- Preliminary data on the possible usefulness of pharmacogenetics testing for clopidogrel are available.

Such convincing evidence has induced the FDA to place a box on clopidogrel's label advising clinicians of possible inadequate responsiveness in genetically determined patients.

Clopidogrel pharmacogenetics represents a sturdy test bench for identifing critical issues that must be addressed, by both the scientific community (clinicians, molecular biologists, bioinformaticians) and industry. Indeed, there are major concerns with clopidogrel pharmacogenetics in the routine management of ACS patients. These involve economic issues and availability of genetic results. To respond to the need for accurate, rapid point-of-care systems, several FDA- or CEIVD-approved solutions have been developed and others are in preliminary development. Even if the costs of commercially available systems are not comparable with those of genotyping systems for research purposes only, their wider diffusion may consistently reduce such costs in the near future. Several rapid systems for genetic testing are now commercially available, guaranteeing results in 1–3 hours. These are point-of-care tests that can be carried out by unskilled personnel and that cost about €100 ($138) (which will be amortized by the reduction in social and economic costs of managing clinical complications in these high-risk patients). In fact, in appropriate clinical settings a reduction in major adverse outcomes may be achieved by a tailored pharmacological strategy in a single patient, and this may result in reduced costs of managing clinical complications. If so, the cost of the pharmacogenetic test is absolutely justified. Moreover, several commercially available systems are truly point-of-care, meaning that pharmacogenetic testing can be performed at the bedside. This too may result in improved management of patients in any phase of the disease. The committed involvement of the scientific community and industry in solving the critical issue of clopidogrel pharmacogenetics represents a virtuous process that has furnished the technology and expertise needed to address future pharmacogenetic challenges [129].

Another, not insignificant, challenge to be overcome is clinicians' lack of confidence in genetic test results, not only with regard to clopidogrel pharmacogenetics but in regard to the future of pharmacogenetics and stratified medicine generally.

Scientific knowledge deriving from genetics, pharmacogenetics, transcriptomics, metabolomics, microbiome, proteomics, and imaging is rapidly increasing. The major challenges now and in the future are the translation and integration of this mass of information in the canon of knowledge of disease and patient management. Three major issues to be addressed are the development of adequate bioinformatics approaches, the continuous multidisciplinary training of all actors in the process (biologists, medical specialists, medical geneticist, bioinformatics experts, etc.), and the development of diagnosis and treatment paths guided by the principles of stratified medicine.

26.1 OVERVIEW

At present choosing the antidepressant (AD) to prescribe that is the most appropriate for the individual patient is based only on some general clinical principles, such as the presence of psychiatric comorbidities, depression subtype (e.g., melancholic or anxious depression), the personal or family history of response to a particular drug, or comorbidity with medical diseases. This entails a trial-and-error approach to choosing the AD and the titration regimen, and partly explains the unsatisfactory remission rates of major depressive disorder (MDD) [1]. It is well established that AD efficacy and side effects show a high variability among individuals [2]. Accordingly, standard dose titration may lead to detrimental undertreatment or disabling side effects, and both may result in early treatment discontinuation. For this reason, predictors of treatment outcomes should be identified to aid the choice of tailored treatments. Clinical predictors of AD response have been investigated, but have produced controversial findings, and they cannot be translated into clinical practice [3]. Indeed, MDD phenotypes are very heterogeneous, and clinical features alone are not sufficiently discriminative.

Current evidence suggests that genetic factors (i.e., genetic polymorphisms) contribute substantially to the variance in AD response (≈50% of variance), with mechanisms that are probably similar to those linked to MDD pathophysiology [4,5].

Consistent evidence demonstrates that MDD has a strong genetic background. Indeed, studies in monozygotic and dizygotic twins estimated the hereditability of MDD to be at least 37% [6]. Further, AD response shows a familiar clustering [4], and the metabolism and distribution of several ADs in unaffected twins suggest a substantial genetic component [7]. For these reasons, the effect of genetic polymorphisms on AD efficacy and side effects (i.e., pharmacogenetics) has been a hot topic for the last two decades.

Genetic difference among individuals is determined by di-, tri- and tetra-nucleotide repeats (satellite sequences); large variants >1 kbp due to deletions, insertions or duplications (copy number variants, or CNVs); and nucleotide substitutions. In particular, there are 7 million substitutions in each individual human genome, and over 80% of them take the form of single-nucleotide polymorphisms (SNPs). Thus, SNPs account for over 80% of the variability among humans, including disease predisposition [8]. As of this writing, the HapMap project has mapped the location of over 3 million SNPs (http://hapmap.ncbi.nlm.nih.gov/). Given their pivotal contribution to unique genetic make-up, SNPs have been the most investigated genetic variant as predictors of AD clinical outcomes.

The first pharmacogenetic studies of AD response were based on the candidate gene approach—that is, the analysis of genetic variants selected a priori on the basis of molecular and pharmacological data and/or animal models. Genes selected this way include those coding for key molecular components of the serotoninergic, noradrenergic, and dopaminergic systems, functional abnormalities in which are thought to contribute to MDD pathophysiology (monoaminergic theory). Their restoration is one of the consequences of AD treatment. According to monoaminergic theory, MDD is caused by decreased monoaminergic neurotransmission in the brain (although this is without doubt an oversimplification) [5]. Thus, the serotonin transporter gene (*SLC6A4*), serotonin 1A receptor (*HTR1A*), serotonin 2A receptor (*HTR2A*), tryptophan hydroxylase 1 and 2 (*TPH1*, *TPH2*), catechol-O-methyltransferase (*COMT*), monoamine oxidase A (*MAOA*), and norepinephrine transporter (*SLC6A2*) were considered among the best a priori candidates. Nevertheless, given the inconsistency of findings obtained by the candidate gene approach, it became clear that the genetic component of AD response is likely linked to a number of genes, each with a small effect size, rather than to one or few major loci.

Recent pharmacogenetic studies have extended the investigation of genetic variability to the whole genome, through genome-wide association studies (GWASs), which allow the genotyping of hundreds of thousands of polymorphisms across the whole genome through microarray technology. The main advantage of GWASs is the high number of loci genotyped without the need for a priori hypotheses. This is a very useful tool because AD mechanisms of action are not fully understood. Unfortunately, GWAS results have fallen below expectations, probably because of some unsolved methodological and technical issues (see Section 26.3.1). Strategies to solve these issues are discussed in Section 26.4.

Despite the inconsistency of previous results and the reported need for methodological improvements, candidate gene studies and GWASs provided well-supported evidence of involvement of genes relating to the monoaminergic system, neurotrophic system, hypothalamus–pituitary–adrenal (HPA) axis, and drug transport/metabolism in AD efficacy (see Tables 26.1 and 26.2 for summaries). The following sections provide a critical review of the main findings in the field of AD pharmacogenetics and discuss the challenge of translating genetic information into clinical applications—the prescribing of gene-guided tailored therapies.

TABLE 26.1 Summary of Candidate-Gene Study Results

Gene	
Polymorphisms Studies with More Than 50% Positive Results	
SLC6A4	5-HTTLPR
COMT	rs4680
IL1B	rs16944
BDNF	rs6265
GNB3	rs5443
Polymorphisms Studies with Equal Number ±1 of Positive and Negative Results	
SLC6A4	STin2 VNTR
TPH1	rs1800532
HTR1A	rs6295;rs1800042
SLC6A2	rs5569;rs2242446
CRHR1	rs242941(rs1876828 and rs242939 in LD)
FKBP5	rs1360780(rs4713916 and rs800373 in LD)
DTNBP1	rs760761; rs2619522
ABCB1	rs2032583;rs2235040
Polymorphisms Studies with More than 50% of Negative Results	
SLC6A4	5-HTTLPR/rs25531 (triallelic locus)
HTR2A	rs7997012;rs6311;rs6313
HTR6	rs1805054
MAOA	VNTR 1.2 kb upstream the coding sequence
GRIK4	rs1954787
ABCB1	rs2032582

Note: Results shown are according to their degree of replication. Only polymorphisms investigated by at least three studies were reported.

26.2 CANDIDATE GENE STUDIES

26.2.1 Antidepressant Pharmacodynamics

In the following subsections, genes involved in antidepressant pharmacodynamics are discussed. Pharmacodynamics includes all biological processes that are related to antidepressant mechanisms of action; that is, molecular targets that are directly modulated by antidepressant drugs (e.g., cell receptors) and the subsequent molecular events that lead to the pharmacological effects.

26.2.1.1 *Monoaminergic System*

According to monoaminegic theory, MDD develops because of a deficit in noradrenergic, dopaminergic, and/or serotonergic neurotransmission. The majority of currently available ADs have been developed on the basis of

TABLE 26.2 Summary of GWAS Results

Study	Top Genes	Phenotype	Biological Rational for Association
STAR*D	*UBE3C*	AD efficacy	Modifies proteins to signal them for degradation; no clear biological link with phenotype
	BMP7	AD efficacy	Induces endochondral osteogenesis; no clear biological link with phenotype
	RORA	AD efficacy	Modulation exerted by ADs may restore circadian rhythm abnormalities of MDD
	ACSS3	AD efficacy	Involved in lipid synthesis and energy generation; no clear biological link with phenotype
	NEDD4L x quality of life	AD efficacy	Modifies proteins to signal them for degradation; no clear biological link with phenotype
	SACM1L	Sexual side effects	Regulates vesicle trafficking in endoplasmic reticulum and Golgi apparatus; no clear biological link with phenotype
	EMID2	Vision/hearing side effects	Involved in the regulation of corneal collagen fibrillogenesis
MARS	*CDH17*	AD efficacy	Calcium-dependent cell adhesion protein; may have an important role in synapse formation in the hippocampus
	EPHB1	AD efficacy	One of the ephrin receptors; regulates chemotaxis, proliferation, and polarity of hippocampus neural progenitors
GENDEP	*UST*	AD efficacy	Involved in synthesis of extracellular matrix components; may be linked to *CSGALNACT1* (see *CSGALNACT1* function)
	IL11	AD efficacy	Involved in inflammation processes, in line with inflammatory theory of MDD
GENDEP + STAR*D	*CSGALNACT1*	AD efficacy	Involved in chondroitin chain biosynthesis; may play some role in neuroplasticity, regeneration, and brain development

Note: Genes reported as "top genes" do not necessarily represent genome-wide significant results. AD—antidepressant; MDD—major depressive disorder.

this assumption, despite the fact that it fails to completely elucidate the disease pathophysiology.

Given the key role of serotonin (5-HT) in the regulation of mood and emotions, [9] genes relating to the serotoninergic system were heavily investigated, among them the serotonin transporter gene (*SLC6A4*), which was hypothesized as an optimal candidate. The serotonin transporter (SERT) regulates brain 5-HT neurotransmission by transporting

5-HT from the synaptic cleft to presynaptic neurons. The blocking of SERT, the main target of ADs, can lead to recovery thanks to an increase in 5-HT availability at the synaptic level.

The most investigated variant in *SLC6A4* is a 44-bp insertion/deletion polymorphism (5-HTTLPR) involving 2 units in a sequence of 16 repeated elements in the promoter region. 5-HTTLPR has a functional effect: the 16-repeat sequence is called the long allele (L) and shows a twice-basal SERT expression compared to the 14-repeat sequence, called the short allele (S) [10]. Interestingly, imaging studies show that S carriers have higher levels of amygdala activity and reduced functional coupling of the amygdala–anterior cingulate cortex (ACC) circuit [11]—phenotypes associated with anxiety and MDD. It was hypothesized that S carriers may be less able to respond to repeated releasing inputs of 5-HT because of the low activity of SERT; the consequent reduction of serotoninergic transmission may be linked to an increased risk of MDD.

For the most part, pharmacogenetic studies demonstrated a poorer AD response in SS carriers, particularly in Caucasians treated with SSRIs, compared to L carriers [12]. A possible explanation is that L carriers have a more dynamic serotonergic system—that is, higher SERT functionality may allow a better balancing of the serotonergic tone (in terms of time and amount) in response to endogenous and exogenous stimuli. The different effects across populations may be due to wide variations in 5-HTTLPR allele frequencies among ethnic groups (the S allele is present in 42% of Caucasians but 79% of Asians) [13].

As a key regulator of SERT activity, 5-HTTLPR may also influence the risk of AD-induced side effects, particularly in the case of SSRIs. Most available studies suggested that the S allele is a risk factor; however, some reported no association (although the latest group of studies was mainly performed on non-Caucasian samples) [14]. This further suggests a population-specific effect of the polymorphism.

Despite the interesting role of 5-HTTLPR, polymorphisms are often not independent; moreover, the SNP rs25531 A/G was reported to lie in the 5-HTTLPR sequence, with a possible influence on the functional effect of 5-HTTLPR itself [15]. Indeed, the rs25531 G variant in association with the L allele (LG) may result in reduced expression of *SLC6A4*, equivalent to that conferred by the S allele [15]. Moreover, single-photon emission-computed tomography imaging suggested that LA/LA carriers may have a more dynamic serotonergic system that seems to confer a higher probability of SSRI response [16]. However, this hypothesis was not supported by pharmacogenetic studies, which showed mainly negative results [12].

Further studies are required to clarify the relative contribution of and interaction among *SLC6A4* polymorphisms; the finding that rs25531 may lie 18 bp 5′ from the site of the L/S repeat and not in it [17] calls into question previous findings.

Another variant of *SLC6A4* influencing SERT expression is a 17-bp VNTR (variable number of tandem repeats) in intron 2 (STin2), which comprises 9, 10, or 12 copies of a 16–17-bp repeat and may influence gene transcription synergistically with 5-HTTLPR [18]. In particular, the 12-repeat variant was demonstrated to cause higher gene expression *in vitro* [19] and *in vivo* [20]. Investigation of the association between this polymorphism and AD response provided mainly negative results, while positive findings suggested a better response in long-allele carriers among Asians and in short-allele carriers among Caucasians [12]. Meta-analytic results further suggested an opposite effect of the variant in Caucasians versus Asians, but results were not unequivocal [21]. Finally, no effect of STin2 on AD-induced side effects was demonstrated [21].

5-HT receptors represent other pivotal regulators of 5-HT neurotransmission, and the association of their variants and AD response was thoroughly investigated.

The serotonin 1A receptor (5-HT1A receptor), encoded by the *HTR1A* gene, is an inhibitory autoreceptor widely distributed in regions that receive serotonergic input from the raphe nuclei: frontal cortex, septum, amygdala, hippocampus, and hypothalamus, and it can be expressed both pre- and postsynaptically. This receptor modulates the serotonergic activity of these areas by reducing the firing rate of raphe nuclei neurons, the amount of 5-HT released per action potential, and the synthesis of the neurotransmitter. The involvement of this gene in AD response is supported by evidence showing that several ADs desensitize raphe 5-HT1A autoreceptors, leading to an enhancement of serotonergic neurotransmission that may be responsible, at least partially, for the AD effect. Furthermore, the blocking of 5-HT1A autoreceptors may accelerate AD action [22].

The most investigated *HTR1A* variants are rs6295 (1019C/G) and rs1800042 (Gly272Asp). The rs6295 G allele results in upregulation of the gene; thus, it may inhibit the therapeutic effect of ADs. Several studies consistently suggested the G allele as a risk factor for MDD, suicidal behavior, and AD nonresponse [23], although some obtained conflicting results [24–27]. Interestingly, an association between rs6295 and AD response may exist only in particular subgroups of patients, such as females [28] and those with melancholic depression [29], confirming the importance of demographic and clinical modulators in pharmacogenetic studies. Regarding rs1800042, initial suggestions that it may modulate AD response [30] were not confirmed [28,31].

Another relevant player in the serotonin synapses is the 5-HT2A receptor (*HTR2A* gene), one of the main postsynaptic serotonin receptors that is distributed widely throughout the CNS with high densities in the frontal cortex. An increasing amount of evidence suggests that 5-HTR2A is involved in MDD pathophysiology and AD mechanisms of action. Indeed, decreased cortical 5-HT2A receptor binding in MDD patients compared to healthy controls was reported [32]. With regard to *HTR2A* polymorphisms, the A allele of the intronic rs7997012 showed a favorable effect in a large MDD sample treated with SSRIs (STAR*D; formally, sequenced treatment alternatives to relieve depression) according to two studies based on independent genotyping assays [33,34].

On the other hand, in samples treated with non-SSRIs or mixed ADs, negative [25,35–38] or opposite [39] results were obtained. Despite negative findings, other SNPs in *HTR2A* (rs9316233 and rs2224721) were implicated in AD efficacy [36], suggesting the gene's contribution to SSRI response through a multilocus model. In other words, inconsistent results on rs7997012 may be partly due to complex interactions with other *HTR2A* SNPs, other genes, or even nongenetic confounders. Indeed, the effect of rs7997012 on AD response may be influenced by an interaction with *HTR2A* rs6311 (1438G/A) and gender [40]. In turn, the effect of rs6311 on AD response may be modified by other polymorphisms. First, rs6311 may impact treatment outcome through an interaction with *GNB3* (guanine nucleotide binding protein [G protein], beta polypeptide 3) rs5443 (C825T) and *SLC6A4* rs25533 [41]. Second, rs6311 is in linkage disequilibrium (LD) with rs6313 (102T/C) [42], and the effect of rs6313 on AD response may depend on the *GRIK4* (glutamate receptor, ionotropic, kainate 4) [43]. Consistent with the hypothesis of a multilocus model, studies that focused only on rs6311 and/or rs6313 did not show any clear evidence of association with AD efficacy [12].

Despite negative reports [44–47], the involvement of rs6311/rs6313 in antidepressant-induced side effects is possible. Indeed, the rs6311 GG and rs6313 CC genotypes may be risk factors for side effect development [21]. Regarding other serotoninergic receptors, preliminary findings have been reported primarily for 5-HT3 and 5-HT6.

The 5-HT3 receptor is expressed throughout the central and peripheral nervous systems and mediates a variety of physiological functions. It is the only ion channel receptor among the serotonin receptors. Five subunits (A–E) of the 5-HT3 receptor have been identified. The genes encoding them have been investigated mainly in regard to AD side-effect profiles rather than response. In particular, *HTR3A* rs1062613 (C178T) and two variants in *HTR3B* (−100 − 102 AAG deletion and rs1176744) have been associated with vomiting and nausea caused by paroxetine intake [46,48,49].

In regard to the 5-HT6 receptor, which is encoded by the *HTR6* gene, several studies reported associations between this gene and brain-related features such as cognitive function, personality traits, and mood regulation [50,51]. 5-HT6 appears to be involved in AD mechanisms of action as well. Indeed, its stimulation causes antidepressant-like behavioral and biochemical modifications, suggesting that this receptor contributes to serotonergic modulation of clinically relevant psychopharmacological processes [52]. In agreement with this hypothesis, the rs1805054 variant (C267T) may modulate AD response [53,54], although further investigations are required to clarify the role of this SNP.

So far we have focused on 5-HT neurotransmission, but another key regulation point of 5-HT activity is the biosynthesis of 5-HT itself. The limiting step of 5-HT biosynthesis is catalyzed by tryptophan hydroxylase (TPH), which is codified by two distinct genes, *TPH1* and *TPH2*. *TPH1* is ubiquitous but predominantly expressed in peripheral organs, while *TPH2* is more selectively expressed in the brain. The rationale behind the investigation of these genes as predictors of AD response derived from the hypothesis that a reduced basal 5-HT synthesis may be a risk factor for MDD.

Regarding *TPH1*, available data mainly pertain to rs1800532 (A218C), a biallelic SNP located in a potential GATA transcription-factor binding site. The A allele is associated with decreased 5-HT synthesis and, according to monoaminergic theory, may determine insufficient AD efficacy [55]. This hypothesis was followed by many pharmacogenetic studies, unfortunately with conflicting results [12]. As for AD-induced side effects, a possible effect of rs1800532 on AD-induced weight gain was only weakly supported [56].

Data on *TPH1* suggest the need for further investigation, in particular because of possible interactions between *TPH1* polymorphisms and polymorphisms in related genes, such as *HTR2A*, *GNB3*, and *COMT* [56,57]. The same is true for *TPH2* since several variants were investigated but with conflicting results [12].

The central serotoninergic system is deeply interrelated with the other monoaminergic circuits. Therefore, the genetic variants reported so far likely interact with polymorphisms in key noradrenergic and dopaminergic genes, contributing to the final clinical phenotype.

The noradrenergic system has been widely investigated because it is one of the main targets of tricyclic ADs. Among the key genes in this system, the most investigated are catechol-O-methyltransferase (*COMT*), monoamine oxidase A (*MAOA*) (both clearly involved in other systems such as the dopaminergic system), and norepinephrine transporter (*SLC6A2*) genes, which code for the main enzymes responsible for amine metabolism.

The catechol-O-methyltransferase gene (*COMT*) plays a key role in monoamine metabolism and seems to be involved in MDD pathophysiology and AD response. Two different transcription sites are responsible for the production of the soluble cytoplasmic (S-COMT) and membrane-bound (MB-COMT) isoform. MB-COMT is believed to be the dominant isoform in the brain, whereas S-COMT predominates in the periphery. MB-COMT assumes greater importance in the frontal cortex and in the striatal neurons postsynaptic to the dopaminergic neurons, where it is responsible for more than 60% of dopamine degradation.

The rs4680 (Val108/158Met) variant has been widely studied because it exhibits a relevant functional effect: the Val/Val genotype catabolizes dopamine at up to four times the rate of the Met/Met homozygote, resulting in a significant reduction of synaptic dopamine following neurotransmitter release. This polymorphism may affect not only synaptic dopamine levels but also serotoninergic activity. It has been hypothesized that rs4680 may affect SSRI response through the modulation of dopamine bioavailability in the prefrontal cortex [58]. Available data mainly reported the Met variant as the favorable allele for AD response, with an allele dose effect (better outcome in Met/Met carriers and intermediate outcome in Met/Val carriers) that confirms the previous hypothesis [59]. There are also preliminary findings about rs4680's possible effect on the risk of weight gain during treatment with various ADs [56]. However, recent negative results indicate the need for further studies [27].

Recent improved coverage of *COMT* genetic variability confirmed the hypothesis that this gene may modulate AD efficacy. Other variants were implicated (rs4633, rs4818, rs165599, rs165774, rs174696, and rs13306278) [35,60,61]. Interestingly, rs13306278 was also associated with an altered ability to bind nuclear proteins [61].

Monoamine oxidase (MAO) is an enzyme family with a key role in the inactivation of neurotransmitters and has a direct impact on the regulation of neurotransmitter levels in the brain. In humans, two distinct isoforms are expressed: MAO-A, the most investigated, mainly breaks down serotonin, norepinephrine, and epinephrine; MAO-B, mainly investigated for its role in Parkinson's disease, breaks down phenethylamine and benzylamine. Both forms equally break down dopamine. The role of MAO-A in MDD pathophysiology and AD response is largely supported by the clinical effectiveness of MAO-A inhibitors (MAOIs), on which pharmacogenetics has provided some interesting findings.

One particular polymorphism in the *MAOA* gene that has been widely investigated is a 30-bp VNTR located 1.2 kb upstream in the *MAOA* coding sequence that seems to influence the transcription rate of the gene and has been linked to variations in enzyme activity [62]. Indeed, *in vitro* studies demonstrated that repeat sequences with 3.5 or 4 copies are transcribed 2–10 times more efficiently than those with 3 or 5 copies [63]. Unfortunately, no clear confirmation has been provided *in vivo* [64,65]. Pharmacogenetic studies retrieved mainly negative findings [12], while some data supported insufficient response in longer alleles [66], with a possible selective effect in females [67,68]. The reported sex-specific effect is not surprising considering that the gene is located on the X chromosome and that neurotransmitter turnover is influenced by sex hormones [69].

Norepinephrine (NE) has a primary role in the regulation of energy and alertness [9], and the beta1 adrenergic receptor (*ADRB1* gene) has been the most investigated candidate. *ADRB1* is an important regulator of mood, memory, neuroendocrine activity, and autonomic function; moreover, it is involved in the mediation of AD response [70]. The functional SNP rs1801253 (G1165C) was associated with enhanced coupling to the stimulatory Gs protein and with increased adenylyl cyclase activation, resulting in better and faster AD response [71].

Few data are available on the alpha2 adrenergic receptor (*ADRA2A* gene), which may influence the risk of weight gain during mirtazapine treatment [72] because it acts as an antagonist of central presynaptic alpha2 receptors. Furthermore, *ADRA2A* is expressed in hippocampal progenitor cells and inhibits hippocampal neurogenesis. The blockade of *ADRA2A* was consistently demonstrated to enhance the AD effect of impipramine [73], suggesting the gene as a coregulator of AD effect.

The norepinephrine transporter (NET) is encoded by the *SLC6A2* gene. It is a monoamine transporter that reuptakes NE from the synapse back to cytosol; hence, other transporters, known as VMATs (vesicular monoamine transporters), sequester NE into vesicles for later storage and release. NET represents one of the primary targets of ADs, especially secondary amine tricyclics [74]. In Asians, rs5569 (G1287A) may be a predictor of response, particularly to noradrenergic antidepressants [62,75,76]. A higher number of variants in Caucasians were investigated, but results so far do not allow any conclusion to be reached [58].

The dopaminergic system has received less attention in the field, although both preclinical [77] and clinical data [78] demonstrated its involvement in the pathogenesis of MDD. In detail, an underactivation of the nigro-striatal dopaminergic system was demonstrated in MDD [78]. An increase of dopaminergic neurotransmission after chronic AD treatment [78,79] and the reversal of AD effect by acute administration of a D2 receptor selective antagonist [80] were also demonstrated.

Dopamine receptors are divided into the D1-like family (D1 and D5, which are coupled to a Gs protein and activate adenylate cyclase) and the D2-like family (D2, D3, and D4, which are coupled to a Gi protein and inhibit adenylate cyclase). Only the D2-like family has been associated with depressive disorders. Despite evidence of involvement of the dopaminergic system in MDD and AD response, few pharmacogenetic data are available. The D2 receptor (DRD2 gene), which plays a pivotal role in hedonic behavior, has no pharmacogenetic evidence of association with AD efficacy [81,82], with the exception of a possible effect on early symptom improvement during AD treatment [83].

A role for the D3 receptor in AD effect was suggested by the demonstration of long-lasting changes in the rat brain during D3 agonist administration, similar to what was observed during AD treatment [84]. Data on the *DRD3* gene are few and do not support its involvement in AD response modulation [82]. Finally, the VNTR polymorphism, located at the third exon of the *DRD4* gene, shows a weak association with AD response [85].

The final important player in the dopaminergic system is the dopamine transporter (DAT, coded by the *SLC6A3* gene), which is responsible for dopamine reuptake from the synaptic cleft into the presynaptic neurons. Some evidence supports the involvement of DAT in synaptic plasticity in brain regions that are involved in MDD pathophysiology (e.g., the hippocampus) and in neuronal development. Furthermore, DAT might modulate AD clinical effects. Interestingly, it was reported that AD drugs modulate the availability of DAT, which supports the role of the dopaminergic system in AD mechanisms of action [80,86]. The most investigated polymorphism in the *SLC6A3* gene is a 40-bp VNTR in exon 15, which was reported to affect DAT expression [87]. The 9/10 and 9/9 genotypes may be associated with the risk of poorer and slower response to AD drugs [88].

26.2.1.2 Glutamatergic System

Increasing evidence suggests that the glutamatergic system plays a role in MDD pathogenesis and in the mechanisms of AD response. The vast majority of excitatory neurotransmission in the CNS is mediated by aminoacid glutamate, which acts both on ionotropic receptors (NMDA, AMPA, and kainate receptors) and on receptors linked to intracellular second messenger systems (metabotropic, or mGlu). Glutamatergic theory posits that glutamate may shape the risk of MDD, influencing neuronal fate (neurotoxicity due to excess influx of Ca++ through the NMDA receptor) or the unfolding of new neuronal nets (neuroplasticity). The greatest evidence of imbalance in glutamatergic signaling was demonstrated in the hippocampus, where it is likely involved in stress-induced neuronal atrophy and death in the CA3 layer (the region of the dentate gyrus) [89]. At this level, the glutamatergic system modulates the growth of neurons and dendrites to form neuronal nets that, thanks to long-term potentiation (LTP), translate salient stimuli in permanent or semipermanent informative biological structures.

During depressive states, the chronic activation of the system, as demonstrated by proton magnetic resonance spectroscopy [90], may be responsible for neuronal death and the subsequent decrease in hippocampal volume. Convincing evidence supports the involvement of glutamatergic pathways in AD mechanisms of action. Indeed, substances with glutamatergic properties have AD effects; [91] for example, some AD treatments lead to the downregulation of the glycine B site (glycine is a modulator of glutamatergic function) and NMDA receptors. The antidepressant tianeptine is also a modulator of glutamatergic function [92] and was demonstrated to target the diffusion of AMPA receptors on cell surfaces [93]; finally, compounds that target the glutamatergic system have consistently been shown to have an antidepressant effect.

Ketamine, which acts through inhibiting NMDA receptors, reverses the behavioral and physiological alterations induced by chronic mild stress in rats, and it has been proved to be an antidepressant in humans [94]. The mechanism of the ketamine antidepressant effect has not as yet been clarified, but it was recently proposed that both NMDA antagonism and AMPA receptor activation are involved. The NMDA receptors have a slower and more prolonged postsynaptic current than do the AMPA receptors, which induce a more rapid dissociation of glutamate; the antidepressant effect probably results from the "correct" balance of NMDA and AMPA receptor activity in definite brain areas. In any case, the antidepressant effect of glutamatergic substances may be partially due to monoaminergic mechanisms: downregulation of the adrenergic receptors and enhancement of the serotoninergic function are associated with administration of glutamatergic ADs. On the other hand, chronic treatment with monoaminergic ADs causes a reduction in glutamate release [94].

Despite the relevance of the glutamatergic system in MDD and AD mechanisms of action, there are as yet few studies focused on glutamatergic variants, and those that are available investigated individual polymorphisms. In detail, *GRIK4* (glutamate receptor, ionotropic, kainate 4) was repeatedly investigated for its putative role in susceptibility for depression because of the suggested antidepressant-like phenotype of *GRIK4*(−/−) mice [95]. Unfortunately, pharmacogenetic results are sparse and inconsistent. Indeed, some studies associated different SNPs (rs1954787 and rs12800734) with AD efficacy without replicated results, while others produced negative findings both for *GRIK4* and for all glutamate NMDA and kainate receptor genes [12]. Interestingly, the GRM7 gene (glutamate receptor, metabotropic 7) may be a predictor of rapid antidepressant response [96]. This is consistent with the evidence that glutamatergic ADs (such as ketamine) are faster acting than their monoaminergic counterparts. Other genes (*GRIK2* and *GRIA3* (glutamate receptor, ionotrophic, AMPA 3)) were associated with treatment-emergent suicidal ideation and AD-induced sexual dysfunction (*GRIK2*, *GRIA1*, *GRIA3*, and *GRIN3A* (glutamate receptor, ionotropic, N-methyl-D-aspartate 3A)), but confirmation of these associations is still needed [58].

The genes discussed so far represent only the first step toward understanding the glutamatergic molecular cascade. A number of interrelated genes are still to be investigated. For example, an interesting line of research points toward the *KCNK2* gene (potassium channel subfamily K member 2), which codes for a 2-pore domain potassium channel involved in the regulation of excitability and the resting potentials of neurons. The opening of these channels may be inhibited by stimulation of the metabotropic glutamate receptors mGluR1 and mGluR5. *KCNK2* is expressed in brain areas implicated in MDD, including the prefrontal cortex, the hippocampus, and other limbic structures. Animal models suggest its involvement in the pathophysiology of MDD and AD response: *KCNK2* KO mice show increased efficacy of 5-HT neurotransmission, resistance to depression, and a substantially reduced elevation of corticosterone levels under stress.

In humans, several SNPs in the *KCNK2* gene were found to be predictors of nonremission after first- and second-line treatments, suggesting that the gene plays a role in TRD (treatment-resistant depression) [97]. This result suggests that the glutamatergic system may represent an alternative molecular pathway for restoring the biological alterations of MDD when the monoaminergic system is "poorly responsive." This hypothesis is consistent with the evidence of ketamine efficacy in TRD. It is important that the frequent inconsistencies in findings involving the glutamatergic and monoaminergic systems, when individually investigated, point to the need for an integrated perspective to provide a preferential point of observation for unraveling the molecular events that drive AD effect. Indeed, these neuronal systems are involved in a complex coregulation.

26.2.1.3 HPA Axis and Inflammation

The inflammatory theory of depression posits that an imbalance in the immune mediators is involved in the pathogenesis of depressive symptoms. Indeed, anyone who has ever had the flu knows that being sick brings with it a loss of appetite and loss of interest in the physical and social environment. These symptoms are similar to those of a major depressive episode. The inflammatory theory is supported by the finding of elevated levels of proinflammatory cytokines and other inflammation-related proteins in the plasma and cerebrospinal fluid (CSF) of MDD subjects as well as in the postmortem brain. ADs can lead to normalization of these parameters [5].

A potent activator of proinflammatory cytokines has been consistently found to induce mild fever, anorexia, anxiety, depressed mood, and cognitive impairment in human volunteers [98]. Moreover, the levels of anxiety, depression, and cognitive impairment are associated with levels of circulating cytokines [98,99], and the administration of cytokines (e.g., INF-α, which is used in the treatment of hepatitis C or malignant melanoma) may cause depressive symptoms, including suicidal ideation [5]. Proinflammatory cytokines cause various clinical aspects of depression, including hyperactivity of the HPA, disturbed 5-HT metabolism, and neurovegetative symptoms. It is known that one-third of MDD subjects have elevated peripheral inflammatory biomarkers, even without a medical illness; a dysregulation of the hypothalamic–pituitary–adrenal (HPA) axis (which contributes to the regulation of inflammatory cell activity and cytokine release) was reported in up to 70% of patients with MDD [100]. Finally, MDD treatment outcome is influenced by the AD-induced modulation of cytokines, obtained through direct or indirect action on intracellular cyclic adenosyl monophosphate (cAMP), 5-HT metabolism, and HPA axis functioning [101].

The main neuroendocrine regulator of the HPA axis is the corticotrophin-releasing hormone (CRH); CRH receptors 1 and 2 (*CRHR1* and *CRHR2*) mediate the effect of glucocorticoids in the CNS. *CRHR1* antagonists have AD effect in both animals and humans [102], suggesting a key role for CRH and its receptors in depression. Concerning CRHR1, some polymorphisms (rs242941, rs1876828, and rs242939) were thought to be related to SSRI response [103], especially in a cluster of patients with anxious depression; however, no confirmation of this result was found [104]. A different SNP was later implicated in AD response [105].

Studies on the *CRHR2* gene suggested a possible involvement of rs2270007 [104] and rs2267716–rs255105 [105] in SSRI response, and the possible involvement of rs917195 in TCAs efficacy [106]. Hyperactivity in the HPA axis in MDD might also be caused by impaired glucocorticoid signaling. Glucocorticoids act through the glucocorticoid receptor (GR), which is coded by the *NR3C1* gene. The GR is a ligand-activated transcription factor. Thus, genetic variants occurring in the NR3C1 gene may significantly affect glucocorticoid sensitivity. Several NR3C1 polymorphisms were consistently associated with depression as well as AD response.

In detail, the ER22/23EK polymorphism, which consists of two linked point mutations in codons 22 and 23, was associated with faster clinical response [107]. The BclI polymorphism, which identifies two alleles with fragment lengths of 4.5 and 2.3 kb, gained attention because replicated evidence indicated that it may be linked to altered GR function [108–110]. Unfortunately, negative findings were provided for BclI as well as for other polymorphisms in *NR3C1* [12]. All the data reported up to now refer to candidate gene studies, while a recent GWAS provided new candidate SNPs (rs852977, rs10482633, and rs10052957) [36].

In the absence of hormones, the GR resides in the cytosol complex with a variety of proteins, including *FKBP5* (FK506-binding protein 52), an established regulator of GR sensitivity. Given its key role, the *FKBP5* gene has received even more investigative attention than *NR3C1* as a predictor of AD efficacy. Unfortunately, results were mainly negative even though some candidate SNPs (rs1360780, rs3800373, and rs4713916) emerged [104,111–114]. Preliminary findings also exist for the CRH-binding protein gene that encodes for a plasma protein involved in the inactivation of CRH [105].

It is now clear that the brain is not a sanctuary for the immune system, as hypothesized in the past; however, inflammatory cytokines have been shown to access the brain and can virtually interact with every pathophysiologic domain known to be involved in MDD, including neurotransmitter metabolism, neuroendocrine function, and neural plasticity [115]. The most investigated cytokine gene is interleukin 1 beta (*IL1B*), which shows multiple and reciprocal interactions with the monoaminergic, cholinergic, and GABAergic systems in the CNS [58]. Pharmacogenetic results are quite promising for this gene: the promoter rs16944 was selectively associated with SSRI response [116–118], and the intronic rs1143643 [118] may be a predictor of AD response. rs1126757 is also a good candidate [119].

An interesting regulator of the release of inflammatory cytokines such as *IL1B* is the purinergic receptor P2X, which is a key mediator in chronic inflammation, neurodegeneration, and chronic pain. P2X7 receptor-deficient mice show a substantially attenuated inflammatory response [120]. Although the expression of this nuclear receptor in neurons is still uncertain, its activation can mediate and/or enhance neurotransmitter release (e.g., glutamate) and may affect neuronal plasticity and neuronal cell death. Thus, P2X7 receptors may act as mediators between the immune and the nervous system and play a role in both neurodegenerative and psychiatric disorders. Some functional polymorphisms identified in the *P2RX7* gene seem to increase the risk of a familial mood disorder and time spent ill [121]. On the basis of these data, further investigation is needed to clarify the contribution of *P2RX7* and other inflammatory genes to AD response.

26.2.1.4 Neurotrophic Factors and Signal Transduction

Neurotrophic factors were first characterized as regulators of neural growth and differentiation during development, but today they are also known to be potent regulators of plasticity and survival of neurons and glia during adulthood. A role for neuronal plasticity in affective disorders was hypothesized after the observation that hippocampus atrophy following stress was reversed by ADs in parallel with an increase in the expression of neurotrophic factors, especially brain-derived neurotrophic factor (*BDNF*) [122]. Indeed, ADs can reverse a decrease in volume of specific brain areas in MDD (the hippocampus, left anterior cingulate gyrus, subgenual region, area 9 (dorsolateral cortex), area 10/47 (rostral orbital cortex), and area 47 (caudal orbital cortex)) [5].

BDNF is the gene that has attracted the most research attention. It is a member of the nerve growth factor (NGF) superfamily, which was demonstrated to be underexpressed during depressive states [123]. AD treatments are consistently associated with increased *BDNF* expression in the hippocampus of adult rats [124]. As a consequence of these findings, *BDNF* polymorphisms have been extensively studied, especially rs6265, a valine to methionine (V66M) substitution in position 196. The Met allele was associated with poorer episodic memory and abnormal hippocampal activation [125]. Pharmacogenetic studies mainly suggested a positive molecular heterosis effect, or a more favorable outcome in Met allele carriers [12]. On the other hand, some studies reported a better response in the Val/Val genotype, and several negative findings exist [12]. There are various reasons for these contradictory results.

One reason is the different ethnicities of the examined samples—considerable *BDNF* allele and haplotype diversity among global populations was reported [126]. Furthermore, different ADs may have different effects on central *BDNF* expression, so the heterogeneity in treatments both among and within samples represents another possible confounding factor. Other polymorphisms in the gene were associated with AD response, but findings are still preliminary. Moreover, the *NTRK2* gene (encoding for the *BDNF* receptor) received attention as a modulator of AD response because of its possible interaction with the *BDNF* gene [62].

Vascular endothelial growth factor (*VEGF*) was first characterized (and named) for its role in vascular permeability, and was later described as a potent endothelial cell mitogen and survival factor. Recently, it was found to be influential beyond the vascular system. Indeed, in addition to regulating endothelial cells and blood vessel formation/permeability, *VEGF* has been hypothesized to be a true neurotrophic factor. Indeed, animal studies demonstrated that *VEGF* levels are increased by several ADs and that VEGF signaling is required for AD-induced behavioral response [127].

In MDD patients, higher expression of *VEGF* mRNA in peripheral leukocytes was associated with a depressive state, and recovery of these levels occurred in parallel with clinical improvement [128]. Although it seems like a good candidate gene, *VEGF* has been poorly studied in AD pharmacogenetics, and markers rs1570360, rs2010963, rs25648, rs833069, rs3025010, rs3025033, and rs3025039 have provided negative results [129].

Dystrobrevin binding protein 1 (*DTNBP1* gene) may contribute to actin cytoskeleton reorganization, neurite outgrowth, synaptic signaling, regulation of glutamatergic neurotransmission [130], and neuroplasticity. This biological function may indicate that *DTNBP1* is promising as a candidate gene in AD response variability, but preliminary data are still difficult to interpret. Indeed, both negative and positive findings were reported for several haplotypes [12].

The complexity of signals produced by neurotrophic factors is mediated through signal transduction proteins, from the cell surface to the cytoplasm and nucleus. The guanine nucleotide binding protein (G protein) beta polypeptide 3 (*GNB3* gene) is involved in generation of second messengers in response to a number of signals—growth factors, neurotransmitters, hormones, and the like. Given the high complexity of G protein signal transduction cascades and their high diffusion, they are thought to be involved in neuronal plasticity [131] as well as in AD response. The most promising variant in *GNB3* is rs5443 (C825T), with a T allele that was associated with the occurrence of a splice variant (Gbeta3s) that appears to have altered activity [132]. Several independent studies found that the T allele predicted better AD response, but some data suggested an opposite effect especially in young subjects [12]. Negative findings [133–135] in Asian samples suggest a possible ethnic stratification.

Glycogen synthase kinase 3 alpha (*GSK3A*) acts as a regulator of Wnt/beta-catenin signaling, which is involved in the control of gene expression, cell behavior, cell adhesion, and cell polarity and plays a major role in neurodevelopment, regulation of neuroplasticity and cell survival [136]. The inhibitory phosphorylation of GSK3 occurs in the context of the signaling cascades in response to 5-HT, 5-HT1 receptor agonists, lithium, and ADs [137]. In particular, *GSK3A* may be an important mediator of 5-HT action in the brain and so of depressive-like behaviors [138]. The T allele of the promoter rs334558 (−50 T/C) was associated with transcriptional strength [139]; in some studies involving bipolar depressed patients different associations were shown depending on type of treatment [140,141]. In patients treated with only AD drugs, the C allele resulted in the favorable variant [142]. Given the interesting biological role of this gene from the perspective of AD mechanisms of action, further investigation will be a promising challenge.

Finally, the *CREB* gene (cAMP-responsive element binding protein) encodes a transcription factor that binds to the cAMP-responsive element and induces gene transcription in response to stimulation of the cAMP pathway. Alternate splicing of this gene results in two transcript variants encoding different isoforms, of which only *CREB1* was studied in relation to AD pharmacogenetics.

CREB activation is involved in proliferation of neuronal precursors, outgrowth of neuronal processes, learning and memory, induction of neurotrophic cellular programs (e.g., transcription of *BDNF*), and regulation of circadian rhythms. In humans, alterations in *CREB* have been associated with the pathophysiology of depression and suicide [143], as well as with the mechanism of AD action and response. Indeed, increased *CREB* levels in rodent models result in antidepressant-like behaviors, and studies on both humans and rodents have shown that *CREB* is upregulated by chronic AD treatment [144]. Thus, it can be hypothesized that specific variants in *CREB1* might be related to a lower likelihood of recovery from MDD, possibly through a differential modulation of gene expression and activation. Despite promising molecular and preclinical findings, *CREB1* has yet to be comprehensively investigated, but preliminary findings suggested its association with treatment-resistant MDD [145]. Future pharmacogenetic investigations of *CREB1* should take into account the number of failed antidepressant treatments.

26.2.2 Antidepressant Pharmacokinetics

Pharmacokinetics refers to all biological processes involved in drug absorption, distribution, transport, metabolism (e.g., by metabolic enzymes such as *cytochrome P450* or *glucuronosyltransferase* enzymes), and excretion from the body.

AD pharmacokinetics may be modified not only by enzyme inhibitors/enhancers, aging, and pregnancy, but also by polymorphisms located in key genes involved in AD metabolism and clearance. The genes coding for P-glycoprotein (P-gp) and cytochrome P450 (CYP) isoenzymes are the most interesting from this point of view because their products play a pivotal role in AD transport and metabolism [58].

P-glycoprotein (the *ABCB1* gene) is an ATP-dependent drug efflux pump for xenobiotic compounds that decreases drug accumulation in multidrug-resistant cells and limits uptake of some lipophilic drugs into key organs such as the brain. Animal studies show that a wide variety of structurally unrelated drugs are efficaciously carried out of the brain by P-gp activity, among which are a long list of ADs (with some exceptions, such as fluoxetine and bupropion) [58]. ABC transporters have been implicated in resistance to pharmacotherapy, most notably in oncology, where the expression of these efflux pumps by cancer cells can confer resistance to chemotherapy [146]. Over 50 functional SNPs have been identified in the *ABCB1* gene to date, and several studies demonstrated that they can impact P-gp expression and function in humans and therefore influence the pharmacokinetics of various drugs, including ADs [146]. The most studied polymorphisms in this gene are rs2032582 and rs1045642, since they alter P-gp expression and/or function [147], but their association with AD efficacy is still controversial [58].

Given that P-glycoprotein activity regulates drug uptake into tissues, *ABCB1* gene variations may also affect the risk of AD-induced side effects. However, this topic has not so far been extensively studied. The most systematic study investigated the correlation between *ABCB1* polymorphisms and the most common SSRI-induced side effects [148]. The main finding was the association between SSRI-related side effects and rs2032583 and rs2235040. Consistent preliminary evidence suggests that genetic variation in the *ABCB1* gene might influence the risk of switching and discontinuation of AD therapy [149]. Additional data indicate that the AD dose needed for remission may be predicted by a variant in the *ABCB1* gene [150].

The cytochrome P450 (CYP) superfamily is a class of enzymes that have a major effect on the oxidation and reduction of both endogenous and xenobiotic substances. The key role of these enzymes in drug metabolism and the highly polymorphic nature of their coding genes make them an interesting subject in pharmacogenetics. The most relevant CYP isoforms for AD metabolism are *CYP2D6*, *CYP2C19*, *CYP2C9*, *CYP1A2*, and *CYP2B6*. The known alleles show normal, reduced/absent, or increased activity (for a complete overview, see http://www.cypalleles.ki.se/), allowing some metabolizing groups to be distinguished.

In any case, this classification does not exactly reflect metabolic status because it does not take into account that some alleles are only partially active and some show different activity depending on the drug metabolized [151].

According to this classification, the wild-type genotype is defined as an extensive metabolizer (EM), characterized by the presence of two active alleles; an intermediate metabolizer (IM) is characterized by the presence of one wild-type allele plus a partially or totally defective allele and is expected to be between the EMs and the poor metabolizers (PMs), which show a combination of two partially or totally defective alleles. Finally, the ultrarapid metabolizer (UM) category exists only for *CYP2D6* and is usually linked to multiple allele copies. Metabolizing status was demonstrated to be associated with AD pharmacokinetics in a number of studies [12]—in particular, the *CYP2D6* gene and venlafaxine, fluoxetine, paroxetine, and nortriptyline pharmacokinetics; and the *CYP2C19* gene and citalopram, escitalopram, and amitriptyline/nortriptyline pharmacokinetics. On the basis of metabolizing status, theoretical dose adjustments were determined [152].

Available data do not support a correlation between AD plasma levels and the response of most ADs (with the exception of TCAs), and this is probably linked to the lack of association between response and CYP450 genetic polymorphisms found for the most part by previous studies [151]. Therefore, evidence does not as yet exist to support the recommendation of CYP genotyping in clinical practice, since the effect of CYP variants on clinical outcomes is still not completely clear for the most studied isoenzymes.

In conclusion, even if genotyping technologies and dose adjustments based on pharmacokinetic findings are already available, further investigation is expected to clarify their usefulness and applicability in clinical practice. Our current knowledge suggests that genotyping might be relevant for choosing a drug when the parent drug or its metabolites are critical for drug safety, and it may be that polymorphic drug metabolism affects the risk of side effects (as for TCAs).

26.3 GENOME-WIDE APPROACHES

In the following subsections, genome-wide association studies (GWAS) and some statistical methodologies based on genome-wide genotyping are discussed. GWAS showed rapid spread in genetic research during the last years, and the improvement of this technique represents a pivotal step in the dissection of antidepressant pharmacogenetics.

26.3.1 Genome-Wide Association Studies

Genome-wide association studies (GWAS) have been proposed as a powerful means of investigating human complex traits and have rapidly gained enthusiastic approval. GWAS provide some advantages compared to candidate gene studies. Indeed, they allow the genotyping of hundreds of thousands of polymorphisms across the whole genome and they overcome the need for a priori hypothesis. The hypothesis-free approach has the advantage of interrogating genes that have not been considered candidates because of our limited understanding of their function. Further, GWAS can uncover important regulatory variations in the large noncoding regions of the genome.

On the other hand, several limitations have to be considered, including the following:

- The available microarray platforms allow the genotyping of less than 50% of genomic variants [153].
- GWAS technology does not allow the reliable genotyping of rare variants (<1% of the population).
- There is the risk of the so called flip-flop phenomenon across different ethnic groups [154] because the functional gene effect is largely unknown and polymorphisms apparently associated with outcomes may only be in LD with truly associated variants.
- It is difficult to balance the risk of false-positive and false-negative findings. Indeed, the risk of false-positive findings should be carefully considered at least when data are unbalanced [155].

Regarding the final item in the list, the risk of a type I error can be very high when there are fewer than 100 observations in the minor genotype group, and this limitation cannot be overcome by increasing the total sample size. On the other hand, at the stringent genome-wide significance threshold, markers that are truly but weakly related to the phenotype may not be detected [156]. Indeed, the significance level is usually set between 1E-7 and 5E-8 [157] because of the very low prior probability of association and the limited number of variants determining the phenotype compared to the total number of markers genotyped. Prior information about genome regions that are related to the phenotype of interest may be used to boost the power of detecting signals, with a consequent balance between the risk of type I and type II errors [158].

Three large GWASs—the Genome-Based Therapeutic Drugs for Depression study (GENDEP) [119], the Sequenced Treatment Alternatives to Relieve Depression study (STAR*D), [159], and the Munich Antidepressant Response Signature study (MARS) [160]—have studied the effect of genetic variants on AD efficacy. In none of these were convincing genome-wide results reported.

In the STAR*D GWAS, among the top findings were the ubiquitin protein ligase E3C (*UBE3C*), the bone morphogenic protein 7 (*BMP7*), and the RAR-related orphan receptor A (*RORA*) genes. The *RORA* gene is related to circadian rhythm regulation [161], which is often altered in MDD. *UBE3C* is involved in protein degradation, while *BMP7*, a member of the transforming growth factor-beta (*TGFB*) superfamily, induces endochondral osteogenesis. For both these genes, a putative biological role in AD response is not an immediate interpretation. The same can be stated for Acyl-CoA synthetase short-chain family member 3 (*ACSS3*), a gene that may be associated with unsustained AD response [162]. Regarding *BMP7*, some kind of replication was obtained through full-exome sequencing, a method based on a similar GWAS principle but focused on exons (i.e., coding regions) only. The finding involved the bone morphogenetic protein 5 (*BMP5*) [163], which is a member of the same family as *BMP7*.

The MARS study retrieved the top signals in the cadherin-17 (*CDH17*) and the EPH receptor B1 (*EPHB1*) genes. Cadherins are calcium-dependent cell adhesion proteins that may play an important role in synapse formation in the hippocampus [164]—a brain region involved in MDD pathogenesis. *EPHB1* is an ephrin receptor, and in adults regulates chemotaxis, proliferation, and polarity of the hippocampus neural progenitors.

The GENDEP study produced interesting results for the interleukin-11 (*IL11*) and uronyl 2-sulphotransferase (*UST*) genes. The finding in the *IL11* gene appears to confirm the inflammatory hypothesis of MDD and the anti-inflammatory properties of ADs. *UST* codes for an enzyme that transfers sulfate to uronyl residues of glycosaminoglycans (components of the extracellular matrix). A collaborative analysis by STAR*D and GENDEP showed the strongest common signal from the chondroitin sulfate N-acetylgalactosaminyltransferase 1 gene (*CSGALNACT1*) [162], which is involved in chondroitin chain biosynthesis in cartilage. This finding may be interesting in view of the signal found in the *UST* gene. Although chondroitin sulfate has a well established role in the skeletal system, it may also play a part in neuroplasticity, regeneration, and brain development [165].

AD efficacy is influenced by environmental factors that interact with genes [166]. Genome-wide data, as well as candidate gene data, have been investigated with the aim of retrieving meaningful gene × environment interactions. In the STAR*D study, the neural precursor cell expressed developmentally downregulated 4-like, E3 ubiquitin protein ligase (*NEDD4L*) gene interacts with patient quality of life in determining AD response [167]. Interestingly, this finding confirmed the hypothesis of involvement of ubiquitin ligases in AD response (see STAR*D findings reported on the previous page).

The most significant GWAS findings diverge across different samples, mainly because of the heavy influence of stratification factors (such as cryptic population stratification) on the typical small effect sizes detected by GWAS. To increase statistical power, recently GWAS meta-analyses have been performed, albeit that they increase signal divergence because of intersample stratification. Accordingly, no significant findings have been reported using this approach [168]. On the other hand, analyses focused on more homogeneous groups in terms of treatment revealed a concordant signal among the main GWAS previously cited, but they explain only ≈1.2% of the variance in response [169].

In addition to therapeutic effects, one study investigated genome-wide data to identify markers of AD-induced side effects. In detail, the SAC1 suppressor of actin mutations 1-like (yeast) (*SACM1L*) gene revealed itself as a putative modulator of bupropion-related sexual side effects [170]. *SACM1L* encodes an integral membrane protein of the endoplasmic reticulum and the Golgi apparatus that influences vesicle trafficking; *SACM1L* shows wide tissue distribution and mutations produce a wide array of phenotypes. This study found that the gene *EMID2* (EMI domain containing 2) affects vision/hearing side effects [171]. *EMID2* has a possible biological rationale for association with these side effects, since it encodes the protein collagen α-1 chain involved in the regulation of corneal collagen fibrillogenesis.

Despite these findings, no clinical applications are expected in the next years given the small effect size of the results, the lack of replication, and the absence of cost−benefit studies. For a summary of GWAS results see Table 26.2.

26.3.2 Pathway Analysis

Recently pathway analysis was proposed as a way to balance some of the limitations of hypothesis-free GWAS. Pathway analysis looks at gene variants that are involved in the same biological pathway. Thus, genome-wide data can be analyzed as units of biologically related genes and not only as single genetic variants. Pathway analysis may yield more insight into disease biology because it overcomes the genetic heterogeneity bias (e.g., due to population stratification and differential rates of genotyping error between the groups under analysis). Also, setting the variants in the same pathway as the unit of analysis may increase the power needed to detect associations and replicate findings [172].

Indeed, although individual SNPs did not reach significance in many GWASs that investigated the genetics of MDD, ranking SNPs previously associated with different psychiatric disorders identified pathway convergence in synaptogenesis, axonal guidance, synaptic plasticity, and calcium signaling [173]. Similarly, some main molecular clusters were associated with AD efficacy. In detail, genes that belong to metabolic pathways and brain development, metabolic and cardiovascular disease, and GABAergic and glutamatergic neurotransmission are putative modulators of AD response [160]. Among genes involved in brain development, the strongest signals were found in the transcription factor nuclear receptor subfamily 2, group E, member 1 (*NR2E1*), the substrate (ephrin-A5; *EFNA5*), and the receptor (EPH receptor A5; *EPHA5*) genes of ephrin A5, which is an important modulator of late-stage nervous system development and differentiation.

The metabolic and cardiovascular disease gene cluster was so named because it includes potential risk genes for cardiovascular disorders, such as CD36 paraoxonase 2 (*PON2*); apolipoprotein B (*APOB*); and phosphoinositide-3-kinase, regulatory subunit 1 (*PIK3R1*). Abnormalities in glucose and lipid metabolism, as well as cellular antioxidant potential, can clearly also influence neuronal survival and activity, particularly synaptic plasticity, and finally impact on AD response.

The gene group related to GABAergic and glutamatergic neurotransmission includes, among others, neuregulin 1(*NRG1*) and homer homolog 1 (*HOMER1*), which are involved in neurodevelopment and neuroplasticity; and glial high-affinity glutamate transporter (*SLC1A2*), which clears glutamate from synapses and can prevent cellular damage from excessive activation of glutamate receptors. The central glutamatergic system represents a key regulator of long-term potentiation, a process that underlies multiple forms of long-term memory in the mammalian brain. Recently, the involvement of the long-term potentiation pathway in AD response was confirmed [162].

The described gene clusters show a clear biological rationale for involvement in AD efficacy, confirming the substantial discovery potential of pathway analysis compared to methods based on the analysis of individual markers.

26.4 CONCLUSION

As reported in this chapter, a high number of pharmacokinetic and pharmacodynamic genes may contribute to the clinical outcomes of AD treatment and explain the hypothesized 50% variance in response ascribed to genetic factors. Nonetheless, pharmacogenetic studies have so far provided poorly replicated and often contradictory results. A possible explanation is the main phenotype investigated so far: MDD itself. Indeed, standard criteria for the diagnosis of MDD are probably not discriminative enough to identify homogeneous patient groups.

There is increasing evidence that MDD represents a common final phenotype deriving from various pathophysiological mechanisms. Therefore, in recent years more homogeneous patient subgroups characterized by common features (i.e., endophenotypes) have been studied. The endophenotype is a concept characterized by specific properties. In detail: (1) the endophenotype is heritable; (2) the endophenotype is primarily state independent (i.e., it manifests in an individual whether or not illness is active); (3) in families, endophenotype and illness cosegregate; and (4) the endophenotype found in affected family members is found in nonaffected family members at a higher rate than in the general population. Thus, endophenotypes are measureable characteristics that fill the gaps between available descriptors and those between the gene and the elusive disease process. Behavioral and neural factors and biomarkers have been tested for their significance in defining MDD endophenotypes [174].

Current and future pharmacogenetic studies are expected to collect detailed data regarding not only major clinical features but also neuroimaging and neuropsychological phenotypes, thus allowing the identification of depressive endophenotypes. Other factors involved in poor replication of pharmacogenetic findings are probably ethnic stratification, poor covering of genetic variance by candidate gene studies, and interaction between genetic and environmental factors. Other issues are represented by the so-called flip-flop phenomenon (investigation of a noncausal variant in LD with a genuine variant [154]), de novo mutations, and epigenetic modifications. Indeed, preliminary findings suggest that epigenetic mechanisms may play a role in regulating the expression of key genes during AD treatment [175]. On the other hand, the effect of de novo (point substitutions or single-nucleotide variants and small insertions or deletions) and recurrent mutations has been hypothesized as a further cause of poor replication of genetic findings.

Regarding pharmacokinetic genes, other specific limitations have to be considered. First, a single drug is metabolized by specific enzymes, but the result of this reaction may be an active molecule that can be metabolized by one or more different enzymes. Second, drug interactions may strongly affect the cytochrome activity in a way that may be dependent on gene variants but is, to an extent, still difficult to define. For example, the enzyme activity of a genetic PM cannot be affected by inducers or inhibitors, but EMs or UMs can be converted to the PM phenotype by strong enzyme inhibitors. Finally, drugs can be metabolized by a set of cytochromes: they should all be investigated by a single test in order to infer sufficient predictive information about drug blood levels.

Assuming that these limitations can be overcome by better study design and technological improvements, there should be a multistep process for identifying genetic marker sets that may be useful in clinical practice (Figure 26.1). This process should include molecular studies, cell line experiments, animal models, neuroimaging, and biomarkers in MDD patients, all of which are expected to identify the biological mechanisms involved in AD effect. In this effort, GWASs can contribute to the discovery of molecules with still unknown function and intergenic markers. Candidate studies can confirm the involvement of marker sets in AD outcome thanks to whole-genome sequencing. Selected genes can thus be grouped into molecular pathways that can be tested as a single unit for their effect on AD response. Finally, cost-effectiveness trials on the identified gene sets should verify the actual applicability of genotyping in clinical practice. This is clearly only one method for identifying genetic markers; several complementary and partially overlapping methods can be used to reach the same goal.

Studies in the multistep discovery process of genetic markers have been performed, even if some steps have yet to be sufficiently analyzed (in particular, pathway and

FIGURE 26.1 **Multistep identification of sets of genetic markers useful in clinical practice.** Shown at the bottom of the pyramid are studies aimed at identifying the biological mechanisms involved in AD action. GWASs attempt to discover molecules with as yet unknown function. Candidate studies can confirm the involvement of gene sets in AD outcomes thanks to whole-genome sequencing. Selected genes can thus be grouped into molecular pathways that can be tested as a single unit for their effect on antidepressant response. Finally, cost-effectiveness trials on the identified gene sets should verify the actual applicability of genotyping in clinical practice.

cost-effectiveness analysis). Nevertheless, some data about the cost-effectiveness of genotyping already exist. Indeed, the genotyping of 5-HTTLPR prior to AD treatment was associated with an increase both in AD response and tolerability compared to nongenotyping. Further, genotyping shows a positive cost-effectiveness profile after at least two recurrent MDD episodes [176]. In addition, a study of cost-effectiveness data from 27 European states regarding AD choice based on response and tolerability predicted by 5-HTTLPR profile compared to an usual algorithm has been performed [177]. It found the probability of an incremental cost-effectiveness ratio value below the WHO-recommended cost-utility threshold to be >90% in high-income countries.

Finally, we underline that pharmacogenetics provides a unique tool for increasing knowledge of AD mechanisms of action. The idea that unsatisfactory AD response rates are partially due to the lack of drugs with alternative mechanism of action is well supported [178]. Thus, the engineering of molecules with truly innovative mechanisms of action appears to be a primary objective together with the identification of response predictors.

KEY CONCEPTS

- The estimated variance in antidepressant response due to genetic variants is around 50%
- Results of candidate gene studies were often contradictory and poorly replicated, but outlined few good candidate genes (SLC6A4, COMT, IL1B, BDNF, and GNB3)
- Genome-wide association studies provide pivotal data to improve the limited knowledge derived by candidate gene studies, and suggested RORA, CDH17, EPHB1, and IL11 as promising new candidate genes
- A multistep and convergent pharmacogenetic approach could provide more informative data than genome-wide association studies and candidate gene studies used as independent tools
- Preliminary cost-effectiveness trials supported the applicability of genotyping prior to antidepressant treatment beginning, but neither approved genetic test nor specific clinical guidelines to use it still exist

GLOSSARY

Genome-wide association study the examination of hundreds of thousands of common genetic variants to study associations with human complex traits.

Linkage disequilibrium the nonrandom association of alleles at two or more loci that descend from single, ancestral chromosomes.

Phenotype an organism's observable characteristic or trait, such as biochemical or physiological properties or behavior. Phenotypes result from the expression of an organism's genes as well as the influence of environmental factors and the interactions between the two.

Polymorphism the natural variation in a DNA sequence that has no evident adverse effects and occurs with fairly high frequency in the general population.

SNP the DNA sequence variation that occurs when a single nucleotide (A, T, C, or G) in the genome differs among members of a biological species or among paired human chromosomes.

VNTR the location in a genome where a short nucleotide sequence is organized as a tandem repeat, often showing variations in length between individuals.

ACRONYMS AND ABBREVIATIONS

AD	antidepressant
GWAS	genome-wide association study
LD	linkage disequilibrium
MDD	major depressive disorder
SNP	single-nucleotide polymorphism
VNTR	variable number of tandem repeats

27.1 OVERVIEW

Since the identification of its pathogenic features by Alois Alzheimer in 1906, more than 90,000 papers have been published on Alzheimer's disease (AD) to date (2.5 million references on cancer since 1818; 1.6 million on cardiovascular disorders since 1927; and 1.01 million on central nervous system disorders since 1893) [1]. The number of people affected by dementia is becoming a public and socioeconomic concern in many countries all over the world, independent of economic conditions. The growth of the elderly population is a common phenomenon in both developed and developing countries, bringing about future challenges in terms of health policy and disability rates.

In the United States, rates for the leading causes of death are heart disease (200.2 per 100,000), cancer (180.7 per 100,000), and stroke (43.6 per 100,000). AD is the fifth leading cause of death in people older than 65 years of age, representing 71,600 deaths per year. AD affects approximately 5.4 million individuals in the United States and is estimated to affect up to 16 million by 2050 [2]. Disability caused by senility and dementia affects 9.2 per 1000 in the population aged 65–74 years, 33.5 per 1000 in those within the 75–84 range, and 83.4 per 1000 in the population over 85 years

[3,4]. In low- to middle-income countries, dementia makes the largest contribution to disability, with a median population-attributable prevalence fraction of 25.1%, followed by stroke (11.4%), limb impairment (10.5%), arthritis (9.9%), depression (8.3%), eyesight problems (6.8%), and gastrointestinal impairments (6.5%) [5].

In Western countries, AD is the most prevalent form of dementia (45–60%), followed by vascular dementia (30–40%), and mixed dementia (10–20%), which in people older than 85 years of age may account for more than 80% of cases.

The different forms of dementia pose several challenges to society and to the scientific community: (1) they represent an epidemiological problem and a socioeconomic, psychological, and family burden; (2) most of them have an obscure/complex pathogenesis; (3) their diagnosis is not easy and lacks specific biomarkers; and (4) their treatment is difficult and inefficient.

In terms of economic burden, approximately 10–20% of direct costs are associated with pharmacological treatment, with a gradual increase that parallels the severity of the disease. A Canadian study [6] shows that the mean total cost to treat patients with very mild AD is $367 per month, compared with $4063 per month for patients with severe or very severe AD. Only 20–30% of patients with dementia respond appropriately to conventional drugs, and the onset of adverse drug reactions imposes the need for other drugs to neutralize side effects, thus multiplying the initial cost of the pharmacological treatment and the health risk for the patients [7]. Wimo et al. [8] studied the economic impact of dementia in Europe in the EU-funded Eurocode project and found that the total cost of dementia in EU27 countries in 2008 was estimated to be €160 billion (€22,000 per dementia patient per year), of which 56% were costs of informal care. The corresponding costs for the whole of Europe were €177 billion. Informal caregiver costs were the largest cost component, accounting for about half to just over 60% of total societal costs, depending on the country and AD severity [9].

In addition (and related) to the problem of direct and indirect costs for the management of dementia, there is an alarming abuse of inappropriate psychotropic drug consumption worldwide. Antipsychotic medications are taken by more than 30% of elderly patients with dementia [10], and conventional antipsychotics are associated with a higher risk of all-cause mortality among nursing home residents [11].

Abuse, misuse, self-prescription, and uncontrolled medical prescription of CNS drugs are becoming major problems with unpredictable consequences for brain health. The pharmacological management of dementia is an issue of special concern because of the polymedication required to modulate its symptomatic complexity where cognitive decline, behavioral changes, and psychomotor deterioration coexist. In parallel, a growing body of fresh knowledge is emerging on the pathogenesis of dementia, together with data on the neurogenomics and pharmacogenomics of CNS disorders. The incorporation of this new armamentarium of molecular pathology and genomic medicine into daily medical practice, together with educational programs for the correct use of drugs, must help researchers and clinicians to (1) understand AD pathogenesis; (2) establish an early diagnosis; and (3) optimize therapeutics either as a preventive strategy or as formal symptomatic treatment [7,12].

27.2 TOWARD A PERSONALIZED MEDICINE FOR DEMENTIA AND NEURODEGENERATIVE DISORDERS

Common features of neurodegenerative disorders include the following:

- Polygenic/complex disorders in which genetic, epigenetic, and environmental factors are involved
- Deterioration of higher activities of the CNS
- Multifactorial dysfunction in several brain circuits
- Accumulation of toxic proteins in the nervous tissue

For instance, the neuropathological hallmarks of AD (amyloid deposition in senile plaques, neurofibrillary tangle formation, and neuronal loss) are merely the phenotypic expression of a pathogenic process in which different gene clusters and their products are potentially involved [7,12].

A large number of the genes that form the structural architecture of the human genome are expressed in the brain in a time-dependent manner along the lifespan. The cellular complexity of the CNS (10^3 different cell types) and synapses (each of the 10^{11} neurons in the brain having around 10^3–10^4 synapses with a complex multiprotein structure integrated by 10^3 different proteins) requires very powerful technology for gene expression profiling, which is still in its very early stages and is not devoid of technical obstacles and limitations [13]. Transcripts of 16,896 genes have been measured in different CNS regions. Each region possesses its own unique transcriptome fingerprint that is independent of age, gender, and energy intake. Fewer than 10% of genes are affected by age, diet, or gender, with most of these changes occurring between middle and old age. Gender and energy restriction have robust influences on the hippocampal transcriptome of middle-aged animals. Prominent functional groups of age- and energy-sensitive genes are those encoding proteins involved in DNA damage responses, mitochondrial and proteasome functions, cell fate determination, and synaptic vesicle trafficking [14].

The introduction of novel procedures in an integral genomic medicine protocol for CNS disorders and dementia is imperative in drug development and in clinical practice in order to improve diagnostic accuracy and to optimize therapeutics. Personalized strategies, adapted to the complexity of each case, are essential to depict a clinical profile based on specific biomarkers correlating with individual genomic profiles [7,15].

Our understanding of the pathophysiology of CNS disorders and dementia has advanced dramatically during the last 30 years, especially in terms of their molecular pathogenesis and genetics. The drug treatment of CNS disorders has also made remarkable strides with the introduction of many new drugs for the treatment of schizophrenia, depression, anxiety, epilepsy, Parkinson's disease, and AD, among many other quantitatively and qualitatively important neuropsychiatric disorders.

Improvement in terms of clinical outcome, however, has fallen short of expectations, with up to one-third of patients continuing to experience clinical relapse or unacceptable medication-related side effects in spite of efforts to identify optimal treatment regimes with one or more drugs. Potential reasons for this historical setback might be: (1) that the molecular pathology of most CNS disorders is still poorly understood; (2) that drug targets are inappropriate, not fitting into the real etiology of the disease; (3) that most treatments are symptomatic but not antipathogenic; (4) that the genetic component of most CNS disorders is poorly defined; and (5) that the understanding of genome–drug interactions is very limited [7,12].

The optimization of CNS therapeutics requires the establishment of new postulates regarding (1) the costs of medicines, (2) the assessment of protocols for multifactorial treatment in chronic disorders, (3) the implementation of novel therapeutics addressing causative factors, and (4) the establishment of pharmacogenomic strategies for drug development [12]. Personalized therapeutics based on individual genomic profiles implies the characterization of five types of gene clusters:

- Genes associated with disease pathogenesis
- Genes associated with the mechanism of action of drugs
- Genes associated with drug metabolism (phase I and II reactions)
- Genes associated with drug transporters
- Pleiotropic genes involved in multifaceted cascades and metabolic reactions

27.3 GENOMICS OF ALZHEIMER'S DISEASE

More than 3000 genes distributed across the human genome have been screened for association with AD during the past 30 years [16]. In the Alzgene database [17] there are 695 genes potentially associated with AD, of which the top ten are (in decreasing order of importance): *APOE* (19q13.2), *BIN1* (2q14), *CLU* (8p21–p12), *ABCA7* (19p13.3), *CR1* (1q32), *PICALM* (11q14), *MS4A6A* (11q12.1), *CD33* (19q13.3), *MS4A4E* (11q12.2), and *CD2AP* (6p12). Potentially defective genes associated with AD represent about 1.39% (35,252.69 Kb) of the human genome, which is integrated by 36,505 genes (3,095,677.41 Kb). The highest number of AD-related defective genes concentrate on chromosomes 10 (5.41%; 7337.83 Kb), 21 (4.76%; 2289.15 Kb), 7 (1.62%; 2584.26 Kb), 2 (1.56%; 3799.67 Kb), 19 (1.45%; 854.54 Kb), 9 (1.42%; 2010.62 Kb), 15 (1.23%; 1264.4 Kb), 17 (1.19%; 970.16 Kb), 12 (1.17%; 1559.9 Kb), and 6 (1.15%; 1968.22 Kb), with the highest proportion (related to the total number of genes mapped on a single chromosome) located on chromosome 10 and the lowest on chromosome Y [18] (Figure 27.1).

The genetic and epigenetic defects identified in AD can be classified into four major categories: Mendelian mutations; susceptibility SNP; mtDNA mutations; and epigenetic changes. Mendelian mutations affect genes directly linked to AD, including 32 mutations in the amyloid beta precursor protein (*APP*) gene (21q21)(AD1), 165 mutations in the presenilin 1 (*PSEN1*) gene (14q24.3)(AD3), and 12 mutations in the presenilin 2 (*PSEN2*) gene (1q31–q42) (AD4) [16–20]. *PSEN1* and *PSEN2* are important determinants of γ-secretase activity responsible for proteolytic cleavage of APP and NOTCH receptor proteins. Mendelian mutations are very rare in AD (1:1000). Mutations in exons 16 and 17 of the *APP* gene appear with a frequency of 0.30% and 0.78%, respectively, in AD patients. Likewise, *PSEN1*, *PSEN2*, and microtubule-associated protein Tau (*MAPT*)(17q21.1) mutations are present in less than 2% of cases. Mutations in these genes confer specific phenotypic profiles to patients with dementia: amyloidogeneic pathology associated with *APP*, *PSEN1*, and *PSEN2* mutations and tauopathy associated with *MAPT* mutations represent the two major pathogenic hypotheses for AD [16–21].

Multiple polymorphic risk variants can increase neuronal vulnerability to premature death (see Appendix A). Among these susceptibility genes, the apolipoprotein E (*APOE*) gene (19q13.2)(AD2) is the most prevalent as a risk factor for AD, especially in those subjects harboring the *APOE-4* allele (Figure 27.2), whereas carriers of the *APOE-2* allele might be protected against dementia. *APOE*-related pathogenic mechanisms are also associated with brain aging and with the neuropathological hallmarks of AD [16].

27.4 PATHOGENIC EVENTS

The dual amyloidogenic-tauopathic theory of AD has dominated the pathogenic universe of AD-related neurodegeneration (and divided the research community) for the past 50 years, nourished by the presence of *APP*, *PSEN1*, *PSEN2*, and *MAPT* mutations in a very small number of cases with early-onset AD. Nevertheless, this theory does not explain AD pathogenesis in full, and consequently novel (or complementary) theories have been emerging recently and during the past decades. A summary of the pathogenic events in AD is given in the following sections.

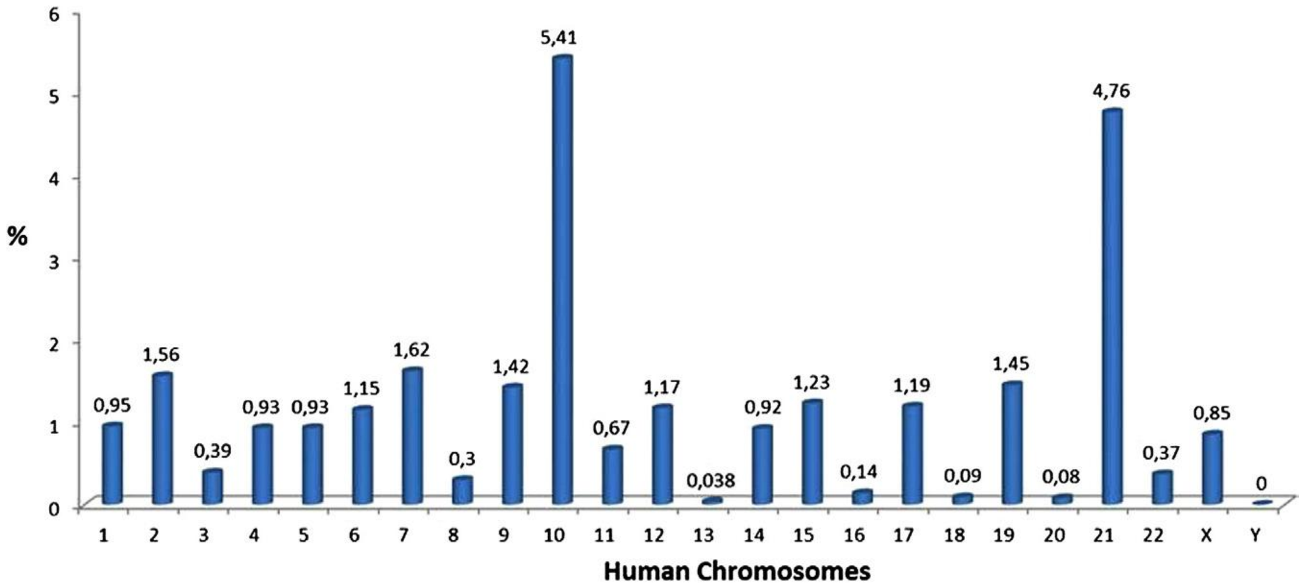

FIGURE 27.1 Distribution of AD-related genes in the human genome.

	Control population	Alzheimer's disease	Vascular dementia
APOE-4/4	1,59	6,06	6,57
APOE-3/4	18,41	30,3	35,85
APOE-3/3	71,11	54,55	48,99
APOE-2/4	1,27	1,3	1,52
APOE-2/3	7,3	7,79	7,07
APOE-2/2	0,32	0	0

FIGURE 27.2 Distribution and frequency of *APOE* genotypes in AD and vascular dementia. *Source: Adapted from Cacabelos* [18].

27.4.1 Genomic Defects

As a complex polygenic/multifactorial disorder, in which hundreds of polymorphic variants of risk might be involved (Appendix A, Figure 27.1), AD fulfils the "golden rule" of complex disorders, according to which the larger the number of genetic defects distributed in the human genome, the earlier the onset of the disease and the poorer its therapeutic response to conventional treatments; conversely, the smaller the number of pathogenic SNPs, the later the onset of the disease and the better its therapeutic response to different pharmacological interventions [12,16,22–28]. Genetic variation associated with different diseases interferes with microRNA-mediated regulation by creating, destroying, or modifying microRNA (miRNA) binding sites. miRNA-target variability is a ubiquitous phenomenon in the adult human brain which may influence gene expression in physiological and pathological conditions. AD-related SNPs interfere with miRNA gene regulation and affect AD susceptibility. Significant interactions include target SNPs present in seven genes related to AD prognosis with the miRNAs miR-214, -23a and -23b, -486-3p, -30e*, -143, -128, -27a and -27b, -324-5p, and -422a. The dysregulated miRNA network contributes to aberrant gene expression in AD [29–31].

27.4.2 Epigenetic Phenomena

Epigenetic factors have emerged as important mediators of development and aging, gene–gene and gene–environmental interactions, and the pathophysiology of complex disorders. Major epigenetic mechanisms (DNA methylation, histone modifications and chromatin remodeling, and noncoding RNA regulation) may contribute to AD pathology [30,31].

27.4.3 Cerebrovascular Dysfunction

Vascular and metabolic dysfunctions are key components in AD pathology throughout the course of disease. Although common denominators between vascular and metabolic dysfunction are oxidative stress and Aβ [32], genetic factors and cardiovascular risk factors may also account for the cerebrovascular damage present in AD [33]. Inherited polymorphisms of the vascular susceptibility gene Ninjurin2 (*NINJ2*) are associated with AD risk [34]. Endothelial dysfunction has been implicated as a crucial event in the development of AD.

Breakdown of the blood–brain barrier (BBB) as a result of disruption of tight junctions and transporters leads to increased leukocyte transmigration and is an early event in the pathology of many CNS disorders. BBB breakdown leads to neuroinflammation and oxidative stress, with mitochondrial dysfunction. The high concentration of mitochondria in cerebrovascular endothelial cells might account for the sensitivity of the BBB to oxidant stressors [35,36].

Chronic brain hypoperfusion may be sufficient to induce premature neuronal death and dementia in vulnerable subjects [16,23–25,37–39]. APOE-related changes in cortical oxygenation and hemoglobin consumption are evident, as revealed by brain optical topography analysis, and reflect that *APOE-4* carriers exhibit deficient brain hemodynamics and a poorer panneocortical oxygenation than do *APOE-3* or *APOE-2* carriers [18]. Hypoperfusion in frontal, parietal, and temporal regions is a common finding in AD. White matter hyperintensities (WMH) correlate with age and with disease severity [40].

Cerebral amyloid angiopathy (CAA) accounts for the majority of primary lobal intracerebral hemorrhages (ICH) among the elderly, and represents the cause of 20% of spontaneous ICHs in patients over 70 years of age. The basis for this disease process is the deposition and formation of eventually destructive amyloid plaques in the walls of brain vessels, predominantly arterial but not excluding venules and capillaries. CAA and CAA-associated microhemorrhages may also participate in the pathogenesis of AD [41]. Aβ deposition in asymptomatic elderly individuals is associated with lobar MH (LMH).

LMH is present in 30.8% of AD, 35.7% of MCI, and 19.1% of controls [42]. Neurovascular dysfunction in AD leads to reduced clearance across the BBB and accumulation of neurotoxic Aβ peptides in the brain. The ABC transport protein P-glycoprotein (P-gp, ABCB1) is involved in the export of Aβ from the brain into the blood. *P-gp*, *LRP1*, and *RAGE* mRNA expression is reduced in mice treated with $A\beta_{1–42}$. In addition to the age-related decrease in P-gp expression, $A\beta_{1–42}$ itself downregulates the expression of P-gp and other Aβ transporters, which could exacerbate the intracerebral accumulation of Aβ and thereby accelerate neurodegeneration in AD and cerebral β-amyloid angiopathy [43].

27.4.4 Phenotypic Expression of Amyloid Deposits and Neurofibrillary Tangles

β-Amyloid deposits in senile and neuritic plaques and hyperphosphorylated tau proteins in neurofibrillary tangles (NFT) are extracellular and intracellular expressions, respectively, of the AD neuropathological phenotype, together with selective neuronal loss in hippocampal and neocortical regions. Aβ plaque in the brain is the primary (postmortem) diagnostic criterion of AD. The main component of senile plaques is Aβ, a 39–43 amino acid peptide, generated by the proteolytic cleavage of amyloid precursor protein (APP) by the action of beta- and gamma-secretases. Aβ is neurotoxic, and this neurotoxicity is related to its aggregation state [16–21].

27.4.5 Neuronal Apoptosis

Neuronal loss is a pathognomonic finding in AD and the final common path of multiple pathogenic mechanisms leading to neurodegeneration in dementia. Atrophy of the medial temporal lobe, especially the hippocampus and the parahippocampal gyrus, is considered to be AD's most predictive structural brain biomarker. The medial and posterior parts of the parietal lobe seem to be preferentially affected, compared to the other parietal lobe parts [18].

27.4.6 Neurotransmitter Deficits

An imbalance of different neurotransmitters (glutamate, acetylcholine, noradrenaline, dopamine, serotonin, and some neuropeptides) has been proposed as the neurobiological basis of behavioral symptoms in AD. Altered reuptake of neurotransmitters by vesicular glutamate transporters (VGLUTs), excitatory amino acid transporters (EAATs), the vesicular acetylcholine transporter (VAChT), the serotonin reuptake transporter (SERT), or the dopamine reuptake transporter (DAT) are involved in the neurotransmission imbalance in AD. Protein and mRNA levels of VGLUTs, EAAT1-3, VAChT, and SERT are reduced in the disease [44].

27.4.7 Oxidative Stress

Oxidative damage is a classic pathogenic mechanism of neurodegeneration [36,45]. It is greater in brain tissue from patients with AD than age-matched controls. Tayler et al. [46] studied the timing of this damage in relation to other pathogenic AD processes. Antioxidant capacity is elevated in AD and directly related to disease severity as indicated by the Braak tangle stage and the amount of insoluble Aβ. Accumulation of Aβ has been shown in brain mitochondria of AD patients and in AD transgenic mouse models. The presence of Aβ in mitochondria leads to free radical generation and neuronal stress.

A novel mitochondrial Aβ-degrading enzyme, presequence protease (Pre), has been identified in the mitochondrial matrix. hPreP activity is decreased in AD human brains and in the mitochondrial matrix of AD transgenic mouse brains (TgmAβPP and TgmAβPP/ABAD). Mitochondrial fractions isolated from AD brains and TgmAβPP mice have higher levels of 4-hydroxynonenal, an oxidative product. Cytochrome c oxidase activity is significantly reduced in the AD mitochondria. Decreased PreP proteolytic activity, possibly due to enhanced ROS production, may contribute to Aβ accumulation in mitochondria, leading to mitochondrial toxicity and neuronal death in AD [47].

27.4.8 Cholesterol and Lipid Metabolism Dysfunction

Cholesterol seems to be intimately linked with the generation of amyloid plaques, which are central to AD pathogenesis. APOE variants are determinants in cholesterol metabolism and diverse forms of dyslipoproteinemia [12,48]. Cholesterol protects the Aβ-induced neuronal membrane disruption and inhibits beta-sheet formation of Aβ on the lipid bilayer [49]. Jones et al. [50] found a significant over-representation of association signals in pathways related to cholesterol metabolism and the immune response in both of the two largest genome-wide association studies for LOAD.

27.4.9 Neuroinflammation and Immunopathology

Several genes associated with immune regulation and inflammation show polymorphic variants of risk in AD, and abnormal levels of diverse cytokins have been reported in the brain, CSF, and plasma of AD patients [16,23]. The activation of inflammatory cascades has been consistently demonstrated in AD pathophysiology, in which reactive microglia are associated with Aβ deposits and clearance. Resident microglia fail to trigger an effective phagocytic response to clear Aβ deposits, although they mainly exist in an "activated" state. Oligomeric Aβ (oAβ) can induce more potent neurotoxicity when compared with fibrillar Aβ (fAβ). $A\beta_{(1-42)}$ fibrils, not $A\beta_{(1-42)}$ oligomers, increase microglial phagocytosis [51]. Among several putative neuroinflammatory mechanisms, the TNF-α signaling system has a central role in this process. In AD, TNF-α levels are altered in serum and CSF. The abnormal production of inflammatory factors may accompany the progression from mild cognitive impairment (MCI) to dementia. Abnormal activation of the TNF-α signaling system, represented by increased expression of sTNFR1, is associated with a higher risk of progression from MCI to AD [52].

27.4.10 Neurotoxic Factors

Old and new theories suggest that different toxic agents, from metals (e.g., aluminium, copper, zinc, iron) to biotoxins and pesticides, might contribute to neurodegeneration. Dysfunctional homeostasis of transition metals is believed to play a role in AD pathogenesis [18].

27.4.11 Other Players

Many novel pathogenic mechanisms potentially involved in AD neurodegeneration have been proposed in recent times. Moreover, there has been a revival of some old hypotheses. Examples of pathogenic players in AD, other than those just discussed, include the Ca^{2+} hypothesis, insulin resistance, NGF imbalance, glycogen synthase kinase-3 (GSK-3), advanced glycation end products (AGEs) and their receptors (RAGE), the efflux transporter P-glycoprotein (P-gp), c-Abl tyrosine kinase, post-transcriptional protein alterations that compromise the proteasome system and the chaperone machinery (HSPB8–BAG3), autophagy as a novel Aβ-generating pathway, hypocretin (orexin), cathepsin B, Nogo receptor proteins, adipocytokines and $CD34^{+}$ progenitor cells, CD147, impairment of synaptic plasticity (PSD-95), anomalies in neuronal cell division and apoptosis, stem cell factor (SCF), telomere shortening, deficiency in repair of nuclear and mitochondrial DNA damage, and microDNAs [18].

27.5 BIOMARKERS AND COMORBIDITY

AD's phenotypic features represent the biomarkers to be used as diagnostic predictors and the expression of pathogenic events to be modified with an effective therapeutic intervention. Important differences have been found in the AD population (as compared with healthy subjects) in different biological parameters, including blood pressure, glucose, cholesterol and triglyceride levels, transaminase activity, hematological parameters, metabolic factors, thyroid function, brain hemodynamic parameters, and brain mapping activity [7,23–25,53–59].

These clinical differences are clear signs of comorbidity rather than typical features of AD. Blood pressure values, glucose levels, and cholesterol levels are higher in AD than in healthy elderly subjects. Approximately 20% of AD patients are hypertensive, 25% are diabetics, 50% are hypercholesterolemic, and 23% are hypertriglyceridemic. More than 25% of patients exhibit high GGT activity, 5–10% show anemic conditions, 30–50% show an abnormal cerebrovascular function characterized by poor brain perfusion, and more than 60% have an abnormal electroencephalographic pattern, especially in frontal, temporal, and parietal regions, as revealed by quantitative EEG (qEEG) or computerized mapping [7,12,23,54]. Significant differences are currently seen between females and males, indicating the effect of gender on the phenotypic expression of the disease. In fact, the prevalence of dementia is 10–15% higher in females than in males from 65–85 years of age. All of these parameters are highly relevant when treating AD patients, because some of them reflect a concomitant pathology that also needs therapeutic consideration.

AD biomarkers can be differentiated into several categories: (1) neuropathological markers; (2) structural and functional neuroimaging markers; (3) neurophysiological markers (EEG, qEEG, brain mapping); (4) biochemical markers in body fluids (e.g., blood, urine, saliva, CSF); and (5) genomic markers (structural and functional genomics, proteomics, metabolomics).

27.5.1 Neuropathology

Plaques and tangles in the hippocampus and cortex are still considered the seminal findings in AD neuropathology and are the conventional means of establishing the boundary between amyloidopathies and tauopathies; however, both phenotypic markers are also present in normal brains, in more than 60% of cases with traumatic brain injury, and in many other brain disorders [60].

27.5.2 Structural and Functional Neuroimaging

Structural and functional neuroimaging techniques (MRI, fMRI, PET, SPECT) are essential tools in the diagnosis of dementia, although the specificity of visual observations in degenerative forms of dementia is of doubtful value. Nevertheless, these procedures are irreplaceable for a differential diagnosis. There is a characteristic regional impairment in AD that involves mainly the temporo–parietal association cortices, the mesial temporal structures, and, to a more variable degree, the frontal association cortex. This pattern of functional impairment can provide a biomarker for diagnosis of AD and other neurodegenerative dementias at the clinical stage of mild cognitive impairment, and for monitoring its progression. Healthy young *APOE ε4* carriers have smaller hippocampal volumes than *APOE ε2* carriers.

The difference in hippocampal morphology is cognitively/clinically silent in young adulthood, but can render *APOE ε4* carriers more prone to the later development of AD, possibly because of lower reserve cognitive capacity [61]. LOAD patients exhibit a selective parahippocampal white matter (WM) loss, while EOAD patients experience a more widespread pattern of posterior WM atrophy. The distinct regional distribution of WM atrophy reflects the topography of gray matter (GM) loss. *ApoE ε4* status is associated with a greater parahippocampal WM loss in AD. The greater WM atrophy in EOAD than in LOAD fits with the evidence that EOAD is a more aggressive form of the disease [62]. FDG-PET is quantitatively more accurate than perfusion SPECT.

Regional metabolic and blood flow changes are closely related to clinical symptoms, and most areas involved in these changes also develop significant cortical atrophy. FDG-PET is complementary to amyloid PET, which targets a molecular marker that does not have a close relation to current symptoms. FDG-PET is expected to play an increasing role in diagnosing patients at an early stage of AD and in clinical trials of drugs aimed at preventing or delaying the onset of dementia [63]. Functional neuroimaging biomarkers are becoming popular, with the introduction of novel tracers for brain amyloid deposits. Amyloid deposition causes severe damage to neurons many years before onset of dementia via a cascade of several downstream effects.

Positron emission tomography (PET) tracers for amyloid plaque are desirable for early diagnosis of AD, particularly to enable preventative treatment once effective therapeutics is available. The amyloid imaging tracers flutemetamol, florbetapir, and florbetaben labeled with ^{18}F have been developed for PET. These tracers are currently undergoing formal clinical trials to establish whether they can be used to accurately image fibrillary amyloid, and to distinguish patients with AD from normal controls and those with other diseases that cause dementia [63].

27.5.3 Neurophysiology

There is a renewed interest in the use of computerized brain mapping as a diagnostic aid and as a monitoring tool in AD [64]. Electroencephalography (EEG) studies in AD show an attenuation of average power within the alpha band (7.5–13 Hz) and an increase in power in the theta band (4–7 Hz) [65]. *APOE* genotypes influence brain bioelectrical activity in AD. In general, *APOE-4* carriers tend to exhibit a slower EEG pattern from early stages [16,18,66].

27.5.4 Biochemistry of Body Fluids

Other biomarkers of potential interest include cerebrospinal fluid (CSF) and peripheral levels of $A\beta_{42}$, protein tau, histamine, interleukins, and some other novel candidate markers such as chitinase 3-like 1 (CHI3L1) protein [7,16,25,67–69]. The concentration of the 42-amino-acid form of Aβ ($A\beta_{1-42}$) is reduced in the CSF of AD patients, which is believed to reflect the AD pathology, with plaques in the brain acting as sinks. Novel C-truncated forms of Aβ ($A\beta_{1-14}$, $A\beta_{1-15}$, and $A\beta_{1-16}$) were identified in human CSF. The presence of these small peptides is consistent with a catabolic amyloid precursor protein cleavage pathway by β- followed by α-secretase. $A\beta_{1-14}$, $A\beta_{1-15}$, and $A\beta_{1-16}$ increase dose-dependently in response to γ-secretase inhibitor treatment, while $A\beta_{1-42}$ levels are unchanged [70].

Kester et al. [71] investigated change over time in CSF levels of amyloid-beta 40 and 42 ($A\beta_{40}$ and $A\beta_{42}$), total tau (tau), tau phosphorylated at threonine 181 (ptau-181), isoprostane, neurofilaments heavy (NfH) and neurofilaments light (NfL). $A\beta_{42}$, tau, and tau phosphorylated at threonine 181 differentiated between diagnosis groups, whereas isoprostane, NfH, and NfL did not. In contrast, effects of follow-up time were found only for nonspecific CSF biomarkers: levels of NfL decreased, and levels of isoprostane, $A\beta_{40}$, and tau increased over time. An increase in isoprostane was associated with progression of mild cognitive impairment in AD and with cognitive decline. Contrary to AD-specific markers, nonspecific CSF biomarkers show change over time, which potentially can be used to monitor disease progression in AD.

27.5.5 Genomics and Proteomics

Structural markers are represented by SNPs in genes associated with AD, polygenic cluster analysis, and genome-wide studies (GWSs). Functional markers attempt to correlate genetic defects with specific phenotypes (genotype–phenotype correlations). In proteomic studies, several candidate CSF protein biomarkers have been assessed in neuropathologically confirmed AD, nondemented (ND) elderly controls, and non-AD dementias (NADD). Markers selected included apolipoprotein A-1 (ApoA1), hemopexin (HPX), transthyretin (TTR), pigment epithelium-derived factor (PEDF), $A\beta_{1-40}$, $A\beta_{1-42}$, total tau, phosphorylated tau, α-1 acid glycoprotein (A1GP), haptoglobin, zinc α-2 glycoprotein (Z2GP), and apolipoprotein E (ApoE). Concentrations of $A\beta_{1-42}$, ApoA1, A1GP, ApoE, HPX, and Z2GP differed significantly among AD, ND, and NADD subjects. The CSF concentrations of these three markers distinguished AD from ND subjects with 84% sensitivity and 72% specificity, with 78% of subjects correctly classified.

By comparison, $A\beta_{1-42}$ alone gave 79% sensitivity and 61% specificity, with 68% of subjects correctly classified. For the diagnostic discrimination of AD from NADD, only the concentration of $A\beta_{1-42}$ was significantly related to diagnosis, with a sensitivity of 58% and a specificity of 86% [72]. Carrying the *APOE-ε4* allele was associated with a significant decrease in CSF $A\beta_{1-42}$ concentrations in middle-aged and older subjects. In AD, $A\beta_{1-42}$ levels are significantly lower in *APOEε4* carriers compared to noncarriers. These findings demonstrate significant age effects on CSF $A\beta_{1-42}$ and pTau181 across the lifespan, and also suggest that a decrease in $A\beta_{1-42}$, but an increase in pTau181 CSF levels, is accelerated by the *APOEε4* genotype in middle-aged and older adults with normal cognition [73].

Han et al. [74] carried out a GWAS to better define the genetic backgrounds of normal cognition, mild cognitive impairment (MCI), and AD in terms of changes in CSF levels of $A\beta_{1-42}$, T-tau, and P-tau181P. CSF $A\beta_{1-42}$ levels decreased with *APOE* gene dose for each subject group. T-tau levels tended to be higher among AD cases than among normal subjects. *CYP19A1* "aromatase" (rs2899472), *NCAM2*, and multiple SNPs located on chromosome 10 near the *ARL5B* gene demonstrated the strongest associations with $A\beta_{1-42}$ in normal subjects.

Two genes found to be near the top SNPs, *CYP19A1* (rs2899472) and *NCAM2* (rs1022442), have been reported as genetic factors related to the progression of AD. In AD subjects, *APOE ε2/ε3* and *ε2/ε4* genotypes were associated with elevated T-tau levels, and the *ε4/ε4* genotype was associated with elevated T-tau and P-tau181P levels. Blood-based markers reflecting core pathological features of AD in presymptomatic individuals are likely to accelerate the development of disease-modifying treatments.

Thambisetty et al. [75] performed a proteomic analysis to discover plasma proteins associated with brain Aβ burden in nondemented older individuals. A panel of 18 2DGE plasma protein spots effectively discriminated between individuals with high and low brain Aβ. Mass spectrometry identified these proteins, many of which have established roles in Aβ clearance, including a strong signal from ApoE. A strong association was observed between plasma ApoE concentration, and Aβ burden in the medial temporal lobe. Targeted voxel-based analysis localized this association to the hippocampus and entorhinal cortex. *APOE ε4* carriers also showed greater Aβ levels in several brain regions relative to *ε4* noncarriers. Both peripheral concentration of the ApoE protein and the *APOE* genotype may be related to early neuropathological changes in brain regions vulnerable to AD pathology even in the nondemented elderly.

27.6 THERAPEUTIC STRATEGIES

Modern therapeutic strategies in AD are aimed at interfering with the main pathogenic mechanisms potentially involved in AD [7,12,16,18,23,24,28,53–59] (Box 27.1). Starting in the early 1990s, the neuropharmacology of AD was dominated by acetylcholinesterase inhibitors, represented by tacrine, donepezil, rivastigmine, and galantamine [76–78]. Memantine, a partial NMDA antagonist, was introduced in the 2000s for the treatment of severe dementia [79]; and the first clinical trials with immunotherapy, to reduce amyloid burden in senile plaques, were withdrawn due to severe ADRs [80,81]. After the initial promise of β- and γ-secretase inhibitors [82,83] and novel vaccines [84,85] devoid of severe side effects, during the past few years no relevant drug candidates have dazzled the scientific community with their capacity to halt disease progression; however, a large number of novel therapeutic strategies for the pharmacological treatment of AD have been postulated, with some apparent effects in preclinical studies (see Box 27.1).

27.6.1 Immunotherapy

There are two main modalities of immunotherapy for AD: (1) passive immunotherapy, with the administration of monoclonal Aβ-specific antibodies [86]; and (2) active immunization with the $A\beta_{42}$ antigen [87,88] or Aβ-conjugated synthetic fragments bound to a carrier protein, thus avoiding potential problems associated with mounting a T-cell response directly against Aβ [89]. A new approach—delivering $A\beta_{42}$ in a novel immunogen-adjuvant manner consisting of sphingosine-1-phosphate (S1P)-containing liposomes, administered to APP/PS1 transgenic mice before and after the detection of AD-like pathology in the brain—has recently been developed [85].

The results from this novel vaccine (EB101) indicate that active immunization significantly prevents and reverses the progression of AD-like pathology and also clears prototypical neuropathological hallmarks in transgenic mice. This new approach strongly induces T-cell, B-cell, and microglial immune response activation, avoiding the Th1 inflammatory reaction [90].

The rationale for amyloid immunotherapy in AD [91] is based on the following assumptions:

- β-amyloid plaques and their aggregated, proto-fibrillar, and oligomeric precursors contain immunologic neo-epitopes that are absent from the full-length amyloid precursor protein (APP), as well as from its soluble proteolytic derivatives restricted to brain tissue; consequently, β-amyloid-based immunotherapies designed to selectively target pathologic neo-epitopes present on Aβ oligomers, protofibrils, or fibrils should not cause autoimmune disease in unaffected tissues throughout the organism
- β-amyloid buildup precedes neurodegeneration and functional loss, and either the prevention of its formation or its removal can be expected to result in the slowing or the prevention of neurodegeneration
- β-amyloid can cause the formation of neurofibrillary tangles in vivo and in vitro. The removal of β-amyloid, or the prevention of its buildup, has the potential not only to correct β-amyloid-related toxicity, but also to prevent the formation of neurofibrillary tangles
- Conformational changes of endogenously occurring proteins and the formation of insoluble aggregates are commonly associated with neurodegeneration and brain disease, so the removal or prevention of these pathologic protein aggregates is also a therapeutic goal in the principle of immunotherapy
- Immunotherapy works in experimental animals and in initial clinical trials: both active immunization and passive antibody transfer consistently reduce brain β-amyloid load, improve β-amyloid-related memory impairments, and protect neurons against degeneration in many independent experiments using different mouse models and primates [90]

Since Aβ immunotherapy has a limited clearance effect of tau aggregates in dystrophic neurites, the development of an alternative therapy that directly targets pathological tau has become crucial. Increased levels of tau oligomers have been observed in the early stage of AD, prior to the detection of neurofibrillary tangles (NFT) formed by aggregation and accumulation of the microtubule-associated protein tau [92]. Several approaches have been taken to treat AD by targeting tau, such as the following:

1. The inhibition of tau hyperphosphorylation, by a kinase inhibitor of soluble aggregated tau formation, which also prevents related motor deficits [93].
2. Activation of the proteolytic pathway, by the degrading action of calpain [94] and puromycin-sensitive aminopeptidase [95].
3. The stabilization of microtubules, treating tauopathies by functionally binding and stabilizing microtubules with mt-binding protein tau [96] and paclitaxel, a drug proven effective in restoring affected axonal transport and motor impairments [97].
4. Tau clearance by immunotherapy in this case, the tau active vaccination uses phosphorylated antigens of tau fragments associated with neurofibrillary tangles [98] that results in an efficient reduction of both soluble and insoluble tau active fragments, reducing phosphorylated NFTs in AD-like mouse brains.

Preclinical studies have shown clear evidence that Aβ immunization therapy provides protection and reverses the pathological effects of AD in transgenic mouse models [99]. This strategy seems to improve cognition performance [100]

BOX 27.1 Experimental Strategies for the Pharmacological Treatment of Alzheimer's Disease

- New cholinesterase inhibitors
- Cholinergic receptor agonists
- Monoamine regulators
- Diverse natural compounds derived from vegetal sources:
  - Alkaloids from the calabar bean (*Physostigma venenosum*)
  - Huperzine A from *Huperzia serrata*
  - Galantamine from the snowdrop *Galanthus woronowii*
  - Cannabinoids (cannabidiol) from *Cannabis sativa*
  - Saffron (*Crocus sativus*)
  - Ginseng (*Panax species*)
  - Sage (*Salvia species*)
  - Lemon balm (*Melissa officinalis*)
  - *Polygala tenuifolia*
  - Nicotine from *Nicotiana species*
  - Grape seed polyphenolic extracts
  - Fuzhisan, a Chinese herbal medicine
  - Resveratrol
  - Xanthoceraside
  - Garlic (*Allium sativum*)
  - Linarin from *Mentha arvensis* and *Buddleja davidii*
  - Carotenoids (e.g., retinoic acid, all-trans retinoic acid, lycopene and β-carotene)
  - Curcumin from the rhizome of *Curcuma longa*
  - Decursinol from the roots of *Angelica gigas*
  - Bacopa monniera LINN *(Syn. Brahmi)*
  - Olive oil
  - Phytoestrogens
  - Walnut extract
  - *Erigeron annuus* leaf extracts
  - Epigallocatechin-3-gallate
  - Luteolin
  - The brown algae (*Ecklonia cava*)
  - Gami-Chunghyuldan (standardized multiherbal medicinal formula)
  - *Punica granatum* extracts
- Plants of different origin:
  - Yizhi Jiannao
  - Drumstick tree (*Moringa oleifera*)
  - Ginkgo/Maidenhair tree (*Ginkgo biloba*)
  - Sicklepod (*Cassia obtisufolia*)
  - Sal Leaved Desmodium (*Desmodium gangeticum*)
  - Lemon Balm (*Melissa officinalis*)
  - Garden sage, common sage (*Salvia officinalis*)
- Immunotherapy and treatment options for tauopathies:
  - Tau kinase inhibitors
  - 2-Aminothiazoles
  - Phosphoprotein phosphatase 2A (PP2A) inhibitors
  - c-Jun N-terminal kinase (JNKs) inhibitors
  - p38 MAP kinase inhibitors (CNI-1493)
  - Harmine (β-carboline alkaloid)
- Immunotherapy and Aβ breakers for AD-related amyloidopathy:
  - Active and passive immunization
- Secretase inhibitors (β- and γ-)
- Neostatins
- Neurosteroids
- Phosphodiesterase inhibitors
- Protein phosphatase methylesterase-1 inhibitors
- Histone deacetylase inhibitors
- mTOR inhibitors
- Peroxisome proliferator-activated receptor agonists
- P-glycoprotein regulators
- Nuclear receptor agonists
- Glycogen synthase kinase-3β (GSK-3β) regulators
- Histamine H3 receptor inverse agonists
- Estrogens
- Kynurenine 3-monooxygenase inhibitors
- Chaperones (small heat shock proteins (sHSPs); Hsp90 inhibitors and HSP inducers)
- microRNAs (miRNAs) and gene silencing (RNA interference)(RNAi)
- Miscellaneous strategies:
  - Sodium fullerenolate
  - Glucagon-like peptide -1 (GLP-1)
  - Chemokines
  - Macrophage inflammatory protein-2 (MIP-2)
  - Stromal cell-derived factor-1α (SDF-1α)
  - Cyclooxygenase-1 and cyclooxygenase-2 inhibitors
  - Bone morphogenetic protein 9 (BMP-9)
  - Granulocyte colony stimulating factor (G-CSF)/AMD3100 (CXCR4 antagonist)
  - Vitamins (A, B, C, D)
  - ω-3 Polyunsaturated fatty acids (n-3 PUFAs)
  - Docosahexaenoic acid (DHA, C22:6 n-3)
  - Sphingosylphosphorylcholine
  - Citidine-5-diphosphocholine (CDP-choline)
  - Cathepsin B inhibitors
  - Pituitary adenylate cyclase–activating polypeptide
  - NAP (Davunetide)
  - Transcription factor specificity protein 1 (Sp1) inhibitors (tolfenamic acid)
  - TNF inhibitors:
    - 2-(2,6-Dioxopiperidin-3-yl)phthalimidine EM-12 dithiocarbamates
    - N-substituted 3-(Phthalimidinp-2-yl)-2,6-dioxopiperidines
    - 3-substituted 2,6-Dioxopiperidines
  - Pyrrolo[3,2-e][1,2,4]triazolo[1,5-a]pyrimidine (SEN1176)
  - Latrepirdine
  - Leucettines
  - Dihydropyridines (inhibitors of L-type calcium channels)
  - Brain-penetrating angiotensin-converting enzyme (ACE) inhibitors
  - NADPH oxidase inhibitors (Apocynin)
  - Heterocyclic indazole derivatives (inhibitors of serum- and glucocorticoid-inducible-kinase 1 [*SGK1*])
  - IgG-single-chain Fv fusion proteins

after $A\beta_{42}$ immunization, in addition to causing an effective reduction in Aβ pathology. A recent immunization study has proven that a fragment of the Aβ peptide bound to polylysines activates the immune response that diminishes AD-like pathology in APP transgenic mice. This result reinforces the notion that the immune-conjugate approach is an effective means of Aβ immunotherapy, and also that the entire Aβ peptide is not necessary for its efficacy. It is in accordance with the hypothesis that specific antibodies directed against the amino-terminal and/or central region of the amyloid peptide provide beneficial protection against amyloid pathology. Passive immunization studies have also been conducted with promising experimental results, showing that a humoral response alone, without Aβ cellular response, is sufficient to reduce the β-amyloid burden and reverse memory deficits [101].

Among the drugs and vaccines currently under development to treat the pathological effects of AD, the most promising are bapineuzumab, solanezumab, CAD106, and EB101. Solanezumab is a monoclonal antibody raised against $A\beta_{13-28}$ that recognizes an epitope in the core of the amyloid peptide, binding selectively to soluble Aβ and with low affinity for the fibrillar Aβ form [102]. Thus, it presents fewer adverse events than does bapineuzumab, which binds to Aβ amyloid plaques more strongly than soluble Aβ [103]. There are a few other monoclonal antibodies against Aβ that have properties different from those of bapineuzumab, such as PF-04360365, which specifically targets the free carboxy-terminus of $A\beta_{1-40}$, MABT5102A, which binds with equally high affinity to Aβ monomers, oligomers, and fibrils, and GSK933776A, which targets the N-terminus of Aβ.

Specific anti-Aβ antibodies are present in pooled preparations of intravenous immunoglobulin (IVIg or IGIV), which has already been approved by the FDA for the treatment of a variety of neurological conditions. Current results from these studies have shown that IVIg treatment may also be an efficacious alternative approach in the treatment of AD neuropathologies [90,104].

Avoiding both the strong Th1 effects of the QS-21 adjuvant and the T-cell epitopes at the C-terminus of Aβ, CAD106 consists of a short N-terminal fragment of Aβ attached to a virus-like particle, with no additional adjuvant [105]. This therapeutic agent is currently in phase II trials. Affiris is testing two short 6-amino-peptides (AD01, AD02), administered with aluminum hydroxide as adjuvant, that mimic the free N-terminus of Aβ and therefore cause cross-reactivity with the native peptide in phase I trials [106]. In terms of prevention and therapeutic treatment, the EB101 vaccine showed for the first time the effectiveness of combining a liposomal immunogen-adjuvant with an Aβ antigen to induce an effective immunological response combined with an anti-inflammatory effect in preclinical studies using APP/PS1 transgenic mice [85,90].

The EB101 vaccine immunization process has shown a marked positive effect as a preventive and therapeutic treatment, reducing amyloidosis-induced inflammation as an effective Th2 immunomodulator. Moreover, this vaccine proved to stimulate innate immunity and enable effective phagocytosis to clear amyloid and neurofibrillary tangles, which are among the major hallmarks of AD-like neuropathology observed. A few other vaccines are currently under development, and recent studies have opened up new perspectives in the immunization approach to AD pathology; in particular, gene-gun-mediated genetic immunization with the $A\beta_{42}$ gene [107] shows that self-tolerance can be broken in order to produce a humoral response to the $A\beta_{42}$ peptide with minimal cellular response.

27.7 PHARMACOGENOMICS

AD patients may take 6–12 different drugs per day for the treatment of dementia-related symptoms, including memory decline (conventional antidementia drugs, neuroprotectants), behavioral changes (antidepressants, neuroleptics, sedatives, hypnotics), and functional decline. Such drugs may also be taken for the treatment of concomitant pathologies (epilepsy, cardiovascular and cerebrovascular disorders, parkinsonism, hypertension, dyslipidemia, anemia, arthrosis, etc). The co-administration of several drugs may cause side effects and ADRs in more than 60% of AD patients, who in 2–10% of cases require hospitalization. In more than 20% of patients, behavioral deterioration and psychomotor function can be severely altered by polypharmacy. The principal causes of these iatrogenic effects are (1) the inappropriate combination of drugs, and (2) the genomic background of the patient, which is responsible for his/her pharmacogenomic outcome.

Pharmacogenomics account for 30–90% of the variability in pharmacokinetics and pharmacodynamics. The genes involved in the pharmacogenomic response to drugs in AD fall into five major categories:

- Genes associated with AD pathogenesis and neurodegeneration (*APP*, *PSEN1*, *PSEN2*, *MAPT*, *PRNP*, *APOE*, and others)
- Genes associated with the mechanism of action of drugs (enzymes, receptors, transmitters, messengers)
- Genes associated with drug metabolism (phase I (*CYP*s) and phase II reactions (*UGT*s, *NAT*s))
- Genes associated with drug transporters (*ABC*s, *SLC*s)
- Pleiotropic genes involved in multifaceted cascades and metabolic reactions (*APOs*, *ILs*, *MTHFR*, *ACE*, *AGT*, *NOS*, etc) [18] (Figure 27.1)

27.7.1 Pathogenic Genes

In more than 100 clinical trials for dementia, *APOE* has been used as the only gene of reference for the pharmacogenomics of AD [7,12,15,16,22–28,53–59]. Several studies indicate that the presence of the *APOE-4* allele differentially affects the quality and extent of drug responsiveness in AD patients treated with cholinergic enhancers (tacrine, donepezil, galantamine, rivastigmine), neuroprotective compounds (nootropics), endogenous nucleotides (CDP-choline), immunotrophins (anapsos), neurotrophic factors (cerebrolysin), rosiglitazone, or combination therapies [108–110]; however, controversial results are frequently found that are due to methodological problems, study design, and patient recruitment in clinical trials.

The major conclusion in most studies is that *APOE-4* carriers are the worst responders to conventional treatments [7,12,15,16,22–28,53–59]. When *APOE* and *CYP2D6* genotypes are integrated in bigenic clusters and the *APOE+CYP2D6*-related therapeutic response to a combination therapy is analyzed in AD patients, it becomes clear that the presence of the *APOE-4/4* genotype is able to convert pure *CYP2D6*1/*1* extensive metabolizers (EMs) into full poor responders to conventional treatments, indicating the existence of a powerful influence of the *APOE-4* homozygous genotype on the drug-metabolizing capacity of pure *CYP2D6* EMs. In addition, a clear accumulation of *APOE-4/4* genotypes is observed among *CYP2D6* poor (PMs) and ultrarapid metabolizers (UMs) [12].

27.7.2 Genes Involved in the Mechanism of Action of CNS Drugs

Most genes associated with the mechanism of action of CNS drugs encode receptors, enzymes, and neurotransmitters on which psychotropic drugs act as ligands (agonists, antagonists), enzyme modulators (substrates, inhibitors, inducers), or neurotransmitter regulators (releasers, reuptake inhibitors) [111]. In the case of conventional antidementia drugs, tacrine, donepezil, rivastigmine and galantamine are cholinesterase inhibitors, and memantine is a partial NMDA antagonist (Table 27.1).

27.7.3 Genes Involved in Drug Metabolism

Drug metabolism includes phase I reactions (i.e., oxidation, reduction, hydrolysis) and phase II conjugation reactions (i.e., acetylation, glucuronidation, sulphation, methylation) (Table 27.2). The principal enzymes with polymorphic variants involved in phase I reactions are the following: cytochrome P450 monooxygenases (CYP3A4/5/7, CYP2E1, CYP2D6, CYP2C19, CYP2C9, CYP2C8, CYP2B6, CYP2A6, CYP1B1, CYP1A1/2), epoxide hydrolase, esterases, NQO1 (NADPH-quinone oxidoreductase), DPD (dihydropyrimidine dehydrogenase), ADH (alcohol dehydrogenase), and ALDH (aldehyde dehydrogenase). The major enzymes involved in phase II reactions include UGTs (uridine 5′-triphosphate glucuronosyl transferases), TPMT (thiopurine methyltransferase), COMT (catechol-O-methyltransferase), HMT (histamine methyl-transferase), STs (sulfotransferases), GST-A (glutathione S-transferase A), GST-P, GST-T, GST-M, NAT1 (N-acetyl transferase 1), NAT2, and others (Table 27.2).

Among these enzymes, CYP2D6, CYP2C9, CYP2C19, and CYP3A4/5 are the most relevant in the pharmacogenetics of CNS drugs [15,111] (Table 27.1). Approximately 18% of neuroleptics are major substrates of CYP1A2 enzymes, 40% of CYP2D6, and 23% of CYP3A4; 24% of antidepressants are major substrates of CYP1A2 enzymes, 5% of CYP2B6, 38% of CYP2C19, 85% of CYP2D6, and 38% of CYP3A4; 7% of benzodiazepines are major substrates of CYP2C19 enzymes, 20% of CYP2D6, and 95% of CYP3A4 [15,111]. Most CYP enzymes exhibit ontogenic-, age-, sex-, circadian-, and ethnic-related differences [112].

In dementia, as in any other CNS disorder, CYP genomics is a very important issue, since in practice more than 90% of patients with dementia are daily consumers of psychotropics. Furthermore, some acetylcholinesterase inhibitors (the most prescribed antidementia drugs worldwide) are metabolized via CYP enzymes (Table 27.1). Most CYP enzymes display highly significant ethnic differences, indicating that the enzymatic capacity of these proteins varies depending upon the polymorphic variants present in their coding CYP genes.

The practical consequence of this genetic variation is that the same drug can be differentially metabolized according to the genetic profile of each subject, and that, if an individual's pharmacogenomic profile is known, his/her pharmacodynamic response is potentially predictable. This is the cornerstone of pharmacogenetics. In this regard, the *CYP2D6*, *CYP2C19*, *CYP2C9*, and *CYP3A4/5* genes and their respective protein products deserve special consideration.

27.7.3.1 CYP2D6

CYP2D6 is a 4.38 kb gene with 9 exons mapped on 22q13.2. Four RNA transcripts of 1190–1684 bp are expressed in the brain, liver, spleen, and reproductive system, where 4 major proteins of 48–55 kDa (439–494 aa) are identified. It is a transport enzyme of the cytochrome P450 subfamily IID or multigenic cytochrome P450 superfamily of mixed-function monooxygenases. The cytochrome P450 proteins are monooxygenases which catalyze many reactions involved in drug metabolism and synthesis of cholesterol, steroids, and other lipids. CYP2D6 localizes to the endoplasmic reticulum and is known to metabolize as many as 25% of commonly prescribed drugs, and more than 60% of current psychotropics. Its substrates include debrisoquine, an adrenergic-blocking drug; sparteine and propafenone, both antiarrhythmic drugs; and amitryptiline, an antidepressant. CYP2D6 is highly polymorphic in the population.

TABLE 27.1 Pharmacogenomic Profile of Antidementia Drugs

Donepezil	
Category	**Antidementia Agent/Cholinesterase Inhibitor**
Mechanism	Centrally active, reversible acetylcholinesterase inhibitor; increases acetylcholine available for synaptic transmission in CNS
Genes	
Pathogenic	APOE, CHAT
Mechanistic	CHAT, ACHE, BCHE
Metabolism: substrate	CYP2D6 (major), CYP3A4 (major), UGTs, ACHE
Metabolism: inhibitor	ACHE, BCHE
Transporter	ABCB1
Galantamine	
Category	**Antidementia Agent/Cholinesterase Inhibitor**
Mechanism	Reversible and competitive acetylcholinesterase inhibition leading to increased concentration of acetylcholine at cholinergic synapses; modulates nicotinic acetylcholine receptor; may increase glutamate and serotonin levels
Genes	
Mechanistic	APOE, APP
Pathogenic	ACHE, BCHE, CHRNA4, CHRNA7, CHRNB2
Metabolism: substrate	CYP2D6 (major), CYP3A4 (major), UGT1A1
Metabolism: inhibitor	ACHE, BCHE
Memantine	
Category	**Antidementia Drug; N-methyl-d-aspartate Receptor Antagonist**
Mechanism	Binds preferentially to NMDA receptor-operated cation channels; may act by blocking glutamate actions, mediated in part by NMDA receptors. Antagonists: GRIN2A, GRIN2B, GRIN3A, HTR3A, CHRFAM7A
Genes	
Pathogenic	APOE, PSEN1, MAPT
Mechanistic	GRIN2A, GRIN2B, GRIN3A, HTR3A, CHRFAM7A
Metabolism: inhibitor	CYP1A2 (weak), CYP2A6 (weak), CYP2B6 (strong), CYP2C9 (weak), CYP2C19 (weak), CYP2D6 (strong), CYP2E1 (weak), CYP3A4 (weak)
Pleiotropic	APOE, MAPT, MT-TK, PSEN1
Rivastigmine	
Category	**Antidementia Agent/Cholinesterase Inhibitor**
Mechanism	Increases acetylcholine in CNS through reversible inhibition of its hydrolysis by cholinesterase
Genes	
Pathogenic	APOE, APP, CHAT
Mechanistic	ACHE, BCHE, CHAT, CHRNA4, CHRNB2
Metabolism: inhibitor	ACHE, BCHE
Pleiotropic	APOE, MAPT

(Continued)

TABLE 27.1 Continued

Tacrine	
Category	**Antidementia agent/cholinesterase inhibitor**
Mechanism	Elevates acetylcholine in cerebral cortex by slowing degradation of acetylcholine
Genes	
Pathogenic	APOE
Mechanistic	ACHE, BCHE, CHRNA4, CHRNB2
Metabolism: substrate	CYP1A2 (major), CYP2D6 (minor), CYP3A4 (major)
Metabolism: inhibitor	ACHE, BCHE, CYP1A2 (weak)
Transporter	SCN1A
Pleiotropic	APOE, MTHFR, CES1, LEPR, GSTM1, GSTT1

Source: Cacabelos [113].

TABLE 27.2 Drug Metabolism-Related Genes

Phase I Enzymes	
Alcohol dehydrogenases	ADH1A, ADH1B, ADH1C, ADH4, ADH5, ADH6, ADH7, ADHFE1
Aldehyde dehydrogenases	ALDH1A1, ALDH1A2, ALDH1A3, ALDH1B1, ALDH2, ALDH3A1, ALDH3A2, ALDH3B1, ALDH3B2, ALDH4A1, ALDH5A1, ALDH6A1, ALDH7A1, ALDH8A1, ALDH9A1, AOX1
Aldo-keto reductases	AKR1A1, AKR1B1, AKR1C1, AKR1D1
Amine oxidases	MAOA, MAOB, SMOX
Carbonyl reductases	CBR1, CBR3, CBR4
Cytidine deaminase	CDA
Cytochrome P450 family	CYP1A1, CYP1A2, CYP1B1, CYP2A6, CYP2A7, CYP2A13, CYP2B6, CYP2C18, CYP2C19, CYP2C8, CYP2C9, CYP2D6, CYP2D7P1, CYP2E1, CYP2F1, CYP2J2, CYP2R1, CYP2S1, CYP2W1, CYP3A4, CYP3A5, CYP3A7, CYP3A43, CYP4A11, CYP4A22, CYP4B1, CYP4F2, CYP4F3, CYP4F8, CYP4F11, CYP4F12, CYP4Z1, CYP7A1, CYP7B1, CYP8B1, CYP11A1, CYP11B1, CYP11B2, CYP17A1, CYP19A1, CYP20A1, CYP21A2, CYP24A1, CYP26A1, CYP26B1, CYP26C1, CYP27A1, CYP27B1, CYP39A1, CYP46A1, CYP51A1, POR, TBXAS1
Cytochrome b5 reductase	CYB5R3
Dihydropyrimidine dehydrogenase	DPYD
Esterases	AADAC, CEL, CES1, CES1P1, CES2, CES3, CES5A, ESD, GZMA, GZMB, PON1, PON2, PON3, UCHL1, UCHL3
Epoxidases	EPHX1, EPHX2
Flavin-containing monooxygenases	FMO1, FMO2, FMO3, FMO4, FMO5, FMO6P
Glutathione reductase/peroxidases	GSR, GPX1, GPX2, GPX3, GPX4, GPX5, GPX6, GPX7
Peptidases	DPEP1, METAP1
Prostaglandin-endoperoxide synthases	PTGS1, PTGS2
Short-chain dehydrogenases/reductases	DHRS1, DHRS2, DHRS3, DHRS4, DHRS7, DHRS9, DHRS12, DHRS13, DHRSX, HSD11B1, HSD17B10, HSD17B11, HSD17B14

TABLE 27.2 Continued

Superoxide dismutase	SOD1, SOD2
Xanthine dehydrogenase	XDH
	Phase II Enzymes
Amino acid transferases	AGXT, BAAT, CCBL1
Dehydrogenases	NQO1, NQO2, XDH
Esterases	CES1, CES2, CES3, CES4, CES5A
Glucuronosyl transferases	DDOST, UGT1A1, UGT1A10, UGT1A3, UGT1A4, UGT1A5, UGT1A6, UGT1A7, UGT1A8, UGT1A9, UGT2A1, UGT2A3, UGT2B10, UGT2B11, UGT2B15, UGT2B17, UGT2B28, UGT2B4, UGT2B7, UGT3A1, UGT8
Glutathione transferases	GSTA1, GSTA2, GSTA3, GSTA4, GSTA5, GSTCD, GSTK1, GSTM1, GSTM2, GSTM3, GSTM4, GSTM5, GSTO1, GSTO2, GSTP1, GSTT1, GSTT2, GSTZ1, MGST1, MGST2, MGST3, PTGES
Methyl transferases	AS3MT, ASMT, COMT, GAMT, GNMT, HNMT, INMT, NNMT, PNMT, TPMT
N-Acetyl transferases	AANAT, ACSL1, ACSL3, ACSL4, ACSM1, ACSM2B, ACSM3, GLYAT, NAT1, NAT2, NAA20, SAT1
Thioltransferase	GLRX
Sulfotransferases	SULT1A1, SULT1A2, SULT1A3, SULT1B1, SULT1C1, SULT1C2, SULT1C3, SULT1C4, SULT1E1, SULT2A1, SULT2B1, SULT4A1, SULT6B1, TST, CHST1, CHST2, CHST3, CHST4, CHST5, CHST6, CHST7, CHST8, CHST9, CHST10, CHST11, CHST12, CHST13, GAL3ST1

Note: See Appendix B for long-form names of genes listed.

There are 141 *CYP2D6* allelic variants, of which -100C>T, -1023C>T, -1659G>A, -1707delT, -1846G>A, -2549delA, -2613-2615delAGA, -2850C>T, -2988G>A, and -3183G>A represent the ten most important [113–115]. Different alleles result in the extensive, intermediate, poor, and ultrarapid metabolizer phenotypes, characterized by normal, intermediate, decreased, and multiplied ability to metabolize the enzyme's substrates, respectively. The hepatic cytochrome P450 system is responsible for the first phase in the metabolism and elimination of numerous endogenous and exogenous molecules and ingested chemicals. P450 enzymes convert these substances into electrophilic intermediates, which are then conjugated by phase II enzymes (e.g., UDP glucuronosyltransferases, N-acetyltransferases) to hydrophilic derivatives that can be excreted. According to the database of the *World Guide for Drug Use and Pharmacogenomics* [113], 982 drugs are *CYP2D6*-related: 371 are substrates, more than 300 are inhibitors, and 18 are CYP2D6 inducers.

In healthy subjects, extensive metabolizers (EMs) account for 55.71% of the population; intermediate metabolizers (IMs) account for 34.7%; poor metabolizers (PMs), 2.28%; and ultrarapid metabolizers (UMs), 7.31%. Remarkable worldwide interethnic differences exist in the frequency of the PM and UM phenotypes [116–118]. On average, approximately 6.28% of the world's population belongs to the PM category. Europeans (7.86%), Polynesians (7.27%), and Africans (6.73%) show the highest rate of PMs, whereas Orientals (0.94%) show the lowest [116]. The frequency of PMs among Middle Eastern populations, Asians, and Americans is in the range of 2–3%. *CYP2D6* gene duplications are relatively infrequent among Northern Europeans, but in East Africa the frequency of alleles with duplication of *CYP2D6* is as high as 29% [119]. In Europe, there is a North–South gradient in the frequency of PMs (6–12% of PMs in Southern European countries, and 2–3% of PMs in Northern latitudes) [111].

In AD, EMs, IMs, PMs, and UMs are 56.38%, 27.66%, 7.45%, and 8.51%, respectively, and in vascular dementia, they are, respectively, 52.81%, 34.83%, 6.74%, and 5.62% (Figure 27.3). There is an accumulation of AD-related risk genes in PMs and UMs. EMs and IMs are the best responders, and PMs and UMs are the worst responders to a combination therapy of cholinesterase inhibitors, neuroprotectants, and vasoactive substances. The pharmacogenetic response in AD appears to depend on the networking activity of genes involved in drug metabolism and genes involved in AD pathogenesis [7,12,15,16,22–28,53–59].

27.7.3.2 CYP2C9

CYP2C9 is a gene (50.71 kb) with 9 exons mapped on 10q24. An RNA transcript of 1860 bp is mainly expressed in hepatocytes, where a protein of 55.63 kDa (490 aa) can be identified. More than 600 drugs are *CYP2C9*-related: 311 act as substrates (177 major, 134 minor); 375, as inhibitors (92 weak, 181 moderate, and 102 strong); and 41 as inducers of the CYP2C9 enzyme [113]. There are 481 *CYP2C9* SNPs. By phenotype (Figure 27.4), in the control population, PMs represent 7.04%, IMs 32.39%, and EMs 60.56%. In AD, PMs, IMs, and EMs are 6.45%, 37.64%, and 55.91%, respectively, and in vascular dementia they are 3.61%, 28.92%, and 67.47%, respectively [18] (Figure 27.4).

27.7.3.3 CYP2C19

CYP2C19 is a gene (90.21 kb) with 9 exons mapped on 10q24.1q24.3. RNA transcripts of 1901 bp, 2395 bp, and 1417 bp are expressed in liver cells, where a protein of 55.93 kDa (490 aa) has been identified. Nearly 500 drugs are *CYP2C19*-related, with 281 acting as substrates (151 major, 130 minor), 263 as inhibitors (72 weak, 127 moderate, and 64 strong), and 23 as inducers of the CYP2C19 enzyme [113]. About 541 SNPs have been detected in the *CYP2C19* gene. The frequencies of the three major *CYP2C19* geno-phenotypes in the control population are *CYP2C19-*1/*1*-EMs, 68.54%; *CYP2C19-*1/*2*-IMs, 30.05%; and *CYP2C19-*2/*2*-PMs, 1.41%. EMs, IMs, and PMs account for 69.89%, 30.11%, and 0%, respectively, in AD, and 66.27%, 30.12%, and 3.61%, respectively, in vascular dementia [18] (Figure 27.5).

27.7.3.4 CYP3A4/5

CYP3A4 is a gene (27.2 kb) with 13 exons mapped on 7q21.1. RNA transcripts of 2153 bp, 651 bp, 564 bp, 2318 bp, and 2519 bp are expressed in intestine, liver, prostate, and other tissues, where four protein variants of 57.34 kDa (503 aa), 17.29 kDa (153 aa), 40.39 kDa (353 aa), and 47.99 kDa (420 aa) have been identified. The human *CYP3A* locus contains the three *CYP3A* genes (*CYP3A4*, *CYP3A5,* and *CYP3A7*), three pseudogenes, and a novel *CYP3A* gene termed *CYP3A43*. The gene encodes a putative protein with 71.5–75.8% identity with the other CYP3A proteins. The predominant hepatic form is CYP3A4, but CYP3A5 contributes significantly to total liver CYP3A activity.

CYP3A4 metabolizes more than 1900 drugs: 1033 act as substrates (897 major, 136 minor); 696, as inhibitors (118 weak, 437 moderate, and 141 strong); and 241, as inducers of the CYP3A4 enzyme [113]. About 347 SNPs have been identified in the *CYP3A4* gene (*CYP3A4*1A*: wild-type), 25 of which are of clinical relevance. Concerning *CYP3A4/5* polymorphisms in AD, 82.75% of cases are EMs (*CYP3A5*3/*3*), 15.88% are IMs (*CYP3A5*1/*3*), and 1.37% are UMs (*CYP3A5*1/*1*). Unlike other human P450s (*CYP2D6*, *CYP2C19*), there is no evidence of a "null" allele for *CYP3A4* [113].

	Control population	Alzheimer's disease	Vascular dementia
PM	7,04	6,45	3,61
IM	32,39	37,64	28,92

27.7.3.5 CYP Clustering

The construction of a genetic map integrating the most prevalent _CYP2D6+CYP2C19+CYP2C9_ polymorphic variants in a trigenic cluster yields 82 different haplotype-like profiles. The most frequent trigenic genotypes in the AD population are _*1*1-*1*1-*1*1_ (25.70%), _*1*1-*1*2-*1*2_ (10.66%), _*1*1-*1*1-*1*1_ (10.45%), _*1*4-*1*1-*1*1_ (8.09%), _*1*4-*1*2-*1*1_ (4.91%), _*1*4-*1*1-*1*2_ (4.65%), and _*1*1-*1*3-*1*3_ (4.33%). These 82 trigenic genotypes represent 36 different pharmacogenetic phenotypes.

According to these trigenic clusters, only 26.51% of patients show a pure 3EM phenotype, 15.29% are 2EM1IM, 2.04% are pure 3IM, 0% are pure 3PM, and 0%

are 1UM2PM (the worst possible phenotype). This implies that only one-quarter of the population normally process the drugs that are metabolized via CYP2D6, CYP2C9, and CYP2C19 (approximately 60% of the drugs in current use) [12]. Taking into consideration the data available, it might be inferred that at least 20–30% of the AD population may exhibit an abnormal metabolism of cholinesterase inhibitors and/or other drugs that undergo oxidation via *CYP2D6*-related enzymes.

Approximately 50% of this population cluster shows an ultrarapid metabolism, requiring higher doses of cholinesterase inhibitors in order to reach a therapeutic threshold. The other 50% of the cluster exhibit a poor metabolism, displaying potential adverse events at low doses. If we take into account that approximately 60–70% of therapeutic outcomes depend on pharmacogenomic criteria (e.g., pathogenic mechanisms associated with AD-related genes), it can be postulated that pharmacogenetic and pharmacogenomic factors are responsible for 75–85% of therapeutic response (efficacy) in AD patients treated with conventional drugs [12,15–18,22–25,28,53–59].

27.7.4 Drug Transporters

ABC genes—especially *ABCB1* (ATP-binding cassette, subfamily B, member 1P-glycoprotein-1, P-gp1, Multidrug Resistance 1, MDR (17q21.12), *ABCC1* (9q31.1), *ABCG2* (White121q22.3), and other genes of this family—encode proteins that are essential for drug metabolism and transport. The multidrug efflux transporters P-gp, the multidrug resistance-associated protein 4 (MRP4), and the breast cancer resistance-protein (BCRP), located on endothelial cells lining the brain vasculature, play important roles in limiting the movement of substances into the brain and in enhancing their efflux from the brain.

Transporters also cooperate with phase I/phase II metabolism enzymes by eliminating drug metabolites. Their major features are their capacity to recognize drugs belonging to unrelated pharmacological classes and their redundancy, by which a single molecule can act as a substrate for different transporters. This ensures efficient neuroprotection against xenobiotic invasions. The pharmacological induction of ABC gene expression is a mechanism of drug interaction, which may affect substrates of the upregulated transporter; overexpression of MDR transporters confers resistance to anti-cancer agents and CNS drugs [120,121].

Also of importance for CNS pharmacogenomics are transporters encoded by genes of the solute carrier superfamily (SLC) and solute carrier organic (SLCO) transporter family, which are responsible for the transport of multiple endogenous and exogenous compounds, including folate (*SLC19A1*), urea (*SLC14A1*, *SLC14A2*), monoamines (*SLC29A4*, *SLC22A3*), aminoacids (*SLC1A5*, *SLC3A1*, *SLC7A3*, *SLC7A9*, *SLC38A1*, *SLC38A4*, *SLC38A5*, *SLC38A7*, *SLC43A2*, *SLC45A1*), nucleotides (*SLC29A2*, *SLC29A3*], fatty acids (*SLC27A1-6*), neurotransmitters (*SLC6A2*[noradrenaline transporter]), *SLC6A3*[dopamine transporter], *SLC6A4*[serotonin transporter, SERT], *SLC6A5*, *SLC6A6*, *SLC6A9*, *SLC6A11*, *SLC6A12*, *SLC6A14*, *SLC6A15*, *SLC6A16*, *SLC6A17*, *SLC6A18*, *SLC6A19*), glutamate (*SLC1A6*, *SLC1A7*), and others [122].

Some organic anion transporters (OAT), which belong to the solute carrier (SLC) 22A family, are also expressed at the BBB, and regulate the excretion of endogenous and exogenous organic anions and cations [123]. The transport of amino acids and di- and tripeptides is mediated by a number of different transporter families, and the bulk of oligopeptide transport is attributable to the activity of members of the *SLC15A* superfamily (peptide transporters 1 and 2 (*SLC15A1*[PepT1]) and *SLC15A2*[PepT2], and peptide/histidine transporters 1 and 2 (*SLC15A4*[PHT1] and *SLC15A3*[PHT2]). ABC and SLC transporters expressed at the BBB may cooperate to regulate the passage of different molecules into the brain [124]. Polymorphic variants in ABC and SLC genes may also be associated with pathogenic events in CNS disorders and drug-related safety and efficacy complications [111,122].

27.7.5 Pleiotropic Activity of *APOE* in Dementia

APOE is the prototypical paradigm of a pleiotropic gene with multifaceted activities in physiological and pathological conditions [16,22]. ApoE is consistently associated with the amyloid plaque marker for AD. *APOE*-4 may influence AD pathology interacting with APP metabolism and Aβ accumulation, enhancing hyperphosphorylation of tau protein and NFT formation, reducing choline acetyltransferase activity, increasing oxidative processes, modifying inflammation-related neuroimmunotrophic activity and glial activation, altering lipid metabolism, lipid transport, and membrane biosynthesis in sprouting and synaptic remodeling, and inducing neuronal apoptosis [16,23–25].

To address the complex misfolding and aggregation that initiates the toxic cascade resulting in AD, Petrlova et al. [26] developed a 2,2,6,6-tetramethylpiperidine-1-oxyl-4-amino-4-carboxylic acid spin-labeled amyloid-β (Aβ) peptide to observe its isoform-dependent interaction with the ApoE protein. Oligomer binding involves the C-terminal domain of ApoE, with ApoE3 reporting a much greater response through this conformational marker. ApoE3 displays a higher affinity and capacity for the toxic Aβ oligomer. ApoE polymorphism and AD risk can largely be attributed to the reduced ability of ApoE4 to function as a clearance vehicle for the toxic form of Aβ. *MAPT* and *APOE* are involved in the pathogenic mechanisms of AD, and both the *MAPT H1/H1* genotype and the *APOE ε4* allele lead to a more rapid progression to dementia among MCI subjects, probably mediating an increased rate of amyloid-β and tau brain deposition [27].

The distribution of *APOE* genotypes in the Iberian peninsula is as follows: *APOE-2/2* 0.32%; *APOE-2/3* 7.3%; *APOE-2/4* 1.27%; *APOE-3/3* 71.11%; *APOE-3/4* 18.41%; and *APOE-4/4* 1.59% [18] (Figure 27.2). These frequencies are very similar in Europe and in other Western societies. There is a clear accumulation of *APOE-4* carriers among patients with AD (*APOE-3/4* 30.30%, *APOE-4/4* 6.06%) and vascular dementia (*APOE-3/4* 35.85%, *APOE-4/4* 6.57%) as compared to controls (Figure 27.2). Different *APOE* genotypes confer specific phenotypic profiles to AD patients [15,16,22]. Some of these profiles may add risk or benefit when patients are treated with conventional drugs, and in many instances the clinical phenotype demands the administration of additional drugs that increase the complexity of therapeutic protocols.

From studies designed to define *APOE*-related AD phenotypes [7,12,23–25,28,53–59], several conclusions can be drawn, which are shown in Box 27.2. These 20 major phenotypic features clearly illustrate the biological disadvantage of *APOE-4* homozygotes and the potential consequences that these patients may experience when they receive pharmacological treatment for AD and/or concomitant pathologies [7,12,23–25,28,53–59].

27.7.6 Pharmacogenomics of Antidementia Drugs

The following list describes the pharmacogenomics of the most common antidementia drugs (Table 27.1).

Donepezil: is a centrally active, reversible acetylcholinesterase inhibitor that increases the acetylcholine available for synaptic transmission in the CNS. The therapeutic response of donepezil is influenced by pathogenic gene variants (*APOE*, *CHAT*), as well as mechanistic gene polymorphic variants (*CHAT*, *ACHE*, and *BCHE*). It is a major substrate of CYP2D6, CYP3A4, ACHE, and UGTs; it inhibits ACHE and BCHE; and it is transported by ABCB1 [113].

Galantamine: is a reversible and competitive acetylcholinesterase inhibitor leading to increased concentration of acetylcholine at cholinergic synapses. It also modulates nicotinic acetylcholine receptors and may increase glutamate and serotonin levels. *APOE*, *APP*, *ACHE*, *BCHE*, *CHRNA4*, *CHRNA7*, and *CHRNB2* variants may potentially influence galantamine efficacy and safety. Galantamine is a major substrate of CYP2D6, CYP3A4, and UGT1A1, and an inhibitor of ACHE and BCHE [113].

BOX 27.2 Key Conclusions Regarding APOE-Related AD Phenotypes

1. The age at onset is 5–10 years earlier in approximately 80% of AD cases harboring the *APOE-4/4* genotype.
2. The serum levels of ApoE are lowest in *APOE-4/4*, intermediate in *APOE-3/3* and *APOE-3/4*, and highest in *APOE-2/3* and *APOE-2/4*.
3. Serum cholesterol levels are higher in *APOE-4/4* than in other genotypes.
4. HDL-cholesterol levels tend to be lower in *APOE-3* homozygotes than in *APOE-4* allele carriers.
5. LDL-cholesterol levels are systematically higher in *APOE-4/4* than in any other genotype.
6. Triglyceride levels are significantly lower in *APOE-4/4*.
7. Nitric oxide levels are slightly lower in *APOE-4/4*.
8. Serum and cerebrospinal fluid Aβ levels tend to differ between *APOE-4/4* and the other most frequent genotypes (*APOE-3/3*, *APOE-3/4*).
9. Blood histamine levels are dramatically reduced in *APOE-4/4* as compared to the other genotypes.
10. Brain atrophy is markedly increased in *APOE-4/4*>*APOE-3/4*>*APOE-3/3*.
11. Brain mapping activity shows a significant increase in slow wave activity in *APOE-4/4* from the early stages of the disease.
12. Brain hemodynamics, as reflected by reduced brain blood flow velocity and increased pulsatility and resistance indices, is significantly worse in *APOE-4/4* (and in *APOE-4* carriers in general, as compared with *APOE-3* carriers); brain hypoperfusion and neocortical oxygenation is also more deficient in *APOE-4* carriers.
13. Lymphocyte apoptosis is markedly enhanced in *APOE-4* carriers.
14. Cognitive deterioration is faster in *APOE-4/4* patients than in carriers of any other *APOE* genotype.
15. In approximately 3–8% of AD cases, some dementia-related metabolic dysfunctions accumulate more in *APOE-4* carriers than in *APOE-3* carriers.
16. Some behavioral disturbances, alterations in circadian rhythm patterns, and mood disorders are slightly more frequent in *APOE-4* carriers.
17. Aortic and systemic atherosclerosis is more frequent in *APOE-4* carriers.
18. Liver metabolism and transaminase activity differ in *APOE-4/4* with respect to other genotypes.
19. Hypertension and other cardiovascular risk factors accumulate in *APOE-4* carriers.
20. *APOE-4/4* carriers are the poorest responders to conventional drugs.

Rivastigmine: is a cholinesterase inhibitor that increases acetylcholine in the CNS through reversible inhibition of its hydrolysis by cholinesterase. *APOE*, *APP*, *CHAT*, *ACHE*, *BCHE*, *CHRNA4*, *CHRNB2*, and *MAPT* variants may affect its pharmacokinetics and pharmacodynamics [113].

Tacrine: is the first FDA-approved antidementia drug. Its use was stopped due to hepatotoxicity. Tacrine is a cholinesterase inhibitor that elevates acetylcholine in the cerebral cortex by slowing degradation of acetylcholine. *ACHE*, *BCHE*, *CHRNA4*, *CHRNB2*, *APOE*, *MTHFR*, *CES1*, *LEPR*, *GSTM1*, and *GSTT1* variants may affect its therapeutic and toxic effects. Tacrine is a major substrate of CYP1A2 and CYP3A4, a minor substrate of CYP2D6, and is transported via SCN1A. It is an inhibitor of ACHE, BCHE, and CYP1A2 [113].

Memantine: is an N-Methyl-D-Aspartate (NMDA) receptor antagonist that binds preferentially to NMDA receptor-operated cation channels. It may act by blocking the actions of glutamate, mediated in part by NMDA receptors, and it is also an antagonist of GRIN2A, GRIN2B, GRIN3A, HTR3A, and CHRFAM7A. Several pathogenic (*APOE*, *PSEN1*, *MAPT*) and mechanistic gene variants (*GRIN2A*, *GRIN2B*, *GRIN3A*, *HTR3A*, *CHRFAM7A*) may influence its therapeutic effects. Memantine is a strong inhibitor of CYP2B6 and CYP2D6, and a weak inhibitor of CYP1A2, CYP2A6, CYP2C9, CYP2C19, CYP2E1, and CYP3A4 [113].

27.7.7 Multifactorial Therapy

Some studies using a multifactorial approach also have shown that diverse pharmacogenomic factors may influence efficacy and safety. In one of these studies [15,58], patients with dementia received the following for three months: a multifactorial therapy integrated by CDP-choline (500 mg/day, p.o.), Nicergoline (5 mg/day, p.o.), Sardilipin (E-SAR-94010) (LipoEsar®)(250 mg, t.i.d.), and Animon Complex® (2 capsules/day)—a nutraceutical compound integrated by a purified extract of *Chenopodium quinoa* (250 mg), ferrous sulphate (38.1 mg equivalent to 14 mg of iron), folic acid (200 µg), and vitamin B$_{12}$ (1 µg) per capsule (RGS: 26.06671/C).

Patients with chronic deficiencies of iron (<35 µg/mL), folic acid (<2.5 ng/mL), or vitamin B$_{12}$ (<150 pg/mL) received an additional supplement of iron (80 mg/day), folic acid (5 mg/day), and B complex vitamins (B$_1$, 15 mg/day; B$_2$, 15 mg/day; B$_6$, 10 mg/day; B$_{12}$, 10 µg/day; nicotinamide, 50 mg/day), respectively, to maintain stable levels of serum iron (50–150 µg/mL), folic acid (5–20 ng/mL) and vitamin B$_{12}$ levels (500–1000 pg/mL) in order to avoid the negative influence of all these metabolic factors on cognition. Patients with hypertension (>150/85 mmHg) received Enalapril (20 mg/day).

The frequency of *APOE* genotypes was *APOE-2/3*, 7.97%; *APOE-2/4*, 1.18%; *APOE-3*, 58.95%; *APOE-3/4*, 27.32%; and *APOE-4/4*, 4.58%. Cognitive function (as assessed by MMSE); 20.51 ± 6.51 vs. 21.45 ± 6.95, $p<0.0000000001$; ADAS-Cog, 22.94 ± 13.87 vs. 21.23 ± 12.84, $p<0.0001$; ADAS-Non-Cog, 5.26 ± 4.18 vs. 4.15 ± 3.63, $p<0.0000000001$; ADAS-Total, 27.12 ± 16.93 vs. 24.28 ± 15.06, $p<0.00009$) improved after treatment. Mood (HAM-A, 11.35 ± 5.44 vs. 9.79 ± 4.33, $p<0.0000000001$; HAM-D, 10.14 ± 5.23 vs. 8.59 ± 4.30, $p<0.0000000001$) also improved. Glucose levels did not change.

Total cholesterol levels (224.78 ± 45.53 vs. 203.64 ± 39.69 mg/dL, $p<0.0000000001$), HDL-cholesterol levels (54.11 ± 14.54 vs. 52.54 ± 14.86 mg/dL, $p<0.0001$), and LDL-cholesterol levels (148.15 ± 39.13 vs. 128.89 ± 34.83 mg/dL, $p<0.0000000001$) were significantly reduced. Folate (7.07 ± 3.61 vs. 18.14 ± 4.23 ng/mL, $p<0.000000001$) and vitamin B$_{12}$ levels (459.65 ± 205.80 vs. 689.78 ± 338.82 pg/mL, $p<0.000000001$) also increased, and both TSH and T$_4$ levels remained unchanged after treatment. The response rate in terms of cognitive improvement was as follows: 59.74% responders (RRs), 24.44% nonresponders (NRs), and 15.82% stable responders (SRs) (no change in MMSE score after three months of treatment). The response rate in cholesterol levels was very similar: 57.78% RRs, 28.50% NRs, and 13.72% SRs [15].

27.7.7.1 *APOE*-Related Cognitive Function Changes

In this study, the basal MMSE score differed in *APOE-2/3* carriers with respect to *APOE-2/4* ($p<0.02$), *APOE-3/4* ($p<0.004$), and *APOE-4/4* ($p<0.0009$), in *APOE-3/3* vs. *APOE-3/4* ($p<0.0005$), and in *APOE-3/3* vs. *APOE-4/4* ($p<0.002$). The best responders were *APOE-3/3* ($p<0.0000000001$) >*APOE-3/4* ($p<0.00001$) >*APOE-4/4* carriers ($p<0.05$). Patients harboring the *APOE-2/3* and *APOE-2/4* genotypes did not show any significant improvement. The response rate by genotype was the following: *APOE-2/3*: 44.26% RRs, 36.07% NRs, 19.67% SRs; *APOE-2/4*: 55.56% RRs, 44.44% NRs, 0.0% SRs; *APOE-3/3*: 63.42% RRs, 21.06% NRs, 15.52% SRs; *APOE-3/4*: 56.94% RRs, 27.75% NRs, 15.31% SRs; and *APOE-4/4*: 51.43% RRs, 28.57% NRs, 20.00% SRs [15] (Figures 27.6 and 27.7).

27.7.7.2 *APOE*-Related Changes in Blood Pressure Values

Systolic blood pressure (SBP) was significantly reduced in patients with the *APOE-3/3* ($p<0.00007$) and *APOE-3/4* genotypes ($p<0.01$), and diastolic blood pressure exhibited a similar pattern (*APOE-3/3*, $p<0.005$; *APOE-3/4*,

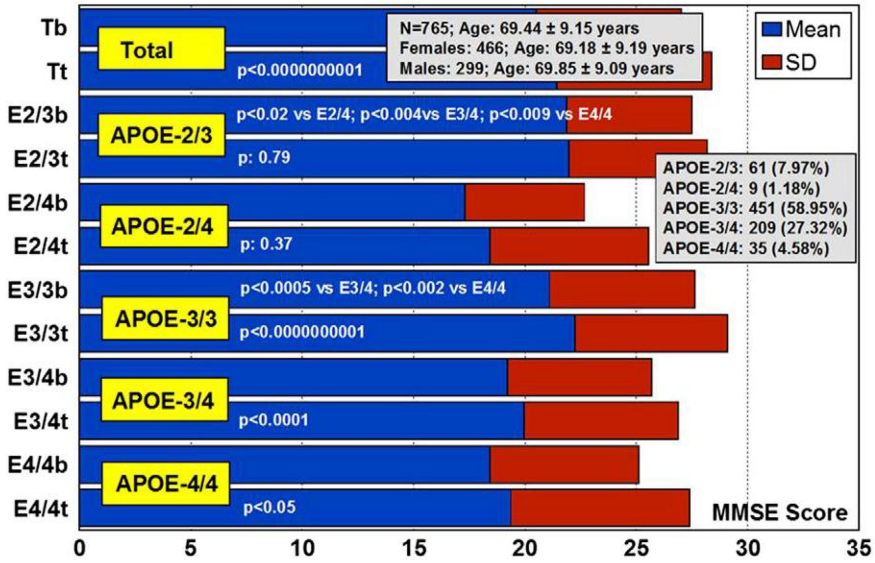

FIGURE 27.6 ***APOE*-related cognitive performance in response to multifactorial therapy in patients with dementia.** Tb—basal MMSE score prior to treatment; Tt—MMSE score after 3 months treatment in total sample. E2/3b—basal MMSE score in *APOE-2/3* carriers; E2/3t—MMSE score after treatment in *APOE-2/3* carriers; E2/4b—basal MMSE score in *APOE-2/4* carriers; E2/4t—MMSE score after treatment in *APOE-2/4* carriers; E3/3b—basal MMSE score in *APOE-3/3* carriers; E3/3t—MMSE score after treatment in *APOE-3/3* carriers; E3/4b basal MMSE score in *APOE-3/4* carriers; E3/4t—MMSE score after treatment in *APOE-3/4* carriers; E4/4b—basal MMSE score in *APOE-4/4* carriers; E4/4—MMSE score after treatment in *APOE-4/4* carriers. *Source: Adapted from Cacabelos et al.* [15].

p < 0.01), with no changes in either SBP or DBP in *APOE-2/3*, *APOE-2/4*, and *APOE-4/4* carriers [15].

27.7.7.3 APOE-Related Blood Lipid Response to Sardilipin

Basal cholesterol levels were significantly different in patients with the *APOE-2/3* genotype vs. *APOE-3/3* (p < 0.007), vs. *APOE-3/4* (p < 0.001), vs. *APOE-4/4* (p < 0.00002); *APOE-2/4* vs. *APOE-4/4* (p < 0.01); *APOE-3/3* vs. *APOE-4/4* (p < 0.005); and *APOE-3/4* vs. *APOE-4/4* (p < 0.01).

The highest cholesterol levels were seen in *APOE-4/4*> *APOE-3/4*> *APOE-3/3*. All patients showed a clear reduction in cholesterol levels after treatment with Sardilipin. This was particularly significant in *APOE-3/3* (p < 0.0000000001) > *APOE-3/4* (p < 0.00000008) > *APOE-4/4* (p < 0.002) > *APOE-2/3* (p < 0.02) > *APOE-2/4* carriers (p: 0.26). The response rate by genotype was as follows: *APOE-2/3*: 63.93% RRs, 29.51% NRs, 6.56% SRs; *APOE-2/4*: 44.44% RRs, 22.22% NRs, 33.34% SRs; *APOE-3/3*: 54.32% RRs, 28.16% NRs, 17.52% SRs; *APOE-3/4*: 53.59% RRs, 31.58% NRs, 14.83% SRs; *APOE-4/4*: 65.71% RRs, 20.00% NRs, 14.29% SRs [15].

HDL-cholesterol levels significantly decreased in *APOE-3/3* ($p<0.001$) > *APOE-3/4* ($p<0.05$), with no significant changes in patients with other genotypes. In contrast, LDL-cholesterol levels showed changes identical to those observed in total cholesterol, with similar differences among genotypes at baseline and almost identical decreased levels after treatment (*APOE-3/3*, $p>0.0000000001$ >*APOE-3/4*, $p<0.00001$ >*APOE-2/3*, $p<0.0004$ >*APOE-4/4*, $p<0.001$ > *APOE-2/4*, p:0.31) [15].

Sardilipin (E-SAR-94010, LipoEsar®, LipoSea®) is a natural product extracted from the marine species *Sardina pilchardus* by means of nondenaturing biotechnological procedures. The main chemical compounds of LipoEsar® are lipoproteins (60–80%), whose micelle structure probably mimics that of physiological lipoproteins involved in lipid metabolism. In preclinical studies, Sardilipinhas been shown to be effective in:

1. Reducing blood cholesterol (CHO), triglyceride (TG), uric acid (UA), and glucose (Glu) levels, as well as liver alanine aminotransferase (ALT) and aspartate aminotransferase (AST) activity.
2. Enhancing immunological function by regulating both lymphocyte and microglia activity.
3. Inducing antioxidant effects mediated by superoxide dismutase activity.
4. Improving cognitive function [15].

According to these results, it appears that the therapeutic response of patients with dyslipidemia to Sardilipin is *APOE*-related. The best responders were patients with *APOE-3/3* >*APOE-3/4* >*APOE-4/4*. Patients with the other *APOE* genotypes (*2/2*, *2/3*, *2/4*) did not show any hypolipidemic response to this novel compound. In patients with dementia, the effects of Sardilipin were very similar to those observed in patients with chronic dyslipidemia, suggesting that the lipid-lowering properties of Sardilipin are *APOE*-dependent [15] (Figure 27.8).

27.8 FUTURE PERSPECTIVE

To make AD a global health priority in the coming years, conceptual and procedural changes are needed on several grounds, such as (1) political, administrative, economic, legal, ethical, industrial, regulatory and educational issues; (2) novel biomarkers (genomics, proteomics, molecular neuroimaging) as diagnostic aids; (3) innovative therapeutics; (4) pharmacogenomics in clinical practice to optimize therapeutics; and (5) selective preventive plans for the population at risk.

There is disharmony concerning the public and governmental interest in dementia and its social, medical, and economic implications. The diagnosis and management of dementia is dissimilar in Europe, North America, Latin America, Asia, Africa, and Oceania. The economic/cultural status of each country (developed versus developing), the

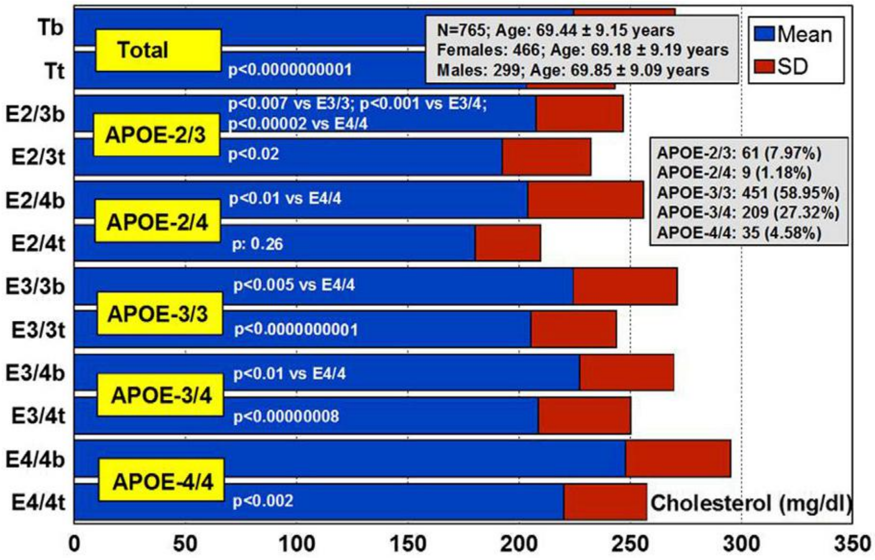

FIGURE 27.8 ***APOE*-related total cholesterol levels in response to multifactorial therapy in patients with dementia.** Tb—basal cholesterol levels prior to treatment; Tt—cholesterol levels after 3 months treatment in total sample. E2/3b—basal cholesterol levels in *APOE-2/3* carriers; E2/3t—total cholesterol levels after treatment in *APOE-2/3* carriers; E2/4b—basal cholesterol levels in *APOE-2/4* carriers; E2/4t—total cholesterol levels after treatment in *APOE-2/4* carriers; E3/3b—basal cholesterol levels in *APOE-3/3* carriers; E3/3t—total cholesterol levels after treatment in *APOE-3/3* carriers; E3/4b—basal cholesterol levels in *APOE-3/4* carriers; E3/4t—total cholesterol levels after treatment in *APOE-3/4* carriers; E4/4b—basal cholesterol levels in *APOE-4/4* carriers; E4/4—total cholesterol levels after treatment in *APOE-4/4* carriers. *Source: Adapted from Cacabelos et al.* [15].

particular epidemiology of aging and dementia in each latitude, national standards of education, health priorities (infectious diseases versus degenerative diseases), and the quality and efficiency of medical services are conditioning factors for investing (or not investing) national resources in dementia as a health priority.

Educational programs, international guidelines, and consensus protocols for the management of dementia are necessary for global harmonization, for professionals from different countries to speak the same conceptual language, and to improve cost-effectiveness ratios [125–128]. There are many legal issues (e.g., informed consent, lawsuit, testament, tutorship) and ethical issues (e.g., clinical trials, use of genetic information, institutionalization) that deserve more attention in order to humanize the end of life in the very frail conditions under which demented patients survive.

The updating of regulatory issues is also a matter of deep concern. Regulatory aspects of drug development are not universal, with notable peculiarities in the European Union (EMA), the United States (FDA), and Japan (Koseisho). Because the costs of dementia cannot be fully assumed by more than 60% of the European population, European authorities must take into account this circumstance when health reform is implemented in the coming years [8,18].

Genomics, transcriptomics, proteomics, and metabolomics will revolutionize medicine in the next decades. Genetic testing is gaining acceptance among physicians and patients in different countries [128–131], although Americans, Europeans, and Japanese differ notably in their knowledge, beliefs, and attitudes regarding genetic testing for AD [128,131,132]. The validation of protocols for genomic screening will contribute to the implementation of structural genomics, functional genomics, and proteomics as diagnostic aids and therapeutic targets [133].

An accurate diagnosis of AD demands the use of reliable biomarkers in routine protocols at a reasonable price [68]. Levels of specific secreted cellular signaling proteins in cerebrospinal fluid or plasma correlate with pathological changes in the AD brain; therefore, proteomic analysis of these levels can be used to discover said biomarkers [134]. It is likely that the best biomarkers result from a combination of genomic, transcriptomic, and proteomic analyses of body fluids. The measurement of these biomarkers correlates with brain imaging markers and cognitive performance [73–75].

New initiatives for the prevention of dementia (global versus selective prevention) will also emerge [135], together with new insights into the role of nutrition and nutrigenomics in brain function and neurodegeneration [59,136]. In terms of prevention, it must be taken into consideration that neuronal death and Aβ accumulation starts many years before the onset of the disease, and that preventive strategies should be selective to protect the population at risk. For this purpose, accurate biomarkers are essential, and surrogate markers are needed to facilitate primary prevention.

Without doubt, the highest priority for the coming decade will be an intense search for novel therapeutic options in the form of both symptomatic treatments and preventive strategies. Past failures must be studied by researchers and the pharmaceutical industry in order to avoid unnecessary expenses in redundant trials that lead nowhere. Combination treatments require further evaluation and more sophisticated strategies than dual combinations [137,138]. The administration of psychotropic drugs to demented patients should be reduced and predicted with pharmacogenetic markers to minimize side effects, cerebrovascular risk, and cognitive deterioration.

Priority areas for pharmacogenetic research are the prediction of serious adverse drug reactions (ADRs) and the determination of efficacy variation [139]. Both are necessary in CNS disorders and dementia to cope with efficacy and safety issues associated with current psychotropics and antidementia drugs, as well as new CNS drugs. With regard to the future of pharmacogenomics as a practical discipline, several issues should be addressed:

- The education of physicians in medical genomics and pharmacogenomics is fundamental (less than 2% of clinicians are familiar with genomic science)
- Genomic screening of gene clusters involved in pharmacogenomic outcomes must become a clinical routine (without genetic testing, there is no pharmacogenetics)
- Each patient must be a carrier of a pharmacogenetic card [140] indicating what kind of drugs he/she can take and which medications he/she should avoid
- Regulatory agencies should request pharmacogenetic data from the pharmaceutical industry when applying for drug approval
- Pharmacogenetic data must be incorporated into patient information leaflets and the pharmaceutical *vade mecum*
- New guidelines for daily praxis, such as those given in the *World Guide for Drug Use and Pharmacogenomics* [113], will promote understanding of the relationship between drugs and genes to make drug prescription truly personalized

27.9 CONCLUSION

AD is a major health problem that comes with a high cost to society. As a clinical entity, AD is a polygenic/complex disorder in which many different gene clusters may be involved. Most genes screened to date belong to different proteomic and metabolomic pathways that potentially affect AD pathogenesis, represented by accumulation of Aβ deposits in senile plaques, intracellular NFTs with hyperphosphorylated tau, and neuronal loss.

The presence of the *APOE-4* allele of the apolipoprotein E gene seems to be a major risk factor for both degenerative and vascular dementia, and *APOE* variants are directly involved in AD pathogenesis at multiple levels. Specific biomarkers (structural and functional genomic markers, proteomic markers in body fluids, neuroimaging markers) are needed for an accurate AD diagnosis. Current pharmacological treatment of AD with cholinesterase inhibitors (donepezil, rivastigmine, galantamine) and memantine is not cost-effective; moreover, the overuse of psychotropic drugs in patients with dementia contributes to deteriorating cognitive and psychomotor functions.

Old treatments addressed memory impairment. New treatments are oriented to halting disease progression by interfering with Aβ accumulation, NFT formation, oxidative stress, neuroinflammation, and cerebrovascular damage. Over the past few years diverse candidate drugs have been investigated in AD models, but not one has reached the market. Since only 25–30% of the population is an extensive metabolizer for drugs metabolized via CYP2D6, CYP2C9, and CYP2C19 enzymes, it seems reasonable to use pharmacogenomic procedures as a way to optimize AD therapeutics, thus reducing ADRs and unnecessary costs. The therapeutic response to conventional drugs in patients with AD is genotype-specific, with *CYP2D6*-PMs, *CYP2D6*-UMs, and *APOE-4/4* carriers shown to be the worst responders. *APOE* and *CYP2D6* may cooperate, as pleiotropic genes, in the metabolism of drugs and hepatic function.

If we know the pharmacogenomic profiles of patients who require treatment with antidementia drugs and/or psychotropic drugs currently in use, we may be able to achieve the following benefits:

- Identifying candidate patients with the ideal genomic profile to receive a particular drug
- Adapting the dose in more than 90% of cases according to the condition of EM, IM, PM, or UM, which will limit the occurrence of direct side effects in 30–50% of cases
- Reducing drug interactions by 30–50% (avoiding the administration of inhibitors or inducers able to modify the normal enzymatic activity on a particular substrate)
- Enhancing efficacy
- Eliminating unnecessary costs (>30% of pharmaceutical direct costs) deriving from the consequences of inappropriate drug selection and overmedication to mitigate ADRs [18]

APPENDIX A

Selected Genes Potentially Associated with Alzheimer's Disease

Locus	Size (Kb)	Symbol	Title/Gene	OMIM	Other Related Diseases

Locus	Size (Kb)	Symbol	Title/Gene	OMIM	Other Related Diseases
14q22.1	241.61	FRMD6	FERM domain-containing 6	614555	
14q23.2	111.52	ESR2	Estrogen receptor 2 (ER beta)	601663	
14q24	71.97	MTHFD1	Methylenetetrahydrofolate dehydrogenase (NADP+ dependent) 1, methenyltetrahydrofolate cyclohydrolase, formyltetrahydrofolate synthetase	172460	Abruptio placentae, spina bifida folate-sensitive
14q24.3	87.26	PSEN1	Presenilin 1	104311	Familial acne inversa 3, dilated cardiomyopathy 1U, frontotemporal dementia, Pick disease
14q24.3	13.44	NPC2	Niemann-Pick disease, type C2	601015	Niemann-Pick disease type C2
14q24.3	21.86	DLST	Dihydrolipoamide S-succinyltransferase (E2 component of 2-oxo-glutarate complex)	126063	
14q24.3	3.46	FOS	FBJ murine osteosarcoma viral oncogene homolog	164810	
14q24.3	5.82	NGB	Neuroglobin	605304	
14q31	62.31	SEL1L	Sel-1 suppressor of lin-12-like (*C. elegans*)	602329	
14q32	76.35	MOK	MOK protein kinase	605762	
14q32.1	13.95	SERPINA1	Serpin peptidase inhibitor, clade A (alpha-1 antiproteinase, antitrypsin), member 1	107400	Emphysema due to AAT deficiency, emphysema-cirrhosis due to AAT deficiency, hemorrhagic diathesis due to antithrombin Pittsburgh, chronic obstructive pulmonary disease
14q32.1	11.68	SERPINA3	Serpin peptidase inhibitor, clade A (alpha-1 antiproteinase, antitrypsin), member 3	107280	Alpha-1-antichymotrypsin deficiency, occlusive cerebrovascular disease
14q32.1	42.88	CYP46A1	Cytochrome P450, family 46, subfamily A, polypeptide 1	604087	
14q32.3	72.36	KLC1	Kinesin light chain 1	600025	
14q32.32	26.40	AKT1	V-akt murine thymoma viral oncogene homolog 1	164730	Breast cancer, colorectal cancer, Cowden syndrome 6, ovarian cancer, proteus syndrome, schizophrenia
15q11-q12	196.68	APBA2	Amyloid beta (A4) precursor protein-binding, family A, member 2	602712	

(*Continued*)

Appendix A Continued

Locus	Size (Kb)	Symbol	Title/Gene	OMIM	Other Related Diseases
15q13.1	32.42	CHRFAM7A	CHRNA7 (cholinergic receptor, nicotinic, alpha 7, exons 5–10) and FAM7A (family with sequence similarity 7A, exons A–E) fusion	609756	
15q14	139.70	CHRNA7	Cholinergic receptor, nicotinic, alpha 7 (neuronal)	118511	Schizophrenia, myoclonic epilepsy
15q21.1	130.54	CYP19A1	Cytochrome P450, family 19, subfamily A, polypeptide 1	107910	Aromatase deficiency, aromatase excess syndrome
15q21.1	2.09	EID1	EP300 interacting inhibitor of differentiation 1	605894	
15q21-q23	136.90	LIPC	Lipase, hepatic	151670	Hepatic lipase deficiency, noninsulin-dependent diabetes mellitus
15q22	153.67	ADAM10	ADAM metallopeptidase domain 10	602192	
15q22.2	31.58	APH1B	APH1B gamma secretase subunit	607630	
15q22.31	48.35	SNX1	Sorting nexin 1	601272	
15q22.33	129.34	SMAD3	SMAD family member 3	603109	
15q24	28.24	CHRNA3	Cholinergic receptor, nicotinic, alpha 3 (neuronal)	118503	Lung cancer
15q24.1	21.11	CSK	C-src tyrosine kinase	124095	
15q25.1	63.28	IREB2	Iron-responsive element binding protein 2	147582	
15q26	150.50	MEF2A	Myocyte enhancer factor 2A	600660	Coronary artery disease 1 with myocardial infarction
16p13.3	17.87	UBE2I	Ubiquitin-conjugating enzyme E2I	601661	
16p13.3	14.60	MEFV	Mediterranean fever	608107	Familial Mediterranean fever
16q12	29.56	VPS35	Vacuolar protein sorting 35 homolog (*S. cerevisiae*)	601501	Parkinson disease 17
16q21	21.92	CETP	Cholesteryl ester transfer protein, plasma	118470	Hyperalphalipoproteinemia
16q22	28.10	NAE1	NEDD8-activating enzyme E1 subunit 1	603385	
16q22.1	17.23	NQO1	NAD(P)H dehydrogenase, quinone 1	125860	Tardive dyskinesia, cancer
17p11.2	25.66	SREBF1	Sterol regulatory element-binding transcription factor 1	184756	

Appendix A Continued

Locus	Size (Kb)	Symbol	Title/Gene	OMIM	Other Related Diseases
17p12	139.28	COX10	Cytochrome c oxidase assembly homolog 10 (yeast)	602125	Charcot-Marie-Tooth type 1A, hereditary neuropathy with liability to pressure palsies
17p13	72.14	MYH13	Myosin, heavy-chain 13, skeletal muscle	603487	
17p13.1	8.80	TNK1	Tyrosine kinase, nonreceptor, 1	608076	
17p13.1	19.15	TP53	Tumor protein p53	191170	Adrenal cortical carcinoma, breast cancer, choroid plexus papilloma, colorectal cancer, hepatocellular carcinoma, Li-Fraumeni syndrome, nasopharyngeal carcinoma, osteosarcoma, pancreatic cancer, basal-cell carcinoma 7, glioma
17p13.1	31.63	MYH8	Myosin, heavy-chain 8, skeletal muscle, perinatal	160741	Carney complex variant, trismus-pseudocamptodactyly syndrome
17q	2.22	PNMT	Phenylethanolamine N-methyltransferase	171190	Essential hypertension
17q11.2	4.17	CDK5R1	Cyclin-dependent kinase 5, regulatory subunit 1 (p35)	603460	
17q11.2	43.97	BLMH	Bleomycin hydrolase	602403	
17q11.2	39.58	SLC6A4	Solute carrier family 6 (neurotransmitter transporter, serotonin), member 4	182138	Sudden infant death syndrome, aggressive behavior, depression, obsessive-compulsive disorder
17q11.2	31.68	THRA	Thyroid hormone receptor, alpha	190120	Hypothyroidism nongoitrous 6
17q11.2	0,086	MIR144	MicroRNA 144	612070	
17q11.2-q12	43.76	NOS2	Nitric oxide synthase 2, inducible	163730	Hypertension
17q11.2-q12	1.93	CCL2	Chemokine (C-C motif) ligand 2	158105	Psoriasis, rheumatoid arthritis, atherosclerosis, spina bifida
17q12	1.91	CCL3	Chemokine (C-C motif) ligand 3	182283	Human immunodeficiency virus type 1
17q21.1	133.95	MAPT	Microtubule-associated protein tau	157140	Pick disease, frontotemporal dementia, cortico-basal degeneration, progressive supranuclear palsy, Parkinson disease, tauopathy and respiratory failure
17q21.1	0,445	STH	Saitohin	607067	

(*Continued*)

Appendix A Continued

Locus	Size (Kb)	Symbol	Title/Gene	OMIM	Other Related Diseases
17q21.32	7.98	GRN	Granulin	138945	Frontotemporal lobar degeneration with ubiquitin-positive inclusions, primary progressive aphasia, neuronal ceroid lipofuscinosis 11
17q21-q22	N/A	GPSC	Gliosis, familial progressive subcortical	N/A	
17q23.1	11.08	MPO	Myeloperoxidase	606989	Myeloperoxidase deficiency
17q23.2	83.06	APPBP2	Amyloid beta precursor protein (cytoplasmic tail) binding protein 2	605324	
17q23.3	21.32	ACE	Angiotensin I converting enzyme (peptidyl-dipeptidase A) 1	106180	Renal tubular dysgenesis, benign serum increase of angiotensin I-converting enzyme, myocardial infarction, stroke, severe acute respiratory syndrome, microvascular complications of diabetes 3
17q24.3	158.72	BPTF	Bromodomain PHD finger transcription factor	601819	
17q24-q25	87.63	GRB2	Growth factor receptor-bound protein 2	108355	
18p11.2	33.49	MC2R	Melanocortin 2 receptor (adrenocorticotropic hormone)	607397	Glucocorticoid deficiency due to ACTH unresponsiveness
18q12.1	33.62	DSC1	Desmocollin 1	125643	
18q12.1	7.26	TTR	Transthyretin	176300	Amyloidotic polyneuropathy, euthyroid hyperthyroxinaemia, amyloidotic vitreous opacities, cardiomyopathy, oculoleptomeningeal amyloidosis, meningocerebrovascular amyloidosis, carpal tunnel syndrome
19p13	14.48	PIN1	Peptidylprolyl *cis/trans* isomerase, NIMA-interacting 1	601052	Cancer
19p13.2	113.86	DNM2	Dynamin 2	602378	Axonal Charcot-Marie-Tooth disease type 2M, Charcot-Marie-Tooth disease type B, centronuclear myopathy
19p13.2	44.47	LDLR	Low-density lipoprotein receptor	606945	Familial hypercholesterolemia
19p13.2	N/A	AD9	Alzheimer disease 9	608907	
19p13.2-p13.1	41.35	NOTCH3	Notch 3	600276	Cerebral arteriopathy with subcortical infarcts and leukoencephalopathy
19p13.3-13.2	42.82	C3	Complement component 3	120700	C3 deficiency, atypical hemolytic uremic syndrome, macular degeneration age-related 9

Appendix A Continued

Locus	Size (Kb)	Symbol	Title/Gene	OMIM	Other Related Diseases
19p13.3	27.06	GNA11	Guanine nucleotide binding protein (G protein), alpha 11 (Gq class)	139313	
19p13.3	25.47	ABCA7	ATP-binding cassette, subfamily A (ABC1), member 7	605414	
19p13.3	10.90	APBA3	Amyloid beta (A4) precursor protein-binding, family A, member 3	604262	
19p13.3	9.29	GRIN3B	Glutamate receptor, ionotropic, N-methyl-D-aspartate 3B	606651	
19p13.3-p13.2	181.75	INSR	Insulin receptor	147670	Diabetes mellitus insulin-resistant with acanthosis nigricans, hyperinsulinemic hypoglycemia 5, leprechaunism, Rabson-Mendenhall syndrome
19p13.3-p13.2	15.78	ICAM1	Intercellular adhesion molecule 1	147840	
19q13	12.47	TOMM40	Translocase of outer mitochondrial membrane 40 homolog (yeast)	608061	
19q13.1	23.02	TGFB1	Transforming growth factor, beta 1	190180	Camurati-Engelmann disease
19q13.1	11.30	APLP1	Amyloid beta (A4) precursor-like protein 1	104775	
19q13.12	11.91	GAPDHS	Glyceraldehyde-3-phosphate dehydrogenase, spermatogenic	609169	
19q13.12	1.41	PSENEN	Presenilin enhancer 2 homolog (*C. elegans*)	607632	Acne inversa 2
19q13.2	43.09	PVRL2	Poliovirus receptor-related 2 (herpesvirus entry mediator B)	600798	Multiple sclerosis
19q13.2	3.61	APOE	Apolipoprotein E	107741	Hyperlipoproteinemia type III, lipoprotein glomerulopathy, sea-blue histiocyte disease, macular degeneration, myocardial infarction
19q13.2	4.69	APOC1	Apolipoprotein C-I	107710	
19q13.2	3.26	APOC4	Apolipoprotein C-IV	600745	Coronary artery disease
19q13.2	3.58	APOC2	Apolipoprotein C-II	608083	Hyperlipoproteinemia type Ib
19q13.2	12.36	BCAM	Basal cell adhesion molecule (Lutheran blood group)	612773	
19q13.3	38.76	CLPTM1	Cleft lip and palate-associated transmembrane protein 1	612585

Locus	Size (Kb)	Symbol	Title/Gene	OMIM	Other Related Diseases
Xq12	186.59	AR	Androgen receptor	313700	Spinal and bulbar muscular atrophy of Kennedy, prostate cancer, complete androgen insensitivity, hypospadia type 1
Xq21.3	843.97	PCDH11X	Protocadherin 11 X-linked	300246	
Xq21.3	N/A	AD16	Alzheimer disease 16	300756	

APPENDIX B

Long-Form Names for Genes Listed in Table 27.2

ADH1A: Alcohol dehydrogenase 1A (class I), alpha polypeptide
AADAC: Arylacetamide deacetylase
AANAT: Aralkylamine N-acetyltransferase
ACSL1: Acyl-CoA synthetase long-chain family member 1
ACSL3: Acyl-CoA synthetase long-chain family member 3
ACSL4: Acyl-CoA synthetase long-chain family member 4
ACSM1: Acyl-CoA synthetase medium-chain family member 1
ACSM2B: Acyl-CoA synthetase medium-chain family member 2B
ACSM3: Acyl-CoA synthetase medium-chain family, member 3
ADH1B: Alcohol dehydrogenase 1B (class I), beta polypeptide
ADH1C: Alcohol dehydrogenase 1C (class I), gamma polypeptide
ADH4: Alcohol dehydrogenase 4 (class II), pi polypeptide
ADH5: Alcohol dehydrogenase 5 (class III), chi polypeptide
ADH6: Alcohol dehydrogenase 6 (class V)
ADH7: Alcohol dehydrogenase 7 (class IV), mu or sigma polypeptide
ADHFE1: Alcohol dehydrogenase, iron containing, 1
AGXT: Alanine-glyoxylate aminotransferase
AKR1A1: Aldo-keto reductase family 1, member A1 (aldehyde reductase)
AKR1B1: Aldo-keto reductase family 1, member B1 (aldose reductase)
AKR1C1: Aldo-keto reductase family 1, member C1
AKR1D1: Aldo-keto reductase family 1, member D1
ALDH1A1: Aldehyde dehydrogenase 1 family, member A1
ALDH1A2: Aldehyde dehydrogenase family 1, subfamily A2
ALDH1A3: Aldehyde dehydrogenase family 1, subfamily A3
ALDH1B1: Aldehyde dehydrogenase 1 family, member B1
ALDH2: Aldehyde dehydrogenase 2 family (mitochondrial)
ALDH3A1: Aldehyde dehydrogenase 3 family, member A1
ALDH3A2: Aldehyde dehydrogenase 3 family, member A2
ALDH3B1: Aldehyde dehydrogenase 3 family, member B1
ALDH3B2: Aldehyde dehydrogenase 3 family, member B2
ALDH4A1: Aldehyde dehydrogenase 4 family, member A1
ALDH5A1: Aldehyde dehydrogenase 5 family, member A1
ALDH6A1: Aldehyde dehydrogenase 6 family, member A1
ALDH7A1: Aldehyde dehydrogenase 7 family, member A1
ALDH8A1: Aldehyde dehydrogenase 8 family, member A1
ALDH9A1: Aldehyde dehydrogenase 9 family, member A1
AOX1: Aldehyde oxidase 1
AS3MT: Arsenic (+3 oxidation state) methyltransferase
ASMT: Acetylserotonin O-methyltransferase
BAAT: Bile acid CoA: amino acid N-acyltransferase (glycine N-choloyltransferase)
CBR1: Carbonyl reductase 1
CBR3: Carbonyl reductase 3
CBR4: Carbonyl reductase 4
CCBL1: Cysteine conjugate-beta lyase, cytoplasmic
CDA: Cytidine deaminase
CEL: Carboxyl ester lipase

CES1:	Carboxylesterase 1
CES1P1:	Carboxylesterase 1 pseudogene 1
CES2:	Carboxylesterase 2
CES3:	Carboxylesterase 3
CES5A:	Carboxylesterase 5A
CHST1:	Carbohydrate (keratan sulfate Gal-6) sulfotransferase 1
CHST2:	Carbohydrate (N-acetylglucosamine-6-O) sulfotransferase 2
CHST3:	Carbohydrate (chondroitin 6) sulfotransferase 3
CHST4:	Carbohydrate (N-acetylglucosamine 6-O) sulfotransferase 4
CHST5:	Carbohydrate (N-acetylglucosamine 6-O) sulfotransferase 5
CHST6:	Carbohydrate (N-acetylglucosamine 6-O) sulfotransferase 6
CHST7:	Carbohydrate (N-acetylglucosamine 6-O) sulfotransferase 7
CHST8:	Carbohydrate (N-acetylgalactosamine 4-0) sulfotransferase 8
CHST9:	Carbohydrate (N-acetylgalactosamine 4-0) sulfotransferase 9
CHST10:	Carbohydrate sulfotransferase 10
CHST11:	Carbohydrate (chondroitin 4) sulfotransferase 11
CHST12:	Carbohydrate (chondroitin 4) sulfotransferase 12
CHST13:	Carbohydrate (chondroitin 4) sulfotransferase 13
COMT:	Catechol-O-methyltransferase
CYB5R3:	Cytochrome b5 reductase 3
CYP1A1:	Cytochrome P450, family 1, subfamily A, polypeptide 1
CYP1A2:	Cytochrome P450, family 1, subfamily A, polypeptide 2
CYP1B1:	Cytochrome P450, family 1, subfamily B, polypeptide 1
CYP2A6:	Cytochrome P450, family 2, subfamily A, polypeptide 6
CYP2A7:	Cytochrome P450, family 2, subfamily A, polypeptide 7
CYP2A13:	Cytochrome P450, family 2, subfamily A, polypeptide 13
CYP2B6:	Cytochrome P450, family 2, subfamily B, polypeptide 6
CYP2C8:	Cytochrome P450, family 2, subfamily C, polypeptide 8
CYP2C9:	Cytochrome P450, family 2, subfamily C, polypeptide 9
CYP2C18:	Cytochrome P450, family 2, subfamily C, polypeptide 18
CYP2C19:	Cytochrome P450, family 2, subfamily C, polypeptide 19
CYP2D6:	Cytochrome P450, family 2, subfamily D, polypeptide 6
CYP2D7P1:	Cytochrome P450, family 2, subfamily D, polypeptide 7 pseudogene 1
CYP2E1:	Cytochrome P450, family 2, subfamily E, polypeptide 1
CYP2F1:	Cytochrome P450, family 2, subfamily F, polypeptide 1
CYP2J2:	Cytochrome P450, family 2, subfamily J, polypeptide 2
CYP2R1:	Cytochrome P450, family 2, subfamily R, polypeptide 1
CYP2S1:	Cytochrome P450, family 2, subfamily S, polypeptide 1
CYP2W1:	Cytochrome P450, family 2, subfamily W, polypeptide 1
CYP3A4:	Cytochrome P450, family 3, subfamily A, polypeptide 4
CYP3A5:	Cytochrome P450, family 3, subfamily A, polypeptide 5
CYP3A7:	Cytochrome P450, family 3, subfamily A, polypeptide 7
CYP3A43:	Cytochrome P450, family 3, subfamily A, polypeptide 43
CYP4A11:	Cytochrome P450, family 4, subfamily A, polypeptide 11
CYP4A22:	Cytochrome P450, family 4, subfamily A, polypeptide 22
CYP4B1:	Cytochrome P450, family 4, subfamily B, polypeptide 1
CYP4F2:	Cytochrome P450, family 4, subfamily F, polypeptide 2
CYP4F3:	Cytochrome P450, family 4, subfamily F, polypeptide 3
CYP4F8:	Cytochrome P450, family 4, subfamily F, polypeptide 8
CYP4F11:	Cytochrome P450, family 4, subfamily F, polypeptide 11
CYP4F12:	Cytochrome P450, family 4, subfamily F, polypeptide 12
CYP4Z1:	Cytochrome P450, family 4, subfamily Z, polypeptide 1
CYP7A1:	Cytochrome P450, family 7, subfamily A, polypeptide 1
CYP7B1:	Cytochrome P450, family 7, subfamily B, polypeptide 1
CYP8B1:	Cytochrome P450, family 8, subfamily B, polypeptide 1
CYP11A1:	Cytochrome P450, family 11, subfamily A, polypeptide 1
CYP11B1:	Cytochrome P450, family 11, subfamily B, polypeptide 1
CYP11B2:	Cytochrome P450, family 11, subfamily B, polypeptide 2

CYP17A1: Cytochrome P450, family 17, subfamily A, polypeptide 1
CYP19A1: Cytochrome P450, family 19, subfamily A, polypeptide 1
CYP20A1: Cytochrome P450, family 20, subfamily A, polypeptide 1
CYP21A2: Cytochrome P450, family 21, subfamily A, polypeptide 2
CYP24A1: Cytochrome P450, family 24, subfamily A, polypeptide 1
CYP26A1: Cytochrome P450, family 26, subfamily A, polypeptide 1
CYP26B1: Cytochrome P450, family 26, subfamily B, polypeptide 1
CYP26C1: Cytochrome P450, family 26, subfamily C, polypeptide 1
CYP27A1: Cytochrome P450, family 27, subfamily A, polypeptide 1
CYP27B1: Cytochrome P450, family 27, subfamily B, polypeptide 1
CYP39A1: Cytochrome P450, family 39, subfamily A, polypeptide 1
CYP46A1: Cytochrome P450, family 46, subfamily A, polypeptide 1
CYP51A1: Cytochrome P450, family 51, subfamily A, polypeptide 1
DDOST: Dolichyl-diphosphooligosaccharide-protein glycosyltransferase subunit (non-catalytic)
DHRS1: Dehydrogenase/reductase (SDR family) member 1
DHRS2: Dehydrogenase/reductase (SDR family) member 2
DHRS3: Dehydrogenase/reductase (SDR family) member 3
DHRS4: Dehydrogenase/reductase (SDR family) member 4
DHRS7: Dehydrogenase/reductase (SDR family) member 7
DHRS9: Dehydrogenase/reductase (SDR family) member 9
DHRS12: Dehydrogenase/reductase (SDR family) member 12
DHRS13: Dehydrogenase/reductase (SDR family) member 13
DHRSX: Dehydrogenase/reductase (SDR family) X-linked
DPEP1: Dipeptidase 1 (renal)
DPYD: Dihydropyrimidine dehydrogenase
EPHX1: Epoxide hydrolase 1, microsomal (xenobiotic)
EPHX2: Epoxide hydrolase 2, microsomal (xenobiotic)
ESD: Esterase D
FMO1: Flavin containing monooxygenase 1
FMO2: Flavin containing monooxygenase 2
FMO3: Flavin containing monooxygenase 3
FMO4: Flavin containing monooxygenase 4
FMO5: Flavin containing monooxygenase 5
FMO6P: Flavin containing monooxygenase 6 pseudogene
GAL3ST1: Galactose-3-O-sulfotransferase 1
GAMT: Guanidinoacetate N-methyltransferase
GLRX: Glutaredoxin (thioltransferase)
GLYAT: Glycine-N-acyltransferase
GNMT: Glycine N-methyltransferase
GPX1: Glutathione peroxidase 1
GPX2: Glutathione peroxidase 2 (gastrointestinal)
GPX3: Glutathione peroxidase 3 (plasma)
GPX4: Glutathione peroxidase 4
GPX5: Glutathione peroxidase 5
GPX6: Glutathione peroxidase 6 (olfactory)
GPX7: Glutathione peroxidase 7
GSR: Glutathione reductase
GSTA1: Glutathione S-transferase alpha 1
GSTA2: Glutathione S-transferase alpha 2
GSTA3: Glutathione S-transferase alpha 3
GSTA4: Glutathione S-transferase alpha 4
GSTA5: Glutathione S-transferase alpha 5
GSTCD: Glutathione S-transferase, C-terminal domain containing
GSTK1: Glutathione S-transferase kappa 1
GSTM1: Glutathione S-transferase mu 1
GSTM2: Glutathione S-transferase mu 2 (muscle)
GSTM3: Glutathione S-transferase mu 3 (brain)
GSTM4: Glutathione S-transferase mu 4
GSTM5: Glutathione S-transferase mu 5
GSTO1: Glutathione S-transferase omega 1
GSTO2: Glutathione S-transferase omega 2
GSTP1: Glutathione S-transferase pi 1
GSTT1: Glutathione S-transferase theta 1
GSTT2: Glutathione S-transferase theta 2
GSTZ1: Glutathione S-transferase zeta 1
GZMA: Granzyme A (granzyme 1, cytotoxic T-lymphocyte-associated serine esterase 3)
GZMB: Granzyme B (granzyme 2, cytotoxic T-lymphocyte-associated serine esterase 1)
HNMT: Histamine N-methyltransferase
HSD11B1: Hydroxysteroid (11-beta) dehydrogenase 1
HSD17B10: Hydroxysteroid (17-beta) dehydrogenase 10
HSD17B11: Hydroxysteroid (17-beta) dehydrogenase 11
HSD17B14: Hydroxysteroid (17-beta) dehydrogenase 14
INMT: Indolethylamine N-methyltransferase
MAOA: Monoamine oxidase A
MAOB: monoamine oxidase B
METAP1: Methionyl aminopeptidase 1
MGST1: Microsomal glutathione S-transferase 1
MGST2: Microsomal glutathione S-transferase 1
MGST3: Microsomal glutathione S-transferase 3
NAA20: N(alpha)-acetyltransferase 20, NatB catalytic subunit

NAT1:	N-acetyltransferase 1 (arylamine N-acetyltransferase)
NAT2:	N-acetyltransferase 2 (arylamine N-acetyltransferase)
NNMT:	Nicotinamide N-methyltransferase
NQO1:	NAD(P)H dehydrogenase, quinone 1
NQO2:	NAD(P)H dehydrogenase, quinone 2
PNMT:	Phenylethanolamine N-methyltransferase
PON1:	Paraoxonase 1
PON2:	Paraoxonase 2
PON3:	Paraoxonase 3
POR:	P450 (cytochrome) oxidoreductase
PTGES:	Prostaglandin E synthase
PTGS1:	Prostaglandin-endoperoxide synthase 1 (prostaglandin G/H synthase and cyclooxygenase)
PTGS2:	Prostaglandin-endoperoxide synthase 2 (prostaglandin G/H synthase and cyclooxygenase)
SAT1:	Spermidine/spermine N1-acetyltransferase 1
SMOX:	Spermine oxidase
SOD1:	Superoxide dismutase 1, soluble
SOD2:	Superoxide dismutase 2, mitochondrial
SULT1A1:	Sulfotransferase family, cytosolic, 1A, phenol-preferring, member 1
SULT1A2:	Sulfotransferase family, cytosolic, 1A, phenol-preferring, member 2
SULT1A3:	Sulfotransferase family, cytosolic, 1A, phenol-preferring, member 3
SULT1B1:	Sulfotransferase family, cytosolic, 1B, member 1
SULT1C1:	Sulfotransferase family, cytosolic, 1C, member 1
SULT1C2:	Sulfotransferase family, cytosolic, 1C, member 2
SULT1C3:	Sulfotransferase family, cytosolic, 1C, member 3
SULT1C4:	Sulfotransferase family, cytosolic, 1C, member 4
SULT1E1:	Sulfotransferase family 1E, estrogen-preferring, member 1
SULT2A1:	Sulfotransferase family, cytosolic, 2A, dehydroepiandrosterone (DHEA)-preferring, member 1
SULT2B1:	Sulfotransferase family, cytosolic, 2B, member 1
SULT4A1:	Sulfotransferase family 4A, member 1
SULT6B1:	sulfotransferase family, cytosolic, 6B, member 1
TBXAS1:	Thromboxane A synthase 1 (platelet)
TPMT:	Thiopurine S-methyltransferase
TST:	Thiopurine S-methyltransferase
UCHL1:	Ubiquitin carboxyl-terminal esterase L1 (ubiquitin thiolesterase)
UCHL3:	Ubiquitin carboxyl-terminal esterase L3 (ubiquitin thiolesterase)
UGT1A1:	UDP glucuronosyltransferase 1 family, polypeptide A1
UGT1A3:	UDP glucuronosyltransferase 1 family, polypeptide A3
UGT1A4:	UDP glucuronosyltransferase 1 family, polypeptide A4
UGT1A5:	UDP glucuronosyltransferase 1 family, polypeptide A5
UGT1A6:	UDP glucuronosyltransferase 1 family, polypeptide A6
UGT1A7:	UDP glucuronosyltransferase 1 family, polypeptide A7
UGT1A8:	UDP glucuronosyltransferase 1 family, polypeptide A8
UGT1A9:	UDP glucuronosyltransferase 1 family, polypeptide A9
UGT1A10:	UDP glucuronosyltransferase 1 family, polypeptide A10
UGT2A1:	UDP glucuronosyltransferase 2 family, polypeptide A1, complex locus
UGT2A3:	UDP glucuronosyltransferase 2 family, polypeptide A3
UGT2B10:	UDP glucuronosyltransferase 2 family, polypeptide B10
UGT2B11:	UDP glucuronosyltransferase 2 family, polypeptide B11
UGT2B15:	UDP glucuronosyltransferase 2 family, polypeptide B15
UGT2B17:	UDP glucuronosyltransferase 2 family, polypeptide B17
UGT2B28:	UDP glucuronosyltransferase 2 family, polypeptide B28
UGT2B4:	UDP glucuronosyltransferase 2 family, polypeptide B4
UGT2B7:	UDP glucuronosyltransferase 2 family, polypeptide B7
UGT3A1:	UDP glycosyltransferase 3 family, polypeptide A1
UGT8:	UDP glycosyltransferase 8
XDH:	Xanthine dehydrogenase

28.1 OVERVIEW

The term "*asthma*" originates from the Greek, meaning short of breath. The term was refined in the nineteenth century by Henry Hyde Salter (1823–1871) with the publication of his *magnum opus* "On Asthma and its Treatment," based on his experience of hundreds of cases. Salter defined asthma as "Paroxysmal dyspnea of a peculiar character with intervals of healthy respiration between attacks," which summarizes the episodic features and symptoms of the disease.

The use of the word *asthma* to define disease has recently attracted criticism [1], and it is now realized that asthma covers a host of overlapping, interrelated, and variable features, including abnormalities of airway inflammation, airway smooth-muscle function, airway immunology, and the airway epithelium [2], all of which contribute to the disease process and lead to symptoms of wheeze, cough, breathlessness, and chest tightness. These symptoms can change over time with or without treatment. Episodes of exacerbation (asthma attacks), which require treatment with systemic steroids can also occur and account for a large part of the disease burden.

A great deal of progress has been made in understanding asthma, with the identification of different clinical phenotypes (i.e., clinically relevant properties) and disease endotypes (pathobiological mechanisms behind disease features). Medicines applicable to an individual rather than to the population are being developed, and a stratified medicinal approach is being applied to both treatment design and disease management. Our understanding of asthma phenotypes remains incomplete because of a lack of large longitudinal studies, the difficulties caused by the impact of treatment on the results of unbiased approaches to disease stratification, a lack of a clear disease definition, and clinical investigations that have poor diagnostic utility. Understanding asthma and the diseases present under this

Handbook of Pharmacogenomics and Stratified Medicine. http://dx.doi.org/10.1016/B978-0-12-386882-4.00028-1

umbrella definition will require integrating bench and bedside approaches using data from ongoing genomic and proteomic profiling studies of large, well-characterized asthma populations—such as the current EU-wide UBIOPRED study (formally, "Unbiased Biomarkers in Prediction of Respiratory Disease Outcomes")—with feedback to improved *in vitro* and *in vivo* animal models and human studies.

28.1.1 Definition

The *International Consensus Report on the Diagnosis and Treatment of Asthma* defines asthma as "a chronic inflammatory disorder of the airways in which many cells play a role, including mast cells and eosinophils. In susceptible individuals this inflammation causes symptoms which are usually associated with widespread, but variable, airflow obstruction that is often reversible either spontaneously or with treatment, and causes an associated increase in airway responsiveness to a variety of stimuli." The interaction of these features determines the clinical manifestations and severity of the disease and the response to treatment [3]. How these features relate to each other, how they are best measured, and how they contribute to clinical manifestations of the disease remains unclear. Age of disease onset also complicates understanding, although there are many shared features in the diagnosis of asthma in children and in adults, there are also important differences. The differential diagnosis, the natural history of wheezing illnesses, and the ability to perform certain investigations are all influenced by age [4].

28.1.2 Incidence/Prevalence

According to the World Health Organization (WHO), between 100 and 150 million people around the globe (roughly equivalent to the population of the Russian Federation) suffer from asthma. Worldwide, deaths from asthma have reached more than 180,000 annually. Overall, asthma affects 5–10% of the population in many developed countries. One study found that the annual estimated incidence of physician-diagnosed asthma ranged from 0.6–29.5 per 1000 persons. Risk factors for incident asthma among children include male gender, atopic sensitization, parental history of asthma, early-life stressors and infections, obesity, and exposure to indoor allergens, tobacco smoke, and outdoor pollutants. Risk factors for adult-onset asthma include female sex, airway hyper-responsiveness, lifestyle factors, and work-related exposures.

28.1.3 Cost

While the exact cost of asthma care is difficult to determine, a 2009 systematic review [5] found eight national studies reporting a national total cost. The total costs in 2008 in U.S. dollars were high and varied widely: Singapore, $49.36M; Canada, $654M; Switzerland, $1413M; Germany, $2740M; United States, $8256M. Although the costs of asthma care vary by country, it is estimated that worldwide the number of disability-adjusted life years (DALYs) lost from asthma is about 15 million per year. Worldwide asthma accounts for around 1% of all DALYs lost, which reflects the high prevalence and severity of asthma. The number of asthma-caused lost DALYs is similar to that for diabetes, cirrhosis of the liver, and schizophrenia. Costs are related to other factors, including asthma control, demographics, medical history, and doses of inhaled corticosteroid (ICS) prescribed [6]. Improving asthma control is associated with decreased cost.

28.2 CLINICAL ASPECTS

28.2.1 Symptoms

Asthma classically causes wheeze, cough, chest tightness, and breathlessness (dyspnoea). The pattern of symptoms can be a clue to the diagnosis. Episodic symptoms worse at night and in the early morning, or in response to exercise, allergen and cold air exposure, or after taking aspirin or beta blockers are very suggestive of asthma. Moreover, symptoms that are relieved by bronchodilators point toward asthma as the underlying cause.

Symptoms that lower the probability of asthma include those of prominent dizziness, light-headedness, and peripheral tingling (all point toward dysfunctional breathing); a chronic productive cough in the absence of wheeze or breathlessness (more likely bronchiectasis); a repeatedly normal physical examination of chest when symptomatic; and voice disturbance, symptoms with colds only, or a significant smoking history. Taking a detailed patient history and recording spirometry when the patient is symptomatic is crucial to the accurate classification of the disease. There are several differential diagnoses that must be considered when making a diagnosis of asthma. These are outside the scope of this chapter. A good guide to the clinical diagnosis and management of asthma are the British Thoracic Society Asthma guidelines, which are updated regularly and are available at www.brit-thoracic.org.uk/clinical-information/asthma/.

Triggers for asthma symptoms include allergens (proteins) derived from, among others, house dust mite (HDM), cat and dog dander, cockroach, and fungi, especially *aspergillus fumigatus*. There are numerous other nonallergic symptom triggers, including weather and atmospheric change, air pollution, exercise, menstruation, emotion and laughter, viral infection, gastroesophageal reflux, and rhinitis. Various occupations can both cause and worsen asthma (e.g., welding, baking, paint spraying).

Asthma symptoms often overlap with other allergies, including oral allergy syndrome and food allergies. Delineating between causes of symptoms can be difficult. If a specific aeroallergen is identified that triggers asthma (classically tree or grass pollen), a course of either sublingual or subcutaneous desensitization can be undertaken to reduce symptoms on exposure to that specific allergen.

There are multiple other symptom triggers that can include both allergic and non-allergic mechanisms; examples include exposure to chemicals, such as perfumes, paint and bleach, plants (e.g., *Ligustrum vulgare*-privet hedges), salicylates, and sulphites.

28.2.2 Associated Comorbidities and Confounders

Multiple factors have been shown to either directly cause or worsen symptoms of asthma [4]. These are listed in Box 28.1. Other factors not directly related to the disease can worsen symptoms and are associated with more frequent exacerbations. These include dysfunctional breathing, vocal cord dysfunction, psychosocial problems, and poor adherence to treatment regimes [4].

Other forms of asthma are recognized, among them occupational, exercise-induced, and pregnancy-related asthma. These subdivisions are somewhat arbitrary, but may have different causes, prognoses, and complexities. For example, occupational asthma includes that triggered by IgE-mediated mechanisms, that due to specific agents with unclear pathophysiology, and that secondary to irritants (also known as RADS-reactive airways dysfunction syndrome). Underlying asthma can also be made worse by occupational exposure (work-aggravated).

Most experts regard exercise-induced asthma as a different disease, albeit one resulting in similar symptoms. Exercise-induced asthma is often diagnosed with different investigations, including eucapnic voluntary hyperventilation or exercise testing. It is associated with certain sports (swimming and cross country skiing in particular) and has a unique pathophysiology directly related to damage of the airway epithelium.

BOX 28.1 Factors Associated with the Triggering or Exacerbating of Asthma

Atopy/allergy (HDM, animal fur, pollens, etc.)
Viral infection
Bacterial infection
Occupation
Medication: beta blockers; nonsteroidal anti-inflammatories
ABPA
Obesity
Gastro-esophageal reflux disease
Hormonal changes: pregnancy; menstruation; menarche
Bronchiectasis
Smoking
Weather changes
Stress/emotion
Exercise

Asthma control can deteriorate in pregnancy, due to both hormonal effects and the physical effects of a gravid uterus on diaphragm and respiratory muscle function. Pregnancy can also impact treatment decisions. Leukotriene modifiers are generally contraindicated, and the health of the fetus as well as that of the mother needs to be considered.

Poor adherence is probably the biggest single issue affecting asthma control. Studies have shown that people with asthma over-report use of ICS; one study found that although 95% of responders said they used their inhalers, only 58% actually did. Adherence to ICS therapy is associated with a lower rate of death, whereas increasing use of reliever (salbutamol/bricanyl) medication, which improves symptoms but does not treat underlying airway inflammation, is associated with increased mortality [7,8].

A 2010 report entitled *Evaluation of the Scale, Causes and Costs of Waste Medicines: Report of DH funded national project* (Trueman et al. York Health Economics Consortium and University of London School of Pharmacy, 2010) put figures to the possible cost benefits from improving asthma treatment adherence in the United Kingdom. It estimated the resulting net benefit associated with compliance to be £2250 per patient, with a reduction in expected annual treatment costs of approximately £75 per patient per year. Based on an asthma point prevalence of 5.8%, the findings suggest that there are almost 1.8 million asthmatics in the United Kingdom who are noncompliant. If interventions were available to change the behavior of all partially compliant medicine users to raise the percentage to 80% or more, the report estimated that over £130 million in treatment cost savings could be realized in the United Kingdom alone. A more modest target of doubling current compliance rates would result in savings of approximately £90 million per year.

28.2.3 Asthma Control

The aim of asthma treatment is to improve symptoms, maintain lung function, and prevent exacerbations. From a patient's perspective, these are simple aims, but for the purposes of study design and treatment trials they do not address the complexity of the disease process. Accordingly, guidelines now specifically address asthma control (symptoms and lung function) and severity (need for treatment) separately. The current Global Initiative for Asthma (GINA) guidelines assess levels of control based on daytime symptoms, limitation of activities, nocturnal symptoms/awakening, need for reliever/rescue treatment, lung function (PEF or FEV_1), and exacerbations [9] (Table 28.1). Aspects of

TABLE 28.1 Global Initiative for Asthma Classification of Asthma Severity

Step	Symptoms/Day	Symptoms/Night	PEF or FEV_1	PEF Variability
Step 1 (intermittent)	Fewer than once/week; asymptomatic, normal PEF between attacks	Two or fewer/month	80% or more	Less than 20%
Step 2 (mild persistent)	More than once/week, fewer than once/day; attacks may affect activity	>2 times a month	>/=80%	20–30%
Step 3 (moderate persistent)	Daily; attacks affect activity	More than once/week	60%–80%	More than 30%
Step 4 (severe)	Continuous; limited physical activity	Frequent	60% or less	More than 30%

Note: Multiple factors, including prevalence of day/night symptoms, airflow limitation, and pulmonary function variability, categorize disease severity. PEF—peak expiratory flow; FEV_1—forced expiratory volume in one second.

control are measured by validated questionnaires, including the Asthma Quality of Life Questionnaire and the Asthma Control Questionnaire.

Treatment steps are defined by the treatment level required to maintain asthma control (Table 28.1), with patients at steps 1–2 having well-controlled asthma requiring little treatment, and patients at step 4 having poorly controlled asthma despite four or five different drugs. The step approach is similar to that used by the British Thoracic Society (BTS) Guidelines [4].

28.2.4 Exacerbations

28.2.4.1 Definition

Asthma is a variable disease both temporally and clinically. There is also overlap between symptoms and exacerbations. This overlap was the subject of a recent consensus document that defined asthma exacerbations as "events characterized by a change from the patient's previous status." Severe exacerbations are "events that require urgent action on the part of the patient and physician to prevent a serious outcome, such as hospitalization or death from asthma," and moderate asthma exacerbations are "events that are troublesome to the patient, and that prompt a need for a change in treatment, but that are not severe…clinically identified by being outside the patient's usual range of day-to-day asthma variation" [10]. The most practical definition of an asthma exacerbation is probably an episode of worsening symptoms not responding to increasing bronchodilator therapy. This definition was employed in an elegant study on the time course of peak flow changes [11]. For the purposes of clinical studies, most authors define *exacerbation* as the need for rescue courses of systemic corticosteroids (prednisolone/prednisone).

28.2.4.2 Cost

Although the majority of patients with asthma are treated and investigated in primary care settings, the main burden of asthma is due to its severe form (i.e., step 4) and exacerbations. Using the United Kingdom as an example (population 60 million), asthma is responsible for more than 1200 deaths per year and for over 50,000 hospital admissions, with an annual expenditure of £800 million on pharmaceutical costs alone.

It was recently estimated that a patient controlled at the mildest end of the spectrum (British Thoracic Society (BTS) guidelines: step 1 with no exacerbations) would cost 50 times less to provide his or her package of care than would a patient at the worst end of the spectrum (BTS guidelines: step 5 with exacerbations) [12]. It is also calculated that 5% of asthma patients are responsible for at least 50% of the total healthcare burden [4]; the most expensive individual cost is an ICU admission (BTS level 3) due to a life-threatening exacerbation. In the U.S. more than half (53%) of asthma sufferers in 2008 had an asthma attack, and of these half of the children and one-third of the adults missed school or work because of it; on average, children missed four days of school and adults missed five days of work.

28.2.4.3 Pathogenesis

Exacerbation pathogenesis is not fully understood. Although research has focused on infective agents, especially viral, there may be other explanations.

Asthma exacerbations are associated with both inflammatory and immunological cell infiltration. The inflammatory cell infiltrate is composed of varying numbers of eosinophils, neutrophils, and lymphocytes. This airway inflammation, combined with smooth-muscle hypertrophy and thickening of the lamina reticularis, is accentuated by mucus plugs, serum protein deposition, inflammatory cell and cellular debris, leading to blockage of the airway (airflow obstruction) and wheeze.

Viral Agents

Approximately 80% of exacerbations are associated with respiratory tract viral infections, with rhinovirus responsible for about two-thirds of cases [13]. Asthmatic subjects also have much more severe lower respiratory tract illness with rhinovirus infection than do healthy control subjects. The mechanism for this is not fully understood. Infection induces inflammation, increasing levels of neutrophils, eosinophils, CD41+ cells, CD81+ cells, and mast cells through increased mRNA expression and translation of IL-6, IL-8, IL-16, eotaxin, IFN-γ-induced protein 10 (IP-10), Chemokine (C-C motif) ligand 5 (CCL5/RANTES), and other proinflammatory cytokines. Other viruses implicated in exacerbations include enterovirus, coronavirus, influenza, parainfluenza, respiratory syncytial virus, metapneumovirus, adenovirus and bocavirus [14]. Although influenza vaccination is recommended for all individuals with asthma, there is currently no hard evidence that this improves outcomes.

Bacterial Agents

Bacterial infection has also been implicated in asthma exacerbation. Individuals with asthma have an increased risk of invasive pneumococcal disease [15], and an increased frequency of detection of *Chlamydophila pneumoniae* [16]. One study found *Mycoplasma pneumoniae* infection in 20% of patients hospitalized for severe asthma [17]. Several trials have evaluated the role of macrolide antibiotics in treating and preventing asthma exacerbations. One study randomized adults with exacerbations to the ketolide antibiotic telithromycin or placebo; the telithromycin group had a small but significant improvement in symptoms and lung function from exacerbation to the end of treatment [18]. Further studies of macrolide antibiotics (which have immunomodulatory as well as antibiotic properties) are under way, but as yet macrolide antibiotics are not recommended by international asthma guidelines.

New techniques for assessing the airway bacterial microbiota have established that the airways are not normally sterile, and may permit the role of bacterial infection in airways disease to be further delineated. A recent study found that pathogenic *Proteobacteria*, particularly *Haemophilus* species, were much more frequent in the bronchi of patients with asthma or COPD than in controls [19].

Allergen Exposure

Prolonged exposure to aeroallergens can result in chronic airway inflammation via Th2-driven IgE mechanisms. This immunological reaction may intensify airway inflammation, increase inflammatory cell activation, and stimulate mucus glands to hypersecrete, leading to airway obstruction. Studies of bronchoalveolar fluid before and after allergen challenge show eosinophilic inflammation as the major airway response, associated with late-phase responses of airflow obstruction. In addition, IL5 and IL13 are significantly raised. Exposure to seasonal allergens has been implicated in sudden asthma-related deaths; HDM, cat, and cockroach allergen sensitization are risk factors for emergency treatment [20]. Grass pollen sensitization, or "thunderstorm asthma," has also been associated with epidemics of exacerbations [21].

Fungal Exposure

Fungal allergens are found both outdoors and indoors, and sensitivity to them is a risk factor for the development, persistence, severity, and mortality associated with asthma. Individuals with asthma are often sensitized to fungi such as *Cladosporium* species, *Alternaria* species, *Penicillium* species, and *Candida* species [22].

Alternaria species sensitization and exposure are associated with symptoms and a 200-fold increased risk of respiratory arrest in subjects with asthma [23]. Fungal exposures may worsen disease by different mechanisms; fungal-associated proteases may lead to the development of allergic airway inflammation along with IgE-mediated responses; fungal allergen-induced asthmatic reactions evoke an IL5 response with increased eosinophil recruitment and degranulation [24].

The relationship between fungal exposure and asthma is complicated by the degree of sensitivity to fungal allergens and the resultant allergy. A specific disease entity called allergic bronchopulmonary aspergillosis (ABPA) exists in which colonization of the respiratory tract with the ubiquitous *Aspergillus fumigatus* is associated with an increased allergic response (both type 1 and type 3) and severe asthma exacerbations. Trials in both ABPA and a related disease, severe asthma with fungal sensitization (SAFS), have shown some benefit with the oral antifungal itraconazole [25], but good-quality trial data are lacking.

28.2.5 Diagnosis

Unlike other chronic conditions, there is no gold standard for the diagnosis of asthma. Although tests of airway function can be used to diagnose and study different aspects of airway disease (airway inflammation/airway hyper-responsiveness), diagnosis still depends on the presence of specific symptoms, which include wheeze, cough, chest tightness, and difficulty breathing. These symptoms are often variable, worse at night, or worse in response to triggers. They often respond to asthma therapy and may be associated with atopy/allergy and a family history of similar problems.

The lack of a gold standard affects clinical provision and studies alike; most estimates suggest that asthma is wrongly diagnosed in approximately 30% of patients [26]. The development of a cheap and reliable noninvasive test that can diagnose asthma is seen as the holy grail for diagnosis-based research.

28.2.5.1 *Airflow Limitation*

Measurements of airflow limitation provide an assessment of the severity, reversibility, and variability of airflow obstruction, and can help confirm the diagnosis of asthma. Spirometry (Forced Expiratory Volume in 1 second (FEV_1), Forced Vital Capacity (FVC), and FEV_1/FVC) is the preferred method of measuring airflow limitation, as it is more repeatable and less effort dependent than peak flow. A FEV_1/FVC ratio of less than 0.7 is consistent with a diagnosis of airflow obstruction, and an increase in FEV_1 of >12% (or >200 ml) after administration of a short-acting bronchodilator indicates reversible airflow limitation consistent with asthma [27]. Importantly, most asthma patients will not exhibit reversibility at each assessment, and repeated testing is advised to confirm a diagnosis. Consequently, an absent response to bronchodilators does not exclude asthma.

Peak expiratory flow (PEF) measurements can be used to monitor asthma. They are ideally compared to the patient's own previous best measurements using his or her own peak flow meter. An improvement of 60 L/min (or >20% of the prebronchodilator PEF) after inhalation of a bronchodilator, or diurnal variation in PEF of more than 20% (with twice-daily readings, more than 10%), suggests poorly controlled asthma.

28.2.5.2 *Other Diagnostic Approaches*

Other approaches have been utilized to diagnose asthma, both to confirm a formal diagnosis and to identify corticosteroid response. These approaches include noninvasive measurements of airway inflammation or assessment of airway hyper-responsiveness. Measuring airway inflammation is relatively easy, either using techniques to induce sputum and then counting the differential eosinophil and neutrophil cell numbers present, or by measuring the fraction of nitric oxide (NO) present in the exhaled breath (F_ENO) using portable chemical analyzers.

Airway hyper-responsiveness can be assessed by several different methods. All are designed to provoke bronchoconstriction, which is measured using spirometry. The concentration (or dose) at which bronchoconstriction occurs is then used to categorize the degree of airway responsiveness and the presence or absence of asthma. Although these tests are widely employed in research settings, their use in a clinical setting is hampered by their varying sensitivity and specificities for asthma diagnosis [4], as both airway inflammation and airway hyper-responsiveness can be present in healthy individuals without symptoms.

28.2.5.3 *Pediatric Asthma*

The symptoms of asthma in children are recurrent wheezing, cough, difficulty breathing, and chest tightness. Evaluation of these symptoms is critical to the diagnosis, treatment, and outcome measures used in clinical studies; however, asthma triggers and inflammatory cell type are increasingly used to define childhood asthma phenotypes.

Pediatric asthma is complicated by wide variations in symptom prevalence. The majority of children with asthma have mild or moderate disease; 5% of all asthmatic children have chronic symptoms and/or recurrent exacerbations, despite maximum treatment with conventional medications [28]. Asthma in childhood is heterogeneous in several ways, including etiology, clinical presentation, and response to treatment. Several attempts have been made to stratify treatment on the basis of different asthma phenotypes in children, with varying degrees of success. Stratifying treatments in pediatric asthma is more complicated because of patient age and the inability (dependent on age) to perform more complicated or invasive tests.

Etiology

In children, the onset and progression of asthma result from a complex interplay between genetic background and environmental exposures. The complexity is confounded by wheezing illnesses consisting of several distinct disease entities, with no general agreement on their number or underlying mechanisms [29].

Among the environmental factors that influence the risk of asthma are viral and bacterial respiratory infections. Exposure to environmental tobacco smoke is also associated with increased rates of early viral illnesses. Other factors associated with the risk of wheeze include physical factors associated with increased breathing (exercise, laughing, crying, and excitement) or allergens (aeroallergens and food allergens). There are considerable age-related changes in the relative importance of trigger factors for wheeze in children.

Human rhinovirus (HRV) has been implicated in both the etiology of asthma and exacerbations; infants who have HRV infections with wheezing are at a significantly increased risk for subsequent asthma, and over 50% of childhood asthma exacerbations are triggered by HRV. It is important to note that exposure to HRV does not lead to wheezing illness in all children, nor does wheezing illness result in asthma in all cases, suggesting that the host genotype also plays a role. A recent study of two cohorts of children with asthma found that variants at the 17q21 locus were associated with asthma in children who had HRV wheezing illnesses, implicating an interaction between HRV wheezing illness in early childhood and the 17q21 genotype (see Section 28.3.2).

Clinical Presentation

The presentation of asthma symptoms and exacerbations in childhood also varies. Some children have frequent exacerbations with few daily symptoms, while others have recurrent symptoms without airway inflammation and exacerbations. Other diseases coexist with childhood asthma, including gastroesophageal reflux disease, severe asthma with fungal sensitization, obesity, and vocal cord dysfunction. Targeting these coexisting disorders has met with varying clinical success [30].

28.3 ASTHMA PATHOPHYSIOLOGY

28.3.1 Biological Basis

An important component of the development of asthma is the inflammatory cascade. This involves the infiltration of a number of inflammatory cells, such as eosinophils, neutrophils, B- and T-lymphocytes, macrophages, mast cells, dendritic cells, and basophils, into the airway, and the release of inflammatory mediators (e.g., leukotrienes, histamine, cytokines, and chemokines) by airway, structural cells (including epithelial, smooth-muscle, endothelial, and fibroblast cells). However, since the degree of inflammation in asthma is not directly related to asthma severity, this suggests that other factors, such as structural changes in the airways, also play a role in disease modulation and progression. These structural changes have been termed *airway remodeling* and may exist in the presence or absence of inflammatory mechanisms in the airway [31].

28.3.1.1 Inflammatory Response

The inflammatory response in asthma is a result of excessive activation of mast cells in the airway, where in the early response to allergen challenge, degranulation of mast cells results in the release of a number of proinflammatory factors such as IL4, leukotrienes, and histamine. This causes an immediate hypersensitivity response that in turn leads to airway narrowing. The concomitant release of other inflammatory factors such as cytokines and chemokines from the same mast cells provides an optimal environment for recruitment to the airways of other inflammatory cells such as eosinophils, basophils, neutrophils, and T-lymphocytes.

Once in the airways, these cells act in tandem with allergen-activated macrophages, resulting in what is termed the late asthmatic response (occurring at 4–8 hours post-challenge). Here, through the action of a number of released potent immunomodulators (e.g., TNFα, IL3, IL4, IL5, and IL13), airway narrowing occurs. This may occur in periods that last more than 24 hours. Of the inflammatory cells involved in the asthmatic response, it is the infiltration of eosinophils that is considered characteristic of the asthmatic phenotype, particularly that of mild/moderate allergic asthma (Figure 28.1). For a more extensive description of inflammatory mechanisms underlying allergic asthma see Hodge & Sayers [32].

Although inflammation in asthma has been extensively studied, the relationship between inflammation and clinical symptoms of asthma is still unclear. This may be partially explained by a possible link between airway inflammation and airway hyper-responsiveness [33]. Here, airways become more susceptible to sensitizing agents, which would otherwise be unable to trigger an airway response, because of (a) increased release of mediators such as histamine and leukotrienes, (b) abnormal smooth-muscle behavior, and (c) airway thickening.

28.3.1.2 Airway Remodeling

Airway remodeling plays an important role in asthma pathogenesis. Airway structural changes characteristic of airway remodeling occur because of prolonged airway inflammation. Here, prolonged release of inflammatory factors results in:

- Thickening of the smooth-muscle bronchial walls, leading to airway narrowing
- Denudation of the bronchial epithelium
- Hyperplasia and hypertrophy of the airway smooth-muscle
- Hyperplasia and hypertrophy of the epithelial goblet cells, resulting in the formation of large mucus plugs liable to occlude the airway and increase airway hyper-responsiveness

Airway remodeling also involves changes occurring in the extracellular matrix and its constituent proteins (collagens I/III/IV, fibronectin, and laminin) and structural changes such as angiogenesis, vasodilation, increased airway blood flow, and changes in autonomic neurological function [34].

The development of asthma results in a degree of airway remodeling. The structural changes that define airway remodeling are an important feature in asthmatic airways, where even in newly diagnosed asthma patients, a degree of structural change can be identified in the bronchial wall [35]. Airway remodeling can be defined as a process of sustained disruption and modification of structural cells and tissues leading to the development of a new airway wall morphology [36]. Airway remodeling (Figure 28.2) is initiated either through various inflammatory pathways, highlighting the importance of the inflammatory pathway [37], or through bronchial hyper-responsiveness, where airway remodeling occurs independently of inflammation [38].

28.3.2 Genetic Basis

Our understanding of the extent and nature of genetic variation in the human genome has dramatically improved since the publication of the first draft genome sequence in 2001,

FIGURE 28.1 **Asthma pathophysiology.** Exposure to allergens—for example, *Dermatophagoides pteronyssinus* 1 (Der p1) and *Dactylis glomerata* (Dacg1)—originating from various sources, including pollen, house dust mite, and mold, are taken up by dendritic cells, B-lymphocytes, epithelial cells, and macrophages, which present the antigens to T-lympocytes. This activates the T-lymphocytes to produce cytokines that regulate immunoglobulin E (IgE) production by the B-lymphocytes. Bound IgE activates mast cells in the airways. Activated mast cells initially release a number of factors, including IL4, leukotrienes, and histamine, that cause airway hyper-responsiveness and result in an early response to allergen stimulus via bronchoconstriction. The concurrent release of cytokines and chemokines from the mast cell recruits eosinophils, basophils, and T-lymphocytes to the airway. These cells, in association with T cell-activated neutrophils and with antigen stimulated macrophages, release chemokines and leukotrienes over an extended period of time, resulting in a late response to allergen stimulus via bronchoconstriction. Prolonged stimulation of the late-response factors ultimately leads to the airway structural changes such as mucus hypersecretion, myofibroblast, and airway smooth-muscle proliferation, which are common to the asthmatic lung.

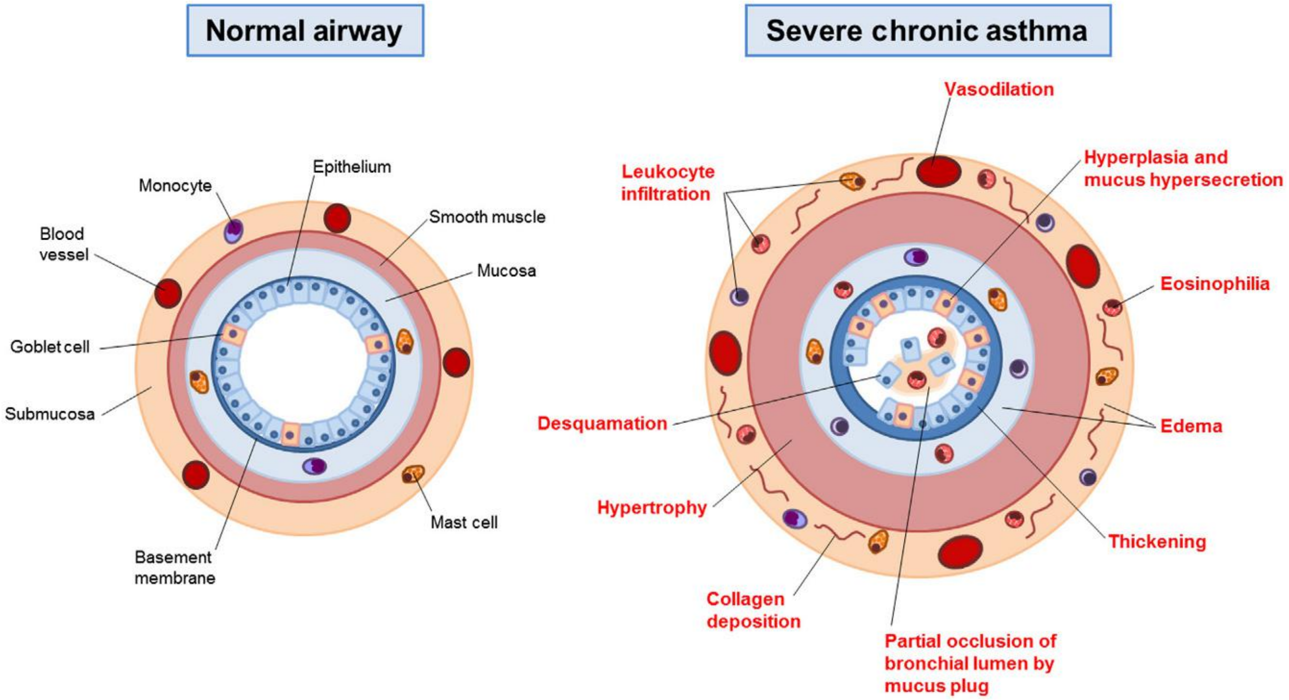

FIGURE 28.2 **Asthmatic airway pathology.** This schematic comparison of a normal airway with that observed in severe chronic asthma indicates histological changes that accompany recurring inflammation seen over time. Unlike that from the unaffected individual, the bronchial mucosa from the severe asthmatic displays thickening of the basement membrane, airway smooth-muscle hypertrophy, leukocyte infiltration, epithelial cell desquamation, goblet cell hyperplasia in the epithelial lining accompanied by mucus hypersecretion, and plugging of the bronchial lumen, as well as edema and collagen deposition in the submucosal area. (Not drawn to scale.) *Source: Reproduced with permission from Hodge and Sayers* [32].

and it continues to improve exponentially with initiatives such as the 100,000 Genomes project, which aims to genome-sequence this number of UK subjects, and the Encyclopedia of DNA Elements Consortium (ENCODE), an initiative to identify the genome's regulatory regions. Recent figures suggest that more than 6.9 million single-nucleotide polymorphisms (SNPs) or single-base-pair changes exist in a genome consisting of 3 billion base pairs. Similarly there is a growing realization that deletions, insertions, and expansions of tandem repeats also represent significant variation. These genetic polymorphisms are found throughout the genome and have the potential to influence gene function in several ways leading to human disease: (1) a coding-region nonsynonymous polymorphism can alter the amino acid sequence and structure/function of the protein; (2) a polymorphism can introduce a stop codon leading to the production of a nonfunctional protein; and (3) a polymorphism in a regulatory region can regulate the expression levels of a gene.

28.3.2.1 A Complex Genetic Disorder

It has long been known that atopic diseases such as asthma run in families. In 1916, using 621 atopic probands and 76 nonatopic controls and their respective families, it was shown that 48.4% of atopic probands had a family history of atopy, compared with 14.5% in the control population [39]. Similarly, a study of 176 families showed a very high concordance of asthma, hayfever, and eczema in parents and children [40]. Twin studies have been useful in identifying a significant concordance of asthma that is higher in monozygotic twins (identical genotype) versus dizygotic twins (on average sharing half of their genes). In the largest study to date, using 11,688 Danish twin pairs, it was suggested that 73% of susceptibility to asthma was genetic, with a substantial environmental component [41]. More recent studies suggest hereditability estimates of 35–95% for asthma [42].

Therefore, asthma is considered a complex genetic disorder and, in contrast to single-gene disorders (e.g., cystic fibrosis), involves multiple genes, with expression influenced by both genetic and environmental factors. Multiple environmental factors are important in asthma development, including tobacco smoke exposure, respiratory viral infections, antibiotic use, diet, and allergen exposure. Gender and ethnic background also make a significant contribution. This complex mode of inheritance combined with the heterogeneity in the presentation of the disease has made gene discovery a challenge. Early studies investigated inheritance through families containing multiple affected children, using linkage analyses and candidate gene approaches based on biology or location in the genome. However, the

GWAS look at the frequency of a large number of common variants between cases and controls. Both approaches lead to novel gene discovery. (Candidate gene approaches omitted for clarity.)

reproducibility of these findings was disappointing primarily because of inadequate power, subject heterogeneity (different phenotype definition), population stratification, and multiple testing without correction.

More recently, hypothesis-free genome-wide association studies (GWAS), which examine association with typically 500,000+ common (>5% frequency) polymorphisms spanning the genome in cases and controls, using very stringent statistical thresholds (Figure 28.3), have been very successful. Via these multiple approaches, over 190 asthma genes have been described in more than 1000 publications. The major reproducible findings for asthma follow below (for more comprehensive reviews see [42,43]). Although this chapter focuses on the genetics of asthma diagnosis, subphenotypes in asthma (e.g., atopy, serum total IgE levels, and lung function (e.g., FEV_1)) have also been investigated for genetic influences.

28.3.2.2 Genes Identified by Positional Cloning (1980s and 1990s)

Positional cloning involves linkage analyses (region or whole genome) followed by fine mapping using association. Linkage analysis uses family data to follow the transmission of genetic information spanning the entire genome (commonly short tandem repeat markers) across generations. These data are used to determine if a genetic marker is close to, or linked with, a gene involved in a particular disease using families with multiple affected children. Once a specific chromosomal region has been identified in this hypothesis-free approach, SNPs spanning the region are tested to see if they are more common in people with asthma compared to people without. The first gene to be identified with confidence using positional cloning was disintegrin and metalloprotease 33 (*ADAM33*) [44].

Using a cohort of 460 families, linkage was demonstrated to a locus on chromosome 20p13 for asthma, bronchial hyper-responsiveness (BHR), and total IgE levels. Subsequently, polymorphisms spanning *ADAM33* were associated with asthma in the second stage. *ADAM33* is thought to contribute to airway remodeling via its enzymatic functions. Using positional cloning, multiple genes have been identified with functions varying from transcription factors to epithelial differentiation and tissue remodeling. These genes have provided a novel insight into potential mechanisms that are altered in asthma (Table 28.2).

Polymorphisms spanning the urokinase plasminogen activator receptor (*PLAUR* or *UPAR*) were also associated with asthma susceptibility and were associated with rate of decline of lung function in asthma through linkage/association analyses on chromosome 19q13 [45]. uPAR is a serine protease receptor involved in multiple mechanisms, including cell proliferation, migration, and extracellular matrix degradations via plasmin generation. These data suggest that genetic factors may be important in determining airway structural changes or “remodeling” in asthma [46].

TABLE 28.2 Asthma Susceptibility Genes Identified Using Positional Cloning, Candidate Gene, and Genome-Wide Association Studies

Gene	Chromosome	Potential Function
Positional cloning		
DPP10	2q14	Involved in cleavage of dipeptides from cytokines
PCDH1	5q31.3	BHR, cell–cell adhesion, epithelial cell differentiation
HLAG	6p21	Regulates responses to inhaled allergens
NPSR1	7p15	Role in ECM expression
PHF11	13q14	Regulator of transcription
PLAUR	19q13	Epithelial function, tissue remodeling
ADAM33	20p13	Potential role in BHR/airway remodeling
Candidate gene		
IL10	1q31	Regulatory T cell function, anti-inflammatory cytokine
CD14	5q31.1	Innate immune responses
IL4	5q31.1	IgE-isotype switch, T cell differentiation
IL13	5q31	Inflammatory cytokine
ADRB2	5q32–34	Muscle relaxation, β_2 adrenergic receptor agonist efficiency
LTA	6p21.3	Immune modulation
HLA-DRB1	6p21.3	Regulate responses to inhaled allergens
HLA-DQB1	6p21.3	Regulate responses to inhaled allergens
TNFA	6p21.3	Inflammatory cytokine
FCER1B	11q12.1	IgE-mediated responses, mast cell degranulation
GSTP1	11q13	Oxidative stress
IL18	11q22.2	Inflammatory cytokine
STAT6	12q13	Transcription factor in IL4 receptor signalling pathway
IL4RA	16p12	IL4 receptor pathway
CCL5	17q11–12	Chemokine, inflammatory cell recruitment, ASM proliferation
TGFB1	19q13.1	Pro-fibrotic cytokine
GWAS		
IL6R	1q21	Regulatory T cell function, T cell differentiation
DENND1B	1q31	Memory T cell functions
IL1RL1	2q11	IL33 receptor, recruitment/activation of inflammatory cells
PDE4D	5q12	Modulates cAMP, role in cell signaling, ASM function

(*Continued*)

TABLE 28.2 Continued

Gene	Chromosome	Potential Function
TSLP	5q22	Activates dendritic cells, role in Th2 immune responses
HLA-DQ	6p21	Cell membrane alloantigens, T cells responses
IL33	9p24	Recruitment/activation of inflammatory cells
LRRC32	11q13	Regulatory T cell function
SMAD3	15q22	TGFβ signaling intermediate, fibrosis
*ORMDL3/GSDMB**	17q21*	Sphingolipid synthesis (ORMDL3), cell apoptosis? (GSDMB)
IL2RB	22q12	Binds IL2/IL15, lymphoid cell differentiation

BHR: bronchial hyper-responsiveness; ECM: extracellular matrix; ASM: airway smooth muscle; IgE: immunoglobulin E; IL: interleukin.

**The 17q21 locus was specifically associated with childhood onset asthma in GWAS. See main text for abbreviations and key references.*

Note: For candidate gene approaches, genes focused to replication in more than 10 studies [47,48]. For GWAS, genes focused to those meeting conventional genome-wide significance ($p < 5 \times 10{-}8$) and/or independent replication in the Caucasian population.

28.3.2.3 Genes Identified in Candidate Gene Studies (1970s to the Present)

Candidate gene studies are hypothesis-driven and based on the suggested biology of a gene product or the location of the gene in a chromosomal region previously linked to asthma. Such studies commonly employ asthma cases versus controls, although family-based association has also been used. For excellent reviews of candidate gene studies in asthma, see Ober and Hoffjan [47] and Undarmaa et al. [48]. The primary highly reproducible genes identified using candidate gene approaches are multiple components of the interleukin 4/13 axis (see Table 28.2), including the cytokine genes themselves (*IL4/IL13*); related receptor (*IL4RA*) and downstream signaling effector signal transducers and activators of transcription (*STAT*) 6. The role of the *IL4/IL13* axis in the pathogenesis of asthma has been extensively documented [49].

Human studies have identified elevated numbers of cells expressing IL13 mRNA in the bronchial tissue of atopic and nonatopic asthmatic subjects [50]; administration of recombinant IL13 in mouse lungs resulted in an increase in airway mucus secretion, development of subepithelial fibrosis, airway hyper-responsiveness (AHR), and eosinophilic airway inflammation—that is, several key features of the human disease [51]. IL13 is produced by a variety of cells, including Th2 CD4+, Th1 CD4+, CD8+ T cells, mast cells, basophils, and eosinophils. IL13 mediates its effects by interacting with a complex receptor system comprising an IL-4Rα/IL13Rα1 heterodimer and the IL13Rα2 receptor [49]. The finding that genetic polymorphisms within *IL13* that determine levels and/or structure and are associated with the development of asthma make biological sense.

28.3.2.4 GWAS in Asthma (2007 to the Present)

The use of GWAS approaches to identify asthma susceptibility genes has revolutionized our understanding of asthma genetics. While positional cloning showed great success with simple Mendelian disorders, it did not perform well for complex diseases. Similarly, candidate gene studies are useful but very inefficient. The capacity to interrogate the entire genome for 500,000+ common SNPs in cases and controls has provided an excellent platform for gene discovery.

The first GWAS for asthma used a discovery cohort of 994 patients with childhood onset asthma and 1243 non-asthma controls, and identified significant association to a locus on chromosome 17q21 [52]. This locus includes genes for *zona pellucida* binding protein 2 (*ZPBP2*), gasdermin B (*GSDMB*) and orm1-like protein 3 (*ORMDL3*). The 17q21 locus has been reproduced as a locus associated with childhood onset asthma in many studies; however, the identification of the specific gene(s) underlying these effects remains to be resolved. *ZPBP2*, *GSDMB*, and *ORMDL3* have been implicated in gene transcription, cell apoptosis, and sphingolipid synthesis, respectively.

This initial GWAS has now been superseded by several larger-scale studies. In particular, the GABRIEL consortium study, involving 10,365 asthma cases and 16,110 controls, identified association between polymorphisms spanning *IL33*, *IL1RL1/IL18R1*, *HLA-DQ*, *SMAD3*, and *IL2RB* [53].

To date, two of the most reproducible association signals are to the IL33 gene on chromosome 9p24 and the IL33 receptor (*IL1RL1* or *ST2*) gene on chromosome 2, both of which highlight the significance of this ligand/receptor system in asthma. Interestingly, these loci are associated with severe asthma as well [54]. There is good evidence from biology that the *IL33/ST2* axis may be of relevance in asthma; mice induced to develop allergic airway disease were treated with an antibody that blocks IL33 binding to its receptor. This treatment was shown to block many of the features of the disease, including reduced serum IgE and airway eosinophil and lymphocyte counts. Significantly, both induction and resolution of the disease were attenuated [55].

In human studies, IL33 has been shown to be elevated in the airways of asthma patients, particularly in the airway structural cells, including the bronchial epithelium, and is induced in these cells by relevant stimulations (e.g., HDM [56]). In addition, a soluble form of the ST2 receptor has been shown to be elevated during asthma exacerbation [57]. Overall, it is thought that the IL33/ST2 axis may be particularly important in attracting and activating inflammatory cells in the airways; however, the precise role(s) of this pathway remains to be resolved.

As outlined in Table 28.2, other genes have been identified using GWAS, including those involved in diverse roles such as inflammatory cell function and airway smooth-muscle contraction, again providing a unique insight into potentially altered mechanisms in asthma. However, most GWAS determined single variants only confer a very modest odds ratio of 1.1–1.5 of developing asthma. For a more comprehensive review of GWAS findings in asthma, see Akhabir and Sandford [43].

28.3.2.5 Reproducibility and Missing Hereditability

Over the last 40 years, there has been great progress in identifying asthma susceptibility genes. Current and future approaches include meta-analyses using cohorts of tens of thousands of asthma patients, the incorporation of gene expression/SNP analyses (the expression quantitative trait loci (eQTL)), the investigation of asthma subphenotypes using GWAS, and whole-genome sequencing.

The real challenge is the translation of these genetic findings into a deeper understanding of the biology of asthma and the potential identification of therapeutic targets. Already several of these newly identified genes (e.g., *IL33* and IL33 receptor (*IL1RL1/ST2*)) represent excellent pharmacological targets, and it is anticipated that genetics in these loci will be essential to identifying patients most likely to gain clinical benefit from targeting this pathway.

The lack of concordance between approaches (e.g., linkage versus GWAS) can be explained by the fact that the methodologies are designed to detect different types of variants, e.g., linkage analysis has good power to detect high-risk disease-causing alleles but is not effective at identifying common alleles of modest effect, as GWAS does. It is reassuring that many of the genes identified in candidate gene approaches have been reproduced in GWAS (e.g., the *IL13/IL4* locus on chromosome 5q31, a region that has also been linked to asthma). While there has been much success in recent years in identifying genes for asthma using GWAS, the overall genetic variation accounted for by these genetic polymorphisms is very small, leading to the concept of "missing hereditability." Possible explanations for missing hereditability include: (1) rare variants (<5% frequency) with larger effect size not measured on existing platforms; (2) structural variation (e.g., copy number variation); (3) gene–environment contributions; (4) gene–gene interactions; (5) epigenetic mechanisms; and (6) overestimation of initial hereditability.

28.4 CURRENT MANAGEMENT OF ASTHMA

The aim of treatment is to achieve control of asthma and prevent exacerbations. Most guidelines adopt a stepwise approach to the management of asthma and advise stepping up treatment as necessary and stepping down when control is achieved for at least three months. Although there are several pharmacological options for asthma treatment (see Figure 28.4), the two main classes remain bronchodilators (short- or long-acting) and corticosteroids.

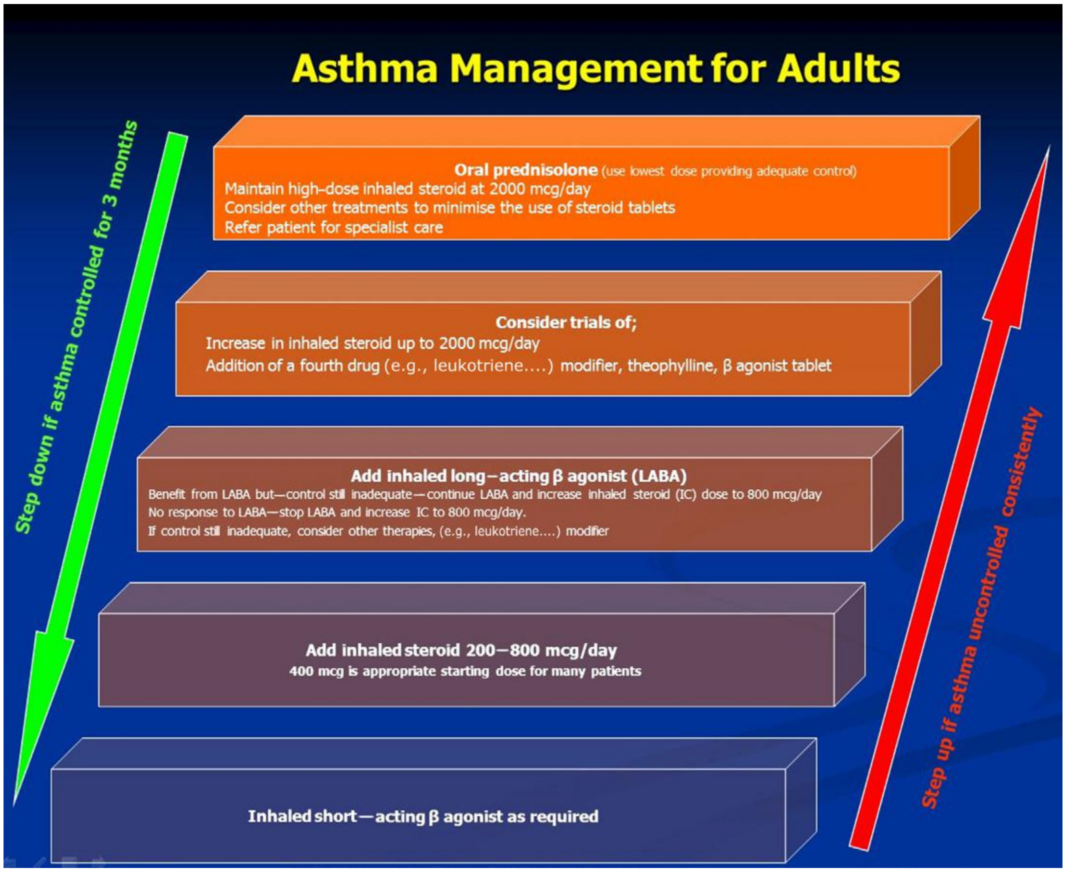
28.4.1 Bronchodilators

Short-acting bronchodilators (e.g., salbutamol/terbutaline) are sympathomimetics (β_2-adrenergic receptor agonists) that relax airway smooth-muscle, enhance mucociliary clearance, decrease vascular permeability, and possibly modulate mediator release from mast cells. They are used for symptom control, acute exacerbations, and exercise-induced asthma. Frequent or regularly scheduled use of rapid-acting inhaled β_2 agonists for long-term management of asthma does not adequately control symptoms, PEF variability, or airway inflammation.

Long-acting bronchodilators (e.g., salmeterol/formoterol) activity is identical to that of short-acting β_2-adrenergic receptor agonists, but should be used in combination with inhaled corticosteroids because of concerns regarding increased mortality when used as a monotherapy. Long-acting bronchodilators are normally introduced at treatment step 3.

28.4.2 Inhaled Corticosteroids

Inhaled corticosteroids (ICS) form the backbone of treatment for all but the very mildest asthma. ICS improve lung



Asthma Management for Adults

Oral prednisolone (use lowest dose providing adequate control)
Maintain high-dose inhaled steroid at 2000 mcg/day
Consider other treatments to minimise the use of steroid tablets
Refer patient for specialist care

Consider trials of;
Increase in inhaled steroid up to 2000 mcg/day
Addition of a fourth drug (e.g., leukotriene….) modifier, theophylline, β agonist tablet

Add inhaled long–acting β agonist (LABA)
Benefit from LABA but—control still inadequate—continue LABA and increase inhaled steroid (IC) dose to 800 mcg/day
No response to LABA—stop LABA and increase IC to 800 mcg/day.
If control still inadequate, consider other therapies, (e.g., leukotriene….) modifier

Add inhaled steroid 200–800 mcg/day
400 mcg is appropriate starting dose for many patients

Inhaled short–acting β agonist as required

Step down if asthma controlled for 3 months

Step up if asthma uncontrolled consistently

FIGURE 28.4 The current stepwise approach to asthma management.

function, symptoms, and quality of life, reduce exacerbations, and improve mortality. They have broad anti-inflammatory and immunosuppressive effects. Corticosteroids enter the cell cytoplasm and bind with the inactive glucocorticoid receptor complex. The activated glucocorticoid receptor binds to DNA at the glucocorticoid response element sequence and promotes synthesis of anti-inflammatory proteins (transactivation), and inhibits transcription and synthesis of many proinflammatory cytokines (transrepression). They also reduce the number of T-lymphocytes, dendritic cells, eosinophils, and mast cells in the airway, and reduce inducible nitric oxide production. ICS (beclomethasone dipropionate/fluticasone propionate/budesonide/flunisolide/ciclesonide/mometasone) all have side effects related to their transactivation properties, including local effects on the oropharynx (hoarseness, candidiasis, cough, and dysphonia) and systemic effects (Cushing syndrome, osteoporosis, cataracts, dermal thinning and bruising, adrenal insufficiency, and growth suppression) in children [58]. Consequently, the lowest dose required to control symptoms and prevent exacerbations should be prescribed.

28.4.3 Other Pharmacological Treatments and Alternative Therapies

Other medications are normally reserved for second- or third-line treatment. These include methylxanthines (theophylline), leukotriene modifiers (montelukast), inhaled anticholinergics (ipratropium bromide/tiotropium), and sodium chromoglycate.

A wide range of interventions have been assessed for both the primary prevention of asthma and the secondary prophylaxis of the disease once present. These treatments have varying effects, but may be recommended in individual cases. Primary prevention measures include aeroallergen and food allergen avoidance, fish oil supplementation, avoidance of tobacco smoke and air pollutants, immunotherapy, and immunization.

Measures that have been assessed for secondary prophylaxis include HDM and allergen avoidance, smoking reduction, subcutaneous and sublingual immunotherapy, dietary manipulation, weight loss, breathing techniques, and exercise training.

28.4.4 Specific Treatment for Severe Asthma

Some investigators argue that severe asthma is an inflammatory condition separate from mild/moderate asthma, rather than simply the severe end of the disease spectrum. This is difficult to prove, as underlying asthma may be complicated by other aspects (obesity/reflux/smoking/poor adherence), making it more difficult to treat and control. There are different definitions of severe asthma, but all require high-dose inhaled corticosteroids or oral corticosteroids and include recurrent exacerbations and poor control.

As high-dose ICS and oral corticosteroids are associated with side effects attempts have been made to design treatments to either reduce the amount of corticosteroid prescribed (steroid-sparing agents) or treat the underlying asthma in a different manner. Steroid-sparing agents trialled include methotrexate, gold, cyclosporin, and azathioprine. Currently, none have been recommended in any asthma guidelines. Box 28.2 lists other treatments used on an individual basis.

BOX 28.2 New and Emerging Therapies Reserved for Severe Asthma

Anti-IgE
Bronchial thermoplasty
Macrolide antibiotics
Antifungals (Itraconazole/Voriconazole)
Anti-IL5
Anti-IL13

28.5 STRATIFIED MEDICINE FOR ASTHMA

The need for a stratified-medicine approach to asthma has become apparent over the last decade. This has followed the realization that the term *asthma* covers a whole range of disease phenotypes. As techniques for investigating and researching asthma have evolved, it has become clear that different disease processes are present that require different treatments and approaches. Whether this represents disease phenotyping or just a better understanding of disease pathogenesis is unclear. Over the years, research focus has moved from the airway smooth-muscle via airway inflammation to airway immunology, and on to the epithelial–mesenchymal trophic unit. Future insight into disease pathogenesis and new treatment developments will follow with the use of the latest technologies, which include “omics” platforms and assessment of airway microbiota.

Improving our understanding of stratified medicine for asthma—targeting the right therapy to the right patient—aims to reduce hospital admissions due to poorly controlled asthma and fatalities. Although most asthma can be controlled by ICS and bronchodilators, there remains a cohort of patients with persistent symptoms, recurrent exacerbations, and worse quality of life. The current stepwise management approach (see Figure 28.4) is inefficient, particularly in light of heterogeneity in clinical presentation and response to existing therapies, making a stratified approach essential.

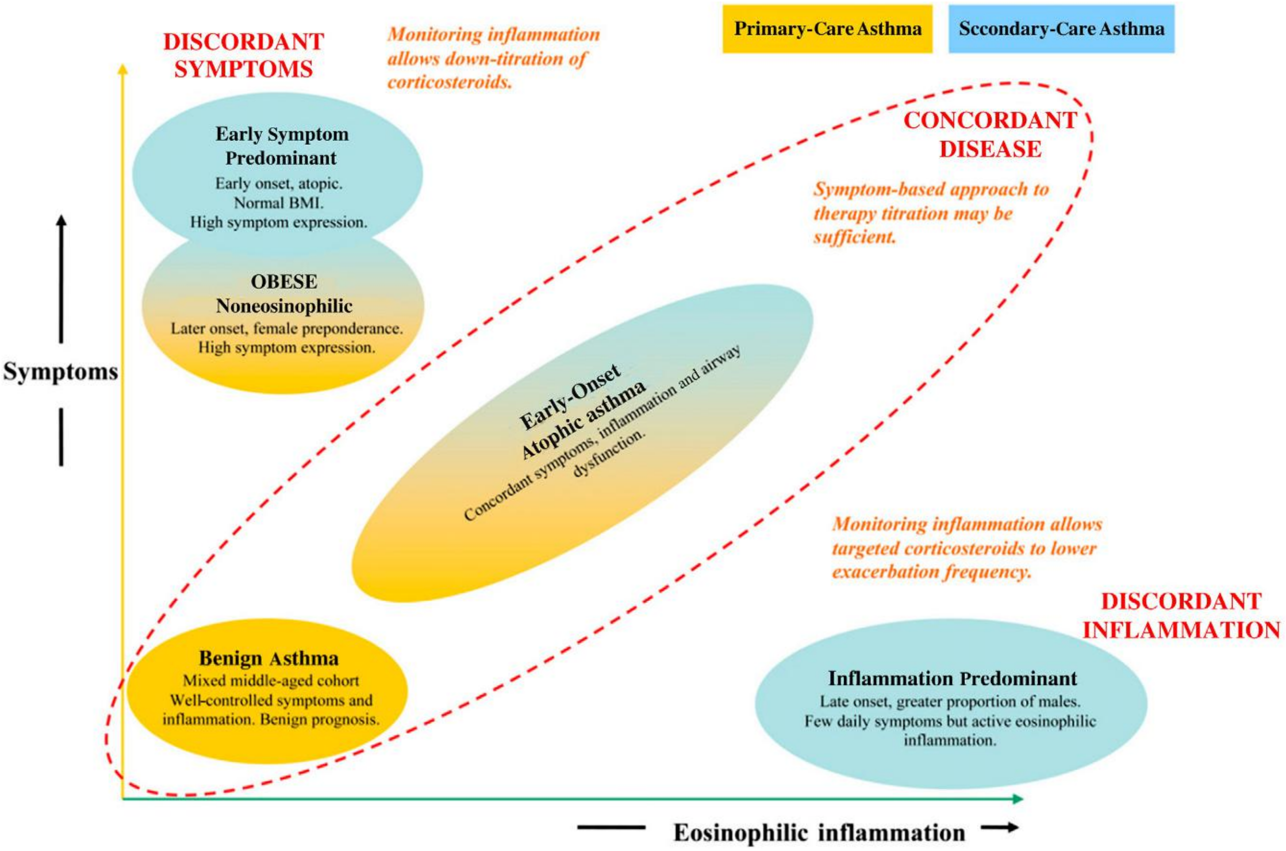
28.5.1 Heterogeneity in Asthma

28.5.1.1 Adult Asthma

Early work conceptualized asthma as extrinsic (allergic) and intrinsic (nonallergic) [59]. However, the recent use of unbiased approaches to classify disease using three large datasets and cluster analysis [60–62] has highlighted the different types of disease under the umbrella term asthma (Figure 28.5). Although these early studies were performed in different parts of the world and had statistical variations, their results were similar. Age at disease onset was found to be a key differentiating factor; early-onset disease was associated with more atopic and allergic conditions, whereas later-onset disease was associated with eosinophilic inflammation and obesity. These studies were all limited by a cross-sectional design and by the fact that treatment may have determined clusters. Longitudinal studies initiated in childhood are ongoing. For example, PACMAN (formally, “Pharmacogenetics of Asthma Medication in Children: Medication and Anti-Inflammatory Effects”) aims to differentiate children with uncontrolled asthma, despite ICS treatment, using a range of clinical and cellular markers [63].

28.5.1.2 Allergy

The role of allergy (an inappropriate and harmful immune response to a normally nonharmful substance which requires sensitization) and that of atopy (the tendency to develop IgE antibodies to commonly encountered environmental allergens by natural exposure in which the route of entry is across intact mucosal surfaces) have been well studied in asthma. People with extrinsic asthma were thought to develop the disease earlier in life, be atopic, and have identifiable allergic triggers as well as other allergic diseases such as rhinitis or eczema. Intrinsic asthma was thought to develop later in life (after 40 years of age), and be associated with aspirin-exacerbated respiratory disease but not with allergic sensitization. When small studies in humans suggested that levels of Th2 cytokines were similar in extrinsic



Primary-Care Asthma
Sccondary-Care Asthma
DISCORDANT SYMPTOMS
Monitoring inflammation allows down-titration of corticosteroids.
Early Symptom Predominant
Early onset, atopic. Normal BMI. High symptom expression.
OBESE Noneosinophilic
Later onset, female preponderance. High symptom expression.
Symptoms
CONCORDANT DISEASE
Symptom-based approach to therapy titration may be sufficient.
Early-Onset Atophic asthma
Concordant symptoms, inflammation and airway dysfunction.
Monitoring inflammation allows targeted corticosteroids to lower exacerbation frequency.
DISCORDANT INFLAMMATION
Benign Asthma
Mixed middle-aged cohort Well-controlled symptoms and inflammation. Benign prognosis.
Inflammation Predominant
Late onset, greater proportion of males. Few daily symptoms but active eosinophilic inflammation.
Eosinophilic inflammation

and intrinsic asthma, and that treatment with ICS was effective in the majority of mild to moderate asthma cases, the distinctions between extrinsic and intrinsic asthma fell out of favor [64].

28.5.1.3 Heterogeneity of Responses to Existing Therapies

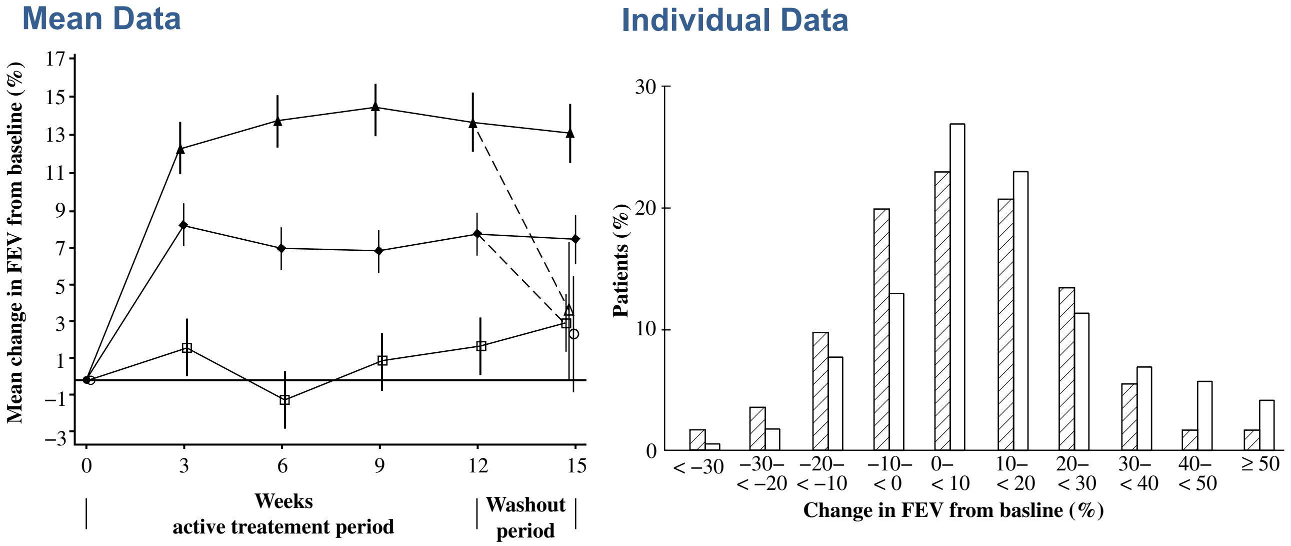
Heterogeneity in response to existing medication is exemplified by Malmstrom's study, which investigated individual response to leukotriene receptor antagonist (LTRA) (montelukast 10 mg once daily), and the inhaled steroid beclomethasone (200 µg twice daily) over a 12-week period in 895 chronic asthma patients [65]. Overall, there was a clear improvement in lung function (primary outcome FEV_1) for both treatments; however, when stratified based on individual patient data, there was a very large degree of heterogeneity for both treatment groups, with some patients showing up to 50% improvement in FEV_1 and others showing a decline in lung function with a 30% decrease in FEV_1 (Figure 28.6). This interindividual variability, a component of clinical trials that is seldom appreciated, is thought to have a strong genetic component.

28.5.2 Problems with Current Therapy

The therapeutic regimen for the treatment of asthma has been well defined and was described earlier in this chapter. Despite such well-defined treatment regimens, which are constantly updated and streamlined, as well as the availability of high-quality medications, in many cases asthma is still not sufficiently controlled. While current asthma therapeutics are able to successfully treat 90–95% of the asthmatic population, around 50% still have daily symptoms and almost all patients report limitations of daily activities [66]. This also leaves around 5–10% of patients who do not respond to conventional treatments. This demonstrates that the current one-size-fits-all approach is not perfect, and emphasizes the need for a stratified medicine approach to asthma.

28.5.2.1 Variable Efficacy and Presentation of Side Effects

Variability in current therapy involves variation in drug efficacy and presentation of side effects, each of which presents challenges to successful maintenance of asthma.



Mean Data

Individual Data

FIGURE 28.6 **Heterogeneity in asthma patient responses to current asthma medication.** While mean data demonstrates a significant improvement in lung function (FEV_1) over 12 weeks for both montelukast (10 mg once daily; circle) and beclomethasone (200 μg twice daily; triangle) versus placebo (open square) in 895 chronic asthma patients, individual data show a broad distribution of responses (Striped bars represent patients receiving montelukast, 10 mg once daily; white bars represent patients receiving inhaled beclomethasone, 200 mg twice daily). *Source: Reproduced with permission from Malmstrom et al.* [65].

Variability in drug efficacy, especially when occurring for β_2-adrenergic receptor agonists and glucocorticosteroids, and in the presentation of side effects, can result in patient therapy having to deviate from the standard therapeutic regimen for the treatment of asthma.

This high degree of interpatient variability in treatment response and in side effects can be attributed to a number of factors: (1) the interaction of genetic factors; (2) individual patient characteristics, such as weight, gender, and pregnancy; and (3) exposure to environmental insults, such as air pollution, allergens, and cigarette smoke. These factors interact, making the control of asthmatic episodes and the reduction of exacerbations more difficult. For example, asthma attacks can affect different age groups differently according to the season—children are more affected in summer while the older population suffers more in winter. When considering variation in treatment efficacy, one must also be mindful of individual patient factors such as inhaler technique and noncompliance (discussed earlier).

Currently asthma therapy is planned without consideration of genetic variance. However, genetic variance is arguably the most important of the factors listed previously—a claim supported by evidence gained from investigating the repeatability of response to therapy. This approach demonstrated that repeatability was between 60–80%, with a substantial proportion of the variance due to genetic factors [67].

28.5.2.2 Nonresponders

One important form of variance in therapeutic efficacy is non-response. Non-response is an important limitation in the maintenance and control of asthma, in that therapeutics expected to manage the disease at a certain level of severity fail outright, leading to the use of a trial approach in which different therapies are utilized with variable results until a suitable regimen is determined. A good example is severe asthma, where the patient is on permanent oral glucocorticosteroid therapy because of nonresponse to other therapies such as ICS, leukotriene receptor antagonists, and β_2-adrenergic receptor agonists. Non-responders present with longer duration of asthma exacerbations and worse morning lung function, as well as a more frequent family history of asthma, when compared to those individuals responsive to glucocorticosteroid therapy [67].

28.5.3 Nongenetic Approaches to Patient Stratification

28.5.3.1 Anti-IgE

The recognition that allergen specific IgE activation of mast cells is central in driving allergic asthma lead to the discovery that the primary mast cell-signaling cascade could be inhibited by a monoclonal antibody toward the IgE binding site to the high affinity receptor (FcER1). Anti-IgE (omalizumab) became the first specific biologic to be used in the treatment of severe allergic asthma. Clinical trials revealed efficacy as well as almost total inhibition of early and late asthmatic responses to inhaled allergen [68].

Following a rigorous examination of trial data by the National Institute for Clinical Excellence (NICE), omalizumab is now recommended as an option for treating severe persistent, confirmed allergic IgE-mediated asthma as an add-on to optimized standard therapy in people aged six and older who need continuous or frequent treatment with oral corticosteroids (defined as four or more courses in the previous year) in the United Kingdom. Although the drug is prescribed for cases of therapy-resistant asthma associated with allergy, it is also licensed for patients with evidence of allergy but a normal IgE. Omalizumab represents the first stratified treatment for asthma, but there is evidence that its use can be further stratified by using biomarkers of Th2 inflammation to predict response. In a recent paper studying the effect of omalizumab on uncontrolled severe persistent allergic asthma, treatment effect was analyzed in relation to F_ENO, blood eosinophils, and serum periostin (an epithelial protein that is induced by IL13). After 48 weeks of omalizumab, reductions in protocol-defined exacerbations were greater in high versus low subgroups for all three biomarkers, suggesting a potential prognostic ability [69].

28.5.3.2 Corticosteroids and Anti-IL13

This biomarker approach has helped divide asthma into and Th2 high and Th2 low disease. Asthma has traditionally been considered a Th2 process linked to atopy and allergy, type I hyper-sensitivity reactions, eosinophilic inflammation, and response to corticosteroids. "Th2 high disease," as evidenced by high F_ENO and a sputum eosinophilia of >2%, has been associated with a better response to corticosteroids when compared to "Th2 low disease" [70–72]. Studies on lebrikizumab, a novel monoclonal antibody to IL13 [73], have suggested that serum periostin may be a biomarker for a more general Th2 asthmatic phenotype. In one study a subgroup of individuals who had asthma and persistent elevation in serum periostin showed greater improvements in airway function and fewer exacerbations after lebrikizumab treatment than those with lower serum periostin. Interestingly, levels of F_ENO, produced by inducible nitric oxide synthase, an enzyme induced in human airway epithelial cells by IL13, were as informative as periostin in identifying Th2-high individuals responsive to lebrikizumab.

28.5.3.3 Anti-IL5

Both the role of stratification based on phenotyping and the need for correct study end points in treatment trials have been informed by the salutary lesson of the anti-IL5 antibody mepolizumab. Although mepoluzimab effectively blocks eosinophilic inflammation, initial studies were disappointing in that no effect was demonstrated on spirometry or peak flow, despite a significant reduction in blood eosinophil numbers [74]. When the effect of the drug was studied on an outcome measure related to eosinophilia, namely severe exacerbations, there were significantly fewer exacerbations with a concomitant improvement in asthma-related quality of life [75]. Tellingly, there were no significant differences with respect to symptoms, postbronchodilator FEV_1, or airway hyper-responsiveness, suggesting that different physiological processes determine these asthma outcomes. The study also helps researchers reflect upon the need to measure the correct end point in a disease that has different pathological mechanisms that all respond differently to treatment.

Phenotyping asthma has led to the identification of new disease targets, but aside from the use of anti-IgE, it has not yet led to a step change in management. Other approaches assessing the separate aspects of asthma pathophysiology—namely, airway inflammation, airway hyper-responsiveness, and airflow obstruction have been trialled with differing results. The key determinant in the design of these stratified approaches was the recognition that although asthma is a disease defined by symptoms, with treatment response also assessed by symptom improvement, there is no clear correlation between pathophysiology and symptomatology/exacerbation risk.

In the FACET study (designed to evaluate the benefits of adding a long-acting β_2-adrenergic receptor agonist to different doses of ICS), higher-dose ICS had a marked beneficial effect on exacerbation frequency, but relatively less effect on symptoms and peak expiratory flow. The opposite was true with the addition of long-acting β_2-agonists [76]. This indicates that exacerbation frequency does not closely relate to symptoms and measures of disordered airway function, suggesting that the mechanisms responsible for these features are different [77].

Numerous studies have demonstrated that in asthma the features of airway inflammation, airway hyper-responsiveness, variable airflow obstruction and associated symptoms can overlap, occur independently or change over time, in response to treatment or other external factors such as allergen exposure, or viral infection. One obvious example of this is eosinophilic bronchitis, a condition characterized by corticosteroid-responsive cough and the presence of a sputum eosinophilia occurring in the absence of variable airflow obstruction or airway hyper-responsiveness [78].

Although asthma guidelines recommend the assessment of airflow obstruction (FEV_1/PEF) and related symptoms for their primary treatment response outcomes, the realization is that this approach looks only at one aspect of asthma pathophysiology which is not closely related to exacerbation risk. This has led to new approaches aimed at reducing asthma exacerbations and symptoms while maintaining corticosteroid burden at the lowest possible level.

28.5.4 Clinicopathophysiological Measures in Asthma with Potential Use in Stratification

28.5.4.1 Airway Hyper-Responsiveness

Airway hyper-responsiveness is defined as increased sensitivity to an inhaled constrictor agonist and a steeper slope of the dose–response curve. Two main forms of bronchoconstrictor stimuli exist: direct and indirect. Direct bronchoconstrictors, such as histamine or methacholine, stimulate receptors on the airway smooth-muscle, while indirect ones cause bronchoconstriction by secondary release of bronchoconstrictor mediators from mast cells or activation of neural pathways. Airway responsiveness is usually measured as the provocative dose of methacholine causing a 20% fall in FEV_1 by linear interpolation of the log dose–response curve (PC_{20}). In the general population, the distribution of airway hyper-responsiveness follows a continuous unimodal log-normal distribution, with asthma sufferers representing the hyper-responsive part of the distribution curve. A PC_{20} is not usually measurable in non-diseased individuals, which suggests a large difference in airway responsiveness between non-diseased individuals and asthma patients.

The cut-off used to identify asthma is normally a methacholine concentration of <8 mg/ml. This value had a sensitivity of 100%, a specificity of 93%, and a negative predictive value of 100% in a study on a population of 500 college students with a diagnosis of current symptomatic asthma. The use of methacholine PC_{20} to diagnose asthma has been evaluated; one study demonstrated that when asthma is defined as consistent symptoms with objective evidence of abnormal variable airflow obstruction, a positive methacholine challenge is more sensitive than PEF amplitude % mean and the acute bronchodilator response in diagnosis [79].

The use of methacholine PC_{20} to guide treatment has also been assessed. Although it was found that PC_{20}-guided treatment resulted in a reduction in asthma exacerbations, this was at the expense of increased inhaled corticosteroid use [80]; consequently, although PC_{20} is often used for asthma diagnosis, or as a study end point, it is not routinely used to guide treatment decisions.

28.5.4.2 *Airway Inflammation*

Asthma has been traditionally viewed as a condition where airway inflammation causes airway hyper-responsiveness, which in turn leads to variable airflow obstruction and symptoms; however, cross-sectional and longitudinal studies of airway inflammation using sputum induction in large populations with a diverse range of presentations suggest that this hypothesis requires modification. A recent bronchoscopy study demonstrated that bronchoconstriction is independent of airway inflammation and can lead to airway remodeling [38].

The development of noninvasive techniques to assess airway inflammation, including induced sputum and F_ENO, has made it possible to relate airway inflammation to objective measures of disordered airway function in larger and more heterogeneous populations than was possible with bronchoscopy studies. In general, these newer studies contradict findings in earlier studies and do not find a correlation between sputum eosinophil count and various markers of airway dysfunction.

It has been observed that a subset of patients with symptomatic asthma do not have sputum evidence of eosinophilic airway inflammation [81]. Many have sputum neutrophilia. This sputum profile is evident in corticosteroid-naïve as well as corticosteroid-treated subjects, suggesting that it is not always an artifact related to treatment. Importantly, patients with noneosinophilic asthma respond less well to inhaled budesonide than do a group with more typical sputum features [82].

Similar sputum findings have been reported in more severe asthmatics; a subgroup of patients with refractory asthma have been identified who have bronchoscopic evidence of neutrophilic airway inflammation, normal eosinophil counts, and a normal basement membrane thickness. These findings suggest the presence of a distinct asthma phenotype characterized by a predominantly neutrophilic airway inflammatory response and relative corticosteroid resistance. Furthermore, there is evidence that neutrophilic asthma may result from activation of the innate immune system with the production of proinflammatory cytokines.

The use of noninvasive measures to guide treatment decisions by stratification based on the presence or absence of airway inflammation has been assessed. The strongest evidence for effect relates to the use of induced sputum to guide corticosteroid dose in moderate to severe asthma. Two studies have shown that using induced sputum differential counts to guide treatment results in fewer exacerbations for the same overall corticosteroid burden [81,83].

Although the evidence is clear that this approach works, induced sputum is not widely employed, possibly because it is seen as time consuming, requiring expertise both to induce the sputum and to perform the differential counts. The discovery that levels of F_ENO, measured via a device similar to a breathalyzer, correlate well with sputum eosinophilia and relate to corticosteroid responsiveness, has driven the application of inflammometry (noninvasive measurement of inflammation in the airways). Inflammometry using F_ENO measurements has also been used to guide and stratify treatment decisions. Though one study was positive in patients with asthma in pregnancy, with a reduction in exacerbations, most have failed to show an improvement when compared to guideline-driven (FEV_1/PEF and symptoms) management. The hunt is still on for a reliable, inexpensive, and valid biomarker of airway inflammation.

28.5.4.3 Small Airways

FEV_1 and PEF measurements reflect changes in the caliber of the large airways. Our knowledge of anatomical and physiological changes in the small airways of patients with asthma is based on small case series of resected lung tissue from patients with asthma undergoing surgery for cancer, or on cases of fatal asthma.

These case series have demonstrated that there is significant inflammation present in the small airways (<2 mm diameter) in asthma. Fatal asthma is associated with peripheral airway inflammation and differences in the number of activated eosinophils in the distal lung. Other studies have revealed alterations in the epithelium and smooth-muscle, as well as mucous hypersecretion and distal airway plugging of the small airways. The presence of inflammation in the small airways in asthma may explain why small airways account for up to 50–90% of total airflow resistance in asthma, but only 10% of airflow resistance in normal airways.

Recently, the development of "small-particle" ICS, designed to target the peripheral lung, and the advent of new technologies—nitrogen washout, impulse oscillometry, and hyperpolarized noble gas magnetic resonance imaging, which allows assessment of peripheral lung function—have led to a resurgence of interest in the distal lung. Studies of small-particle ICS have been inconsistent; those comparing small-particle and standard-particle ICSs have failed to demonstrate improved asthma outcomes when administered in clinically comparable doses. Future asthma treatment may yet be stratified by the presence or absence of small airway inflammation.

28.5.4.4 Stratifying Treatment Response in Children Based on Clinical Parameters

There have been several attempts to base treatment decisions on measures of airway inflammation, including induced sputum and F_ENO in children. Generally, they have been unsuccessful, although some experts do stratify treatment decisions on the response to oral or intramuscular steroids.

28.5.5 Current Asthma Therapies—Pharmacogenetic Approaches to Stratification

While methods of stratifying asthma patients to specific treatments based on nongenetic factors such as clinical outcomes, cellular measures, or protein biomarkers have shown some success, a large body of work has investigated the potential of genetic markers as predictors of patient responses to existing therapies, i.e., pharmacogenetics. Pharmacogenetics, the investigation of the effect of genetic polymorphisms on response to treatment or risk of adverse side effects, is one of the first steps in developing personalized prescribing. The use of genetic information to stratify patient prescribing is potentially more desirable compared to nongenetic stratification, as technology now allows a small amount of blood or saliva sample to be taken and a DNA test can be completed within hours.

To date, asthma pharmacogenetic studies have suffered from relatively small retrospective designs and a focus on only a few candidate genes; however, more recent, larger prospective studies have been completed that provide greater confidence in original findings and hypothesis-free approaches such as GWAS. These studies are primarily focused on pharmacodynamic aspects (e.g., improvement in lung function post-treatment), and only limited information is available about the impact of pharmacogenetics on adverse effects.

Pharmacogenetics in asthma is relatively advanced compared to that for other diseases. Genetic factors influencing the main treatment classes (i.e., β_2-adrenergic receptor agonists, corticosteroids, and leukotriene modifiers) have been identified with some confidence (Table 28.3). An overview of these findings follows; however, for more in-depth analyses, see Portelli and Sayers [84].

28.5.5.1 β_2-Adrenergic Receptor–Agonist Pharmacogenetics

β_2-adrenergic receptor agonists carry out their function through the β_2-adrenergic receptor—a 413-amino-acid G-protein-coupled receptor encoded by an intronless gene (*ADRB2*) located on chromosome 5q31.32. Binding of agonists to the receptor activates adenyl cyclase through stimulatory Gs proteins, which in turn activate protein kinase A. The latter phosphorylates several target proteins, resulting in a decrease in intracellular calcium that, importantly, causes smooth-muscle relaxation in the airways. It is not surprising that the majority of evidence of genetically driven effects on β_2-adrenergic receptor–agonist therapy stem from the *ADRB2* gene, which has therefore been extensively studied for pharmacogenetic effects on β_2-adrenergic receptor–agonist responses.

ADRB2 is a highly polymorphic gene containing 51 known and validated polymorphisms, of which 49 are SNPs and 2 are insertion/deletion variants. Most studies have focused on the role of four nonsynonymous coding-region polymorphisms: Arg16Gly (Arginine-to-Glycine substitution at position 16 in the protein), Gln27Glu, Val34Met, and Thr164Ile [85]. In a Caucasian population, the frequency of the polymorphisms at positions 16 and 27 were identified as 59% (Arg16Glu) and 29%, (Gln27Glu) [85]. The remaining Val34Met and Thr164Ile polymorphisms are rare, having approximate frequencies of <0.001% and 0.05%, respectively. The Arg16 variant has been shown to have pharmacogenetic potential through association with;

TABLE 28.3 Recently Identified Pharmacogenetic Effects on Current Asthma Therapies

Gene	Key Polymorphism	Pharmacogenetic Effect
β_2-adrenergic receptor agonists (e.g., salbutamol, salmeterol)		
ADRB2	Arg16Gly	Mixed reports (see text)
	Gln27Glu	Mixed reports (see text)
	PolyC (3′UTR)	Counteracts *ADRB2* downregulation
ARGI	rs2781659 (5′ region)	Haplotypes increase *ARG1* transcription, leading to improved response to β_2AR agonist
GSNOR	rs1154400 (5′ region)	Differential response to β_2AR agonist; *GSNOR* haplotypes determine *GSNOR* transcription
SPATS2L	rs295137 (5′ region)	Differential response to β_2AR agonist; *SPATS2L* expression inversely related to β_2AR levels
COL22A1	rs6988229 (intron)	Differential response to β_2AR agonist
Leukotriene modifiers (e.g., montelukast, zafirlukast, zileuton)		
ALOX5	rs2115189 (intronic)	Causes differential response to zileuton and montelukast therapy (FEV$_1$ change)
	rs4987105 (Thr120Thr)	Causes differential response to montelukast therapy (FEV$_1$ change)
	rs4986832 (5′ region)	
LTC4S	A-444C	Associated with LTRA and LTSI response (FEV$_1$ change) in some but not all studies.
	rs272431(intron)	Causes differential response to zileuton therapy (FEV$_1$ change)
CYSLT2	rs91227 (3′UTR) rs912278 (3′UTR)	Associated with morning PEF in subjects taking montelukast
MRP1	rs119774 (intronic)	Causes differential response to zileuton and montelukast therapy (FEV$_1$ change)
OATP2B1	rs12422149 (Arg312Gln)	In some but not all studies, reduced morning plasma concentrations of montelukast, resulting in lack of clinical benefit
CHRM2	4 SNPs	Causes differential response to montelukast therapy (FEV$_1$ change)
Corticosteroids (e.g., prednisolone, beclomethasone, fluticasone)		
CRHR1	rs242941 (intronic)	Associated with corticosteroid response (FEV$_1$ change)
TBX21	rs224001 (His33Gln)	Improvements in BHR with corticosteroid treatment
NK2R	rs7703891 (Gly231Glu)	Improved asthma control with corticosteroid treatment

TABLE 28.3 Continued

Gene	Key Polymorphism	Pharmacogenetic Effect
DUSP1	rs881152 (5′ region)	Associated with bronchodilator response and asthma control in presence of corticosteroids
FCER2	rs28364072 (intron)	Associated with asthma exacerbations in presence of corticosteroids
GLCCI	rs37972 (5′ region)	Associated with corticosteroid response (FEV_1 change); potential transcriptional mechanism
CRHR1	5 SNPs	ACQ post-corticosteroid
COL2A1	3 SNPs	FEV_1 change post-corticosteroid
CYP3A4	CYP3A4*22	Asthma control post-corticosteroid; *CYP3A4*22* previously associated with *CYP3A4* levels
Combination Therapy (β_2-adrenergic receptor–agonist and corticosteroid)		
CHRM2	3 SNPs	ACQ score
HSPA8	rs1461496	FEV_1 change
NOS3	rs1799983 (Glu298Asp)	FEV_1 change

Note: See main text for abbreviations and key references. ACQ—Asthma Control Questionnaire; FEV_1—forced expiratory volume in 1 second.

- An enhanced acute response to β_2-adrenergic receptor agonists
- A decline of asthma control following prolonged use of β_2-adrenergic receptor agonists
- A subsensitivity of response for bronchoprotection by β_2-adrenergic receptor agonists

However, several studies have failed to reproduce these effects, meaning that a common consensus on the contribution of Arg16 has yet to be reached. This lack of consensus can be explained when we consider that there are at least 12 different haplotypes (a specific combination of SNPs across the gene) in *ADRB2*. Investigations into the effect of a genotype in isolation, without consideration of its haplotype, is likely to introduce confounding into the association.

Functional effects of coding-region polymorphisms in *ADRB2* have been identified through *in vitro* work carried out in cell lines. These have included the following:

- Impaired agonist binding and reduced adenyl cyclase activity in the Thr164Ile variant receptor
- An enhanced agonist-mediated receptor downregulation for the Gly16 variant
- A resistance to downregulation for the Glu27 variant

More recent clinical studies have been hindered by relatively small sample sizes. For example, Lee et al. identified an association between Gln27Glu and Terbutaline nebulizer response and an absence of effect for the Arg16Gly polymorphism in children, in 27 patients [86]. In one of the larger studies, Basu et al. identified an Arg16 copy number-dependent increase in disease exacerbations in 1182 patients with asthma aged 3 to 22 years on daily exposure to β_2-adrenergic receptor agonist (regularly inhaled corticosteroid plus salbutamol on demand group, and regularly inhaled corticosteroid plus salmeterol and salbutamol on demand group) [87].

It is important to note that this effect was driven by asthma patients who used salbutamol and/or salmeterol daily, supporting the suggestion that the Arg16 polymorphism has an integral role in the effectiveness of β_2-adrenergic receptor–agonist therapy [87]. However, as with other studies, study limitations did not allow a clear association to be made between the *ADRB2* gene (via its polymorphisms) and β_2-adrenergic receptor–agonist efficacy. Namely, all participants were using β_2-adrenergic receptor–agonists as a reliever; a study arm of non-β_2-adrenergic receptor–agonist reliever use would have provided a clearer interpretation of the detrimental effects of salbutamol/salmeterol in the Arg16 subjects.

Large studies have failed to observe a clinically relevant effect of these polymorphisms. These include longitudinal studies of β_2-adrenergic receptor–agonist efficacy and the study of concomitant administration of corticosteroids.

A good example is a study of 2250 asthma patients randomly assigned to: (1) budesonide plus formoterol maintenance and reliever therapy; (2) fixed-dose budesonide plus formoterol; or (3) fixed dose fluticasone plus salmeterol for six months. No overall effect of the Gly16Arg genotype on clinical outcomes was found [88]. Another contributing factor to the pronounced differences in the conclusions from different studies investigating these *ADRB2* polymorphisms is trial design variation.

Other *ADRB2* Polymorphisms

The majority of studies have focused on the *ADRB2* Arg16Gly polymorphism; however, other potential pharmacogenetically relevant polymorphisms also affect β_2-adrenergic receptor–agonist efficacy. Multiple polymorphisms in the gene's regulatory regions that have potential clinical relevance are present in *ADRB2*. By studying eight common haplotypes based on 26 SNPs, a recent *in vitro* approach using "whole gene" transfection identified differential effects on receptor expression and downregulation that are haplotype-driven [89]. This study identified four common haplotypes with elevated receptor expression and two haplotypes with enhanced receptor downregulation. Another area recently investigated is polymorphisms occurring in the gene's untranslated regions, which may have an effect on gene expression and resultant drug efficacy.

28.5.5.2 Novel Regulators of β_2-Adrenergic Receptor–Agonist Responses

Multiple genes are likely to be involved in the regulation of β_2-adrenergic receptor–agonist response and expression of side effects, due to the agonists' known complex and multifactorial mechanism of action. One gene that has been associated with patient response to these agonists is Arginase 1 (*ARG1*), which was identified using a novel algorithm implemented in a family-based association test (FBAT) [90]. In this study of 209 children and their parents, the *ARG1* SNP, rs2781659, was associated with bronchodilator response (BDR) when SNPs from 111 candidate genes (42 involved in β_2-adrenergic receptor–signaling/regulation, 28 involved in glucocorticoid regulation, and 41 from prior asthma association studies) were investigated for their association with acute response to inhaled β_2-adrenergic receptor–agonist in 209 children and their parents. In agreement with this study polymorphisms spanning *ARG1* and influencing patient response to salbutamol have also been identified in a candidate gene study involving 221 asthma subjects [91].

The *ARG1* polymorphisms identified in both studies were in linkage disequilibrium (LD) (inherited together), suggesting a common causative mechanism involving potential transcriptional regulation due to the polymorphisms' location (predominantly 5′ to the gene). This alteration in transcription has now been confirmed in promoter-reporter studies, which found that the key *ARG1* haplotype associated with improved BDR drives the highest level of *ARG1* promoter activity [92]. In the study by Vonk et al., *ARG2* SNPs were also associated with patient responses to salbutamol [91], suggesting an integral role for the arginase family in β_2-adrenergic receptor–agonist therapy.

Recently a S-nitrosoglutathione reductase (*GSNOR*) SNP (rs1154400, promoter region) was associated with a decreased response to salbutamol in 107 African-American children [93]. In the same study, a post hoc multilocus analysis discovered that a combination of rs1154400 with *ADRB2* Arg16Gly, Gly27Glu, and the carbamoyl phosphate synthetase-1 (*CPS1*) SNP rs2230739 gave a 70% predictive value for lack of response to therapy [93], implying that pharmacogenetic regulation of β_2-adrenergic receptor–agonist therapy may depend on several loci acting together via gene–gene interactions. In confirmation, 4/5 SNPs tested in *GSNOR* were associated with asthma patient responses to salbutamol in 168 Puerto Rican asthma patients [94]. These SNPs were also associated with asthma susceptibility, and the key risk haplotype was associated with increased transcriptional activity based on promoter-reporter studies [94]. *GSNOR* is an alcohol dehydrogenase that breaks down GSNO, an endogenous bronchodilator [95]. In addition, GSNO regulates nitrosylation of proteins, leading to alterations in function, including G-protein coupled receptor kinase 2 (*GRK2*), which phosphorylates and desensitizes the β_2-adrenergic receptor [96].

Other novel genes have recently been associated with β_2-adrenergic receptor–agonist therapy including the spermatogenesis–associated, serine-rich 2-Like (*SPATS2L*) and collagen (*COL22A1*) genes [97]. The *COL22A1* gene, through association with the intronic SNP rs6988229, was associated with acute bronchodilator response to inhaled salbutamol in a genome-wide association study in which ~500,000 SNPs were tested in 403 Caucasian trios. This association was replicated in a pooled population of three asthma trial populations, as well as in three additional asthma populations [97]. *SPATS2L* was also identified as a modulator of β_2-adrenergic receptor–agonist function through a GWAS. Here, the SNP rs295137, located near the *SPATS2L* gene, was significantly associated with percentage change in baseline FEV_1 in 1644 Caucasian asthma patients; this was replicated in two alternate Caucasian populations ($n \sim 500$ each). Molecular biology techniques confirmed these results and identified that *SPATS2L* may be an important regulator of β_2-adrenergic receptor downregulation.

The identification of patients at risk from potential adverse effects of β_2-adrenergic receptor–agonists remains a critical clinical question, as does the targeting of this class of drug to patients most likely to benefit from it. While there has been clear progress with respect to study design (e.g., examining haplotypes instead of genotypes in isolation) and adequately powered studies using thousands of individuals, there is still a need for large prospective studies of asthma patients with matched phenotypes and carefully controlled covariates that include environmental influences. Similarly, these studies would benefit from GWA approaches and the identification of gene–gene interactions.

28.5.6 Pharmacogenetic Approaches to Disease Management: *ADRB2* Arg16 and Second-Line Therapy

While investigations of the effect of genetic polymorphisms on β_2-adrenergic receptor–agonist responses have predominantly focused on clinical end points (e.g., lung function parameters) in the different genotype groups, there has been recent interest in the real-life application of genetic knowledge. As outlined, the first-line treatment for asthma is a short-acting β_2-adrenergic receptor–agonist (e.g., salbutamol) as needed (step 1); if symptoms persist, the addition of inhaled corticosteroid (e.g., beclomethasone) is considered (step 2); for further control, a long-acting β_2-adrenergic receptor agonist (e.g., salmeterol) or a leukotriene receptor antagonist (LTRA) (e.g., montelukast) is added (step 3) (Figure 28.4).

In a recent study, Lipworth et al. set out to use genetic information on the *ADRB2* Arg16 polymorphism to inform the choice of prescribing salmeterol or montelukast as add-on therapy [98]. Children with persistent asthma and homozygous for the Arg16 genotype ($n = 62$) were randomized to receive salmeterol (50 μg, bd) or montelukast (5 or 10 mg, once daily) as an add-on to inhaled fluticasone propionate for one year. The study tested whether carriers of the Arg16 genotype were more prone to adverse effects (e.g., prolonged β_2-adrenergic receptor–agonist use associated exacerbations), and hence whether montelukast provided superior control for this preselected population.

Outcomes were school absences (primary outcome), exacerbation score, reliever use (salbutamol), morning dyspnoea, and Asthma Control Questionnaire (ACQ) quality-of-life scores. Montelukast provided superior benefit for all measures, with clinically relevant differences within three months. No significant difference in FEV_1 (% Pred) was observed, providing further evidence of limited correlation between lung function and symptom-based scores [98]. These results suggest that larger and longer prospective studies are warranted to provide more definitive data on the clinical utility of Arg16 stratification including a Gly16 study arm and the use of additional markers to define the population would provide clearer interpretation.

28.5.7 Leukotriene Synthesis Inhibitor and Leukotriene Receptor Antagonist Pharmacogenetics

As outlined, leukotriene synthesis inhibitors (LTSIs) and leukotriene receptor antagonists (LTRAs) are commonly used as an add-on therapy in asthma to provide greater control or steroid-sparing effects. The cysteinyl leukotrienes (LTC_4, LTD_4, LTE_4) and dihydroxy leukotriene (LTB_4) contribute to the inflammatory process in asthma and are synthesized from arachidonic acid via the 5-lipoxygenase pathway (Figure 28.7). Cysteinyl leukotrienes have been implicated in bronchoconstriction, mucus secretion, vascular permeability, inflammatory cell infiltration and cytokine production. Arachidonic acid is converted to 5-hydroperoxyeicosatetraenoic acid and leukotriene A_4 (LTA_4) by 5-lipoxygenase (5-LO/*ALOX5*) and 5-lipoxygenase-activating protein (FLAP/*ALOX5AP*), which acts as an adaptor protein for this reaction. LTA_4 is then converted to leukotriene B_4 (LTB_4) by LTA_4 hydrolase (LTA4H) or, alternatively, is conjugated with reduced glutathione to form LTC_4 via the actions of leukotriene C4 (LTC_4) synthase (LTC4S). LTC_4 is next transported to the extracellular space via the multidrug resistance protein 1 (MRP1) (Figure 28.7). Leukotriene modifiers include LTSIs, which act by targeting 5-LO (e.g., zileuton), resulting in a decrease in all leukotriene biosynthesis (LTC_4, LTD_4, LTE_4, and LTB_4) or LTRAs, which act by specifically blocking cysteinyl leukotrienes from binding to their primary receptor, CYSLTR1, which is found on many cell types including inflammatory cells and airway smooth-muscle cells, (e.g., montelukast and zafirlukast).

Data demonstrating the large degree of heterogeneity of asthma patient responses to this class of drug are summarized in Figure 28.6. These data have led to extensive genetic studies investigating the roles of SNPs in a large number of candidate genes associated with leukotriene production and/or activity and acute responses to LTRAs and LTSIs. Associations have been described for polymorphisms in *ALOX5*, *ALOX5AP*, *LTC4S*, *CYSLTR1*, *CYSLTR2*, and *MRP1*; however, many of these studies have been small and so have led to a lack of reproducibility in findings [99]. More recent studies have looked at different aspects of leukotriene modifier functions, including the association of montelukast absorption (i.e., pharmacokinetics) with polymorphisms in *OATP2PB1* [100]. However, others have failed to observe these associations [101].

28.5.7.1 5-Lipoxygenase (ALOX5)

5-LO (along with 5-LO-activating protein) is the major regulatory switch for leukotriene production, and extensive studies have demonstrated that the level of 5-LO can have dramatic effects on both cysteinyl and dihydroxy leukotriene production. 5-LO catalyzes the conversion of arachidonic acid to LTA_4, one of the early stages in leukotriene production (Figure 28.7). *ALOX5* is found on chromosome 10q11.2 and is a large gene composed of 14 exons and 13 introns; it spans approximately 82 kb. Multiple studies suggest that *ALOX5* polymorphisms can influence clinical responses to LTRAs and LTSIs—in particular, a functional repeat polymorphism in the promoter region (resulting in alterations in SP1 transcription factor binding) have been associated with altered gene transcription and with response to the LTSI, ABT-761 [99,102].

These early studies have now been extended to investigate multiple polymorphisms, spanning the entire gene, and association with LTRA and/or LTSI responses in asthma patients. For example, Tantisira et al. observed an association between *ALOX5* intronic SNPs—rs892690, rs2029253, and rs2115819—and change in FEV$_1$ post-LTSI(zileuton)—in a cohort of 577 asthma patients [103]. The rs2115819 SNP was also a predictor of response to the LTRA, montelukast, in a previous study of 252 asthma subjects using percentage change in FEV$_1$ as the primary outcome [104]. In both cases, the GG versus GA or AA genotype had the greatest improvement in lung function (FEV$_1$) post-drug [104]. The lack of association for the rs892690, and rs2029253 SNPs in the montelukast study may be due to the reduced power of this study compared to the zileuton study. The functional significance of these SNPs remains to be resolved, and it is important to note that they may not be the causative genetic change, and that polymorphisms inherited at the same time (i.e., in LD) may be of relevance.

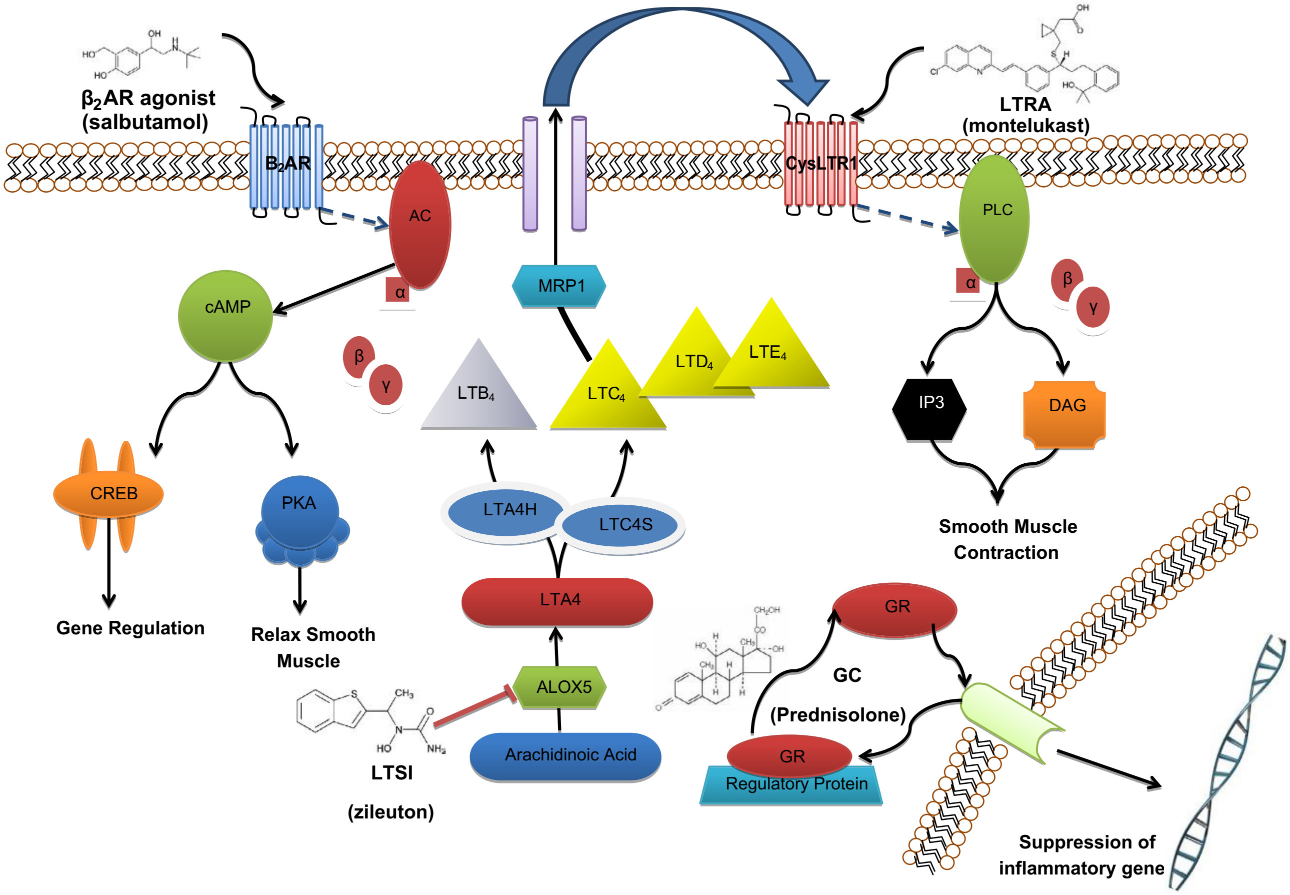

FIGURE 28.7 Targets of current asthma medication. β$_2$-adrenergic receptor agonists bind to the β$_2$-adrenergic receptor and mediate smooth-muscle relaxation via cAMP production and PKA, and regulate various genes via the transcription factor CREB. The cysteinyl leukotrienes LTC$_4$, LTD$_4$ and LTE$_{4,}$ and dihydroxy leukotriene, LTB$_4$ are produced in a series of steps via an enzymatic cascade. Following translocation into the extracellular space, cysteinyl leukotrienes activate their cognate GPCRs (including CysLTR1) and mediate a variety of effects, including smooth-muscle contraction. Corticosteroids enter the cell and bind to receptors that are stabilized by regulatory proteins. The glucocorticoid receptor (GR) then crosses the nuclear membrane, binds to a response element, and modulates transcription. AC—adenyl cyclase; ALOX5—arachidonate 5-lipoxygenase; β2AR agonist—beta2-adrenergic receptor agonist; β2AR—beta2-adrenergic receptor; cAMP—cyclic adenosine monophosphate; cysLTR—cysteinyl leukotriene receptor; CREB—cyclic AMP response-element binding; DAG—Di-acyl Glycerol; GC—glucocorticoid; GPCR—G-protein-coupled receptor; GR—glucocorticoid receptor; IP3—inositol-tri-phosphate; LTA$_4$—leukotriene A$_4$; LTB$_4$—leukotriene B$_4$; LTC$_4$—leukotriene C$_4$; LTD$_4$—leukotriene D$_4$; LTE$_4$—leukotriene E$_4$; LTC4S—leukotriene C$_4$ synthase; LTA4H—leukotriene A$_4$ hydrolase—MRP1—multidrug resistance protein 1; LTSI—leukotriene synthesis inhibitor; LTRA—leukotriene receptor antagonist; PKA—cyclic AMP-dependent protein kinase; PKC—protein kinase C; PLC—phospholipase C. *Source: Reproduced with permission from Portelli and Sayers* [84].

Two *ALOX5* SNPs (rs4987105 (synonymous Thr120Thr) and rs4986832 (5′ region)) were also associated with improvement in PEF on treatment with montelukast in a 12-week study in 174 asthma patients. This further confirmed the relevance of *ALOX5* SNPs and this key enzyme in leukotriene production [105]. Additional support for the relevance of *ALOX5* in asthma control is provided by a recent study of 270 children which found that the *ALOX5* Sp1 promoter polymorphism determined urinary LTE_4 levels and was associated with reduced lung function and, potentially, an ACQ score in non-5 copy carriers [106]. In this study, there was an inverse relationship between urinary LTE_4 levels and FEV_1.

28.5.7.2 Leukotriene C_4 Synthase

Another important enzyme in the leukotriene pathway is leukotriene C_4 synthase (*LTC4S*), which specifically results in the generation of the first cysteinyl leukotriene, LTC_4, by conjugating glutathione to LTA_4. There has been intense research into the role of *LTC4S* in asthma susceptibility because this enzyme, like 5-LO, is thought to be a key regulatory switch for cysteinyl leukotrienes, which are thought to play a more prominent role in asthma (e.g., via bronchoconstriction) than the dihydroxy LTB_4. *LTC4S* is relatively small, spanning 2.51 kb on chromosome 5q35. In particular, a promoter polymorphism (A-444C, rs730012) has been intensely investigated for pharmacogenetic effects as it is thought to alter *LTC4S* levels via transcription (higher levels in C allele carriers) and therefore alter LTC_4 production [107].

Of the ten published studies investigating the role of *LTC4S*-444 A>C, five showed an improvement in outcome measures, including FEV_1 post-LTRA therapy for carriers of the C allele, as hypothesized, although results were not always statistically significant. In a more recent study of zileuton responses (FEV_1 change over time) in 577 asthma subjects, the *LTC4S*-444 polymorphism showed no effect; however, an alternative *LTC4S* polymorphism (rs272431, intron 1) was associated with improved response (mean FEV_1) [103]. As these results were obtained in different populations and using different end points, the relative contribution of the *LTC4S* polymorphism to LTRA or LTSI therapeutic responses in asthma are still unclear. Larger prospective studies using multiple ethnic groups are required.

28.5.7.3 Cysteinyl Leukotriene Receptor 1 and 2 Genes (CYSLTR1/CYSLTR2)

Montelukast and other LTRAs target the cysteinyl leukotriene receptor 1, which is expressed in a variety of cells, including airway smooth-muscle and various inflammatory cells (e.g., eosinophils), therefore inhibiting the activation of this receptor by cysteinyl leukotrienes (Figure 28.7). Cysteinyl leukotriene receptor 1 is thought to be the main receptor mediating cysteinyl leukotriene receptor smooth-muscle contraction and inflammatory cell cytokine production in asthma. Again, genetic variation in the target receptor for these compounds may influence how effective they are in carriers of these alleles by regulating receptor function/expression. The cysteinyl leukotriene receptor 1 gene, *CYSLTR1*, is intronless and found on chromosome Xq13-21; it generates a 337 amino acid G-protein-coupled receptor (GPCR).

A second receptor for cysteinyl leukotrienes has also been described and, while not the target of LTRAs, may modulate the effects of cysteinyl leukotrienes *in vivo*. The gene for cysteinyl leukotriene receptor 2 is found on chromosome 13q14 and encodes for a 346 amino acid GPCR. Interestingly, in combination with several *ALOX5* SNPs, polymorphisms spanning *CYSLTR1* have been identified as determinants of responses to montelukast, suggesting SNP–SNP interactions may be important [108]. However, direct evaluation of *CYSLTR1* polymorphisms and responses to montelukast [104] or zileuton [102] have not identified a significant effect for them to date. Studies of *CYSLTR2* are limited; however, SNPs rs91227 and rs912278 (3′UTR) have been associated with an improvement in morning PEF following administration of montelukast for 12 weeks [105].

28.5.7.4 Novel Genes Associated with Clinical Responses to Leukotriene Modifier Drugs

While the majority of studies have focused on candidate polymorphism analyses in genes directly involved in leukotriene production or activity, several studies have identified additional genes of relevance to LTSI and LTRA response. In addition to its effects on vasodilation and bronchoconstriction, the prostaglandin D2 receptor (gene: *PTGDR*) is thought to regulate, at least in part, levels of leukotriene C_4. In a study of 100 asthmatic children prescribed montelukast (5 mg/day), a modest effect of the *PTGDR*-4441T/C was observed.

Similarly, in a more extensive study of 169 SNPs in 26 candidate genes in asthma patients prescribed fluticasone, fluticasone propionate plus salmeterol or montelukast, a significant association between four SNPs in the cholinergic muscarinic receptor 2 gene (*CHRM2*) and montelukast response (change in FEV_1) over 16 weeks was observed [106]. *CHRM2* and *CHRM3* are thought to mediate airway tone via regulation of contractile/relaxation responses and targeting of *CHRM3* using antagonists; for example, tiotropium has shown clinical efficacy in multiple respiratory diseases. These data potentially suggest that the nature of the airway obstruction/tone determined by altered *CHRM2* expression and/or activity may influence responses to montelukast.

While the majority of studies have investigated the association between gene polymorphisms and acute responses to asthma therapy, a recent study by Mougey et al. identified that solute carrier organic anion transporter family, member 2B1 (*SLCO2B1*, alternative name: organic anion transported SB1; *OATP2B1*), was able to mediate montelukast permeability using a model cell system engineered to express the OATP2B1 protein [100]. Subsequently, the same group also showed that an alteration in the protein structure of OATP2B1 that occurs naturally—that is, Arg312Gln (rs12422149)—was associated with reduced morning plasma concentrations of montelukast following an evening dose during one month or six months of treatment in 80 asthma patients [100]. More specifically, GA (Arg/Gln) genotype carriers had ∼20% lower montelukast concentration than the GG (Arg) group at one month, and ∼30% lower concentration at six months, and of clinical relevance A allele carriers did not demonstrate benefit from montelukast using a symptom-based score [100].

The same researchers have now replicated these findings on montelukast absorption [109]; however, another study did not replicate this finding and failed to identify any effect of the Arg312Gln polymorphism on montelukast plasma concentrations, albeit in a different study design involving fewer subjects [101]. These studies highlight the potential importance of genetic factors influencing drug transporters that may be anticipated to affect pharmacokinetics and the pharmacodynamics. Similarly, several SNPs in another transporter protein, multidrug resistance protein 1 (*MRP1*) (alternative name: ATP binding cassette, subfamily C, member 1 (*ABCC1*))—for example, rs119774—have been associated with montelukast response (change in FEV_1 % predicted) [110] and zileuton response [103]. This association potentially confirms the pharmacogenetic significance of this *MRP1* SNP marker. This *SNP* is intronic, and the underlying functional mechanism, including which genetic variant explains these effects, remains to be resolved.

Overall, there has been good progress in the pharmacogenetics of leukotriene modifier therapy in asthma, with SNPs in multiple leukotriene-synthesising enzymes (e.g., *ALOX5*) showing robust association with LTA and LTSI responses. Multiple genes in the leukotriene synthesis pathway and/or receptors have polymorphisms that have been associated with asthma susceptibility, which implies that there may be a more leukotriene-driven asthma that is therefore more amenable to treatment with LTSIs and LTRAs. Of interest in this drug class, preliminary data suggest a significant contribution of SNPs in drug transporter genes, ultimately determining both the pharmacokinetics and the pharmacodynamics. These data set the scene for larger prospective studies to provide accurate effect sizes and determine clinical implications with greater confidence.

28.5.8 Corticosteroid Pharmacogenetics

Corticosteroids are an important pharmacogenetic target in asthma. Initial investigations into a pharmacogenetic approach for the corticosteroid element of asthma therapy focused on the glucocorticoid receptor gene (*GR*, alternative name: nuclear receptor subfamily 3, group C, member 1, *NR3C1*), which maps to chromosomal region 5q31—a region associated with multiple asthma phenotypes. As with other genes discussed in this chapter, several polymorphisms have been described in the *GR* gene that have functional consequences, such as a Val641Asp polymorphism that has been shown to influence the binding affinity for dexamethasone. However, similar to most polymorphisms shown to have potential pharmacogenetic effects, several of these polymorphisms are rare and their functional significance is questionable [84]. Despite this, the *GR* remains a tantalizing target for asthma pharmacogenetics, and it is surprising that there have not been further recent investigations into the role of GR polymorphisms in corticosteroid responses.

GR is not the only gene to be associated with genetic-based variance in corticosteroid efficacy in asthma treatment. A number of other genes have been implicated, including *CRHR1*, *TBX1*, *NK2R*, *STIP1*, *DUSP1*, and *FCER2*, and these are discussed below.

28.5.8.1 Corticotrophin-Releasing Hormone Receptor 1 Gene

SNPs in the corticotrophin-releasing hormone receptor 1 (*CRHR1*) gene are associated with response to inhaled corticosteroid treatment, based on end point change in FEV_1 following 8 weeks of treatment in three asthmatic cohorts using a candidate gene approach (131 SNPs in 14 genes, $n = 1117$ asthma subjects). For example, the intronic *CRHR1* SNP rs242941 exhibited genotype-specific changes in the percentage predicted change in FEV_1 in response to corticosteroid therapy in 470 adult asthma subjects [111]. This study was the first to show a pharmacogenetic effect for steroid efficacy in an asthmatic cohort, and it highlights the *CRHR1* gene to be at least one of a number of factors determining corticosteroid efficacy. *CRHR1* is thought to influence responses to exogenously administered corticosteroid through the regulation of endogenous levels of corticosteroid.

28.5.8.2 T Box 21 and Neurokinin 2 Receptor Genes

The T box 21 (*TBX21*) gene has been shown to be a predictor of improvement in bronchial hyper-responsiveness (BHR) (4 year change) post-corticosteroid treatment in children, based on a genotype-dependant variation of the nonsynonymous SNP rs2240017 (His33Gln), where the presence of the G allele gave greatest improvements [112]. However, the association of this gene remains under question because of its low allele frequency in Caucasians (MAF ∼0.04), which resulted in only a few subjects ($n = 5$) being available to contribute to this observation [112]. Additional data have given more confidence to the involvement of *TBX21* because the His33Gln polymorphism was significantly associated with improved asthma control in the presence of corticosteroids, although the alternative allele to that described was associated with greater control in 53 Korean asthma patients during 5–12 weeks treatment [112]. Interestingly in the same study, Ye et al. identified a novel gene, the Neurokinin 2 receptor (*NK2R*), which was associated with improved asthma control in the presence of corticosteroids; the G allele (Gly) of the *NK2R* SNP rs77038916G/A, (Gly231Glu) was associated with the greatest improvement. Neurokinin A induces bronchoconstriction and inflammation, therefore modulation of the neurokinin receptor may influence the magnitude of these responses.

28.5.8.3 Stress-Induced Phosphoprotein 1 Gene

Multiple SNPs in the stress-induced phosphoprotein 1 gene (*STIP1*) were associated with variable FEV_1 responses to treatment with the inhaled corticosteroid flunisolide in 382 asthma subjects [103]. This study investigated SNPs spanning eight candidate genes and identified *STIP1* SNPs rs4980524, rs6591838, and rs2236647 as SNPs affecting percent change in FEV_1 in response to flunisolide at 4 weeks and 8 weeks [103]. *STIP1* codes for an adaptor protein that coordinates functions with HSP70 and may be involved in formation of the glucocorticosteroid receptor heterocomplex.

28.5.8.4 Dual-Specificity Phosphatase 1 Gene

The dual-specificity phosphatase 1 (*DUSP1*) gene encodes a protein that has dual specificity for tyrosine and threonine and inactivates p38 mitogen-activated protein kinase (MAPK). Recently, several SNPs including a 5′ region SNP, rs881152, were associated with (1) bronchodilator responses and (2) asthma control in the presence of corticosteroid in a cohort of asthma patients (n = 430) [113]. The mechanism underlying these effects is unclear; however, it was suggested that corticosteroid induces *DUSP1* expression, which may be altered in carriers of the rs881152 5′-region SNP. This influences the ability of *DUSP1* to target the p38 MAPK signaling pathway.

28.5.8.5 Low-Affinity IgE Receptor Gene

In a cohort of 311 asthmatic children, the low-affinity IgE receptor gene (*FCER2*) has been highlighted as putatively involved in corticosteroid (budesonide) regulation of exacerbation by virtue of an association between the SNP T2206C (rs28364072, intronic) and the relative risk of severe exacerbations while taking budesonide [114]. Interestingly, the C allele was also associated with elevated IgE levels in the 311 asthma patients [114]. Importantly, this pharmacogenetic association has now been replicated in two other asthma cohorts (n = 386 and 939, respectively), with the 2206C allele being associated with increased hospital visits and uncontrolled asthma in patients receiving ICS [115]. It is not surprising that this polymorphic variation in an IgE receptor influences receptor expression, which alters IgE levels and is associated with more severe forms of asthma. In turn, these subjects cannot be adequately controlled by corticosteroid treatment.

The first GWAS in asthma, published in 2012, identified SNPs in the glucocorticoid-induced transcript 1 gene (*GLCC1*) as determinants of glucocorticoid response in 935 asthma subjects [116]. This study examined 534,290 SNPs using the Human Hap 550v3 Beadchip to identify 100 SNPs of interest in an initial cohort of 403 parent–child trios. The primary outcome was change in FEV_1. Of interest was a SNP in the *GLCC1* gene promoter region (rs37972C/T) that was associated with attenuation in FEV_1 improvement post-corticosteroid in three of four cohorts tested [116].

A subsequent GWAS identified the *T-gene* as a novel player in lung function response (FEV_1) to inhaled corticosteroids. Analyses were carried out in 418 Caucasian asthmatics and replicated in a secondary asthmatic population (n = 407), where 3 out of 47 successfully replicated SNPs were associated under the same genetic model in the same direction, including 2 of the top 4 SNPs ranked by p value. These SNPs (rs3127412C/T and rs6456042A/C) were in strong LD with a variant located in the *T-gene*, suggesting that this gene is a novel player in the pharmacogenetic regulation of corticosteroid efficacy. This was confirmed by a follow-up association, where the *T-gene* variant was associated with lung function response to inhaled corticosteroids in the initial GWAS analysis (an average 2–3-fold increase in FEV_1 response for homozygous wild-type subjects; rs3127412 TT; and rs6456042 CC) [117].

Not all recent developments have been due to GWAS. For example, a recent hypothesis-driven study implicated the cytochrome P450 3A enzymes in glucocorticosteroid efficacy through modulations in corticosteroid metabolism. In this study, Roberts et al. showed, through mRNA-driven studies confirmed via microsomes and recombinant enzymes, that CYP3A4 and CYP3A5 metabolize corticosteroids (budesonide) into inactive metabolites [118]. They suggested that differences in the expression or function of these enzymes in the lung and/or liver could influence corticosteroid efficacy in the treatment of asthma.

28.5.8.6 Combination Therapy (β_2-Adrenergic Receptor–Agonist/Corticosteroid) Pharmacogenetics

To date, the majority of pharmacogenetic studies have focused on one class of asthma therapy. However, several recent studies have investigated combination therapy, which more accurately reflects the clinical situation. We have summarized the main findings regarding the influence of *ADRB2* polymorphisms, including Arg16Gly, on combination therapies, particularly fluticasone/salmeterol and budesonide/formoterol in Section 28.5.5.1. However, it is clear that reports on associations between *ADRB2* Arg16 and increased exacerbation in asthma patients using regular salbutamol in addition to their maintenance combination are mixed, with some studies failing to report the association, potentially because of differences in study design.

More recently, additional genes have been investigated for SNP associations with patient responses to combination therapy. In a study of 81 asthma patients regularly using an ICS/LABA combination, it was shown that polymorphisms in the nitrous oxide synthase 3 (*NOS3*) gene involving an amino acid change (G894T, Glu298Asp), were associated with post-drug improvement in lung function (change in FEV_1 (% Pred)) [119]. *NOS3* codes for a key enzyme in the production of NO in the airways, and F_ENO has been shown to be elevated in asthma and is considered a marker of ongoing inflammation.

Importantly, earlier data identified that the Glu298Asp polymorphism is functional in *NOS3* and influences levels of F_ENO with the TT genotype associated with lower F_ENO levels. These data suggest that lower *NOS3* activity and potentially lower F_ENO levels identify patients more likely to respond to combination therapy; however, larger prospective trials are required to validate these findings because they are potentially counterintuitive if NO is a marker of inflammation and ICS target inflammation.

A recent 16-week study on the effect of genetic determinants (169 SNPs in 26 candidate genes) on asthma patient response to combined fluticasone propionate/salmeterol therapy identified three SNPs in the cholinergic muscarinic receptor 2 gene (*CHRM2*) that are associated with asthma ACQ scores, and found a single SNP, rs1461496 in heat shock 70kD protein 8 (*HSPA8*), to be associated with change in FEV_1 [106]. Of interest, *CHRM2* SNPs were also associated with responses (lung function) to montelukast (see earlier), suggesting that the "tone" of the airways as determined by muscarinic receptors is important for therapies that target airway contraction. *HSPA8* is involved in protein folding in the cell, but it is important to note that *HSPA8* SNPs previously were not associated with response to ICS [120].

28.6 DRUG DEVELOPMENT IN ASTHMA AND EMERGING TARGETS

Drug development in asthma has been slow to generate new classes, and the major advances in patient care have come from new compounds and/or indications for existing drug classes (e.g., improved duration of action for LABAs). One potential explanation for this limited progress is the design of and recruitment to Phase I and Phase II trials for the evaluation of new compounds. We have already outlined how initial trials of anti-IL5 demonstrated disappointing effects on lung function and asthma symptoms. Only after careful selection of patients, based on clinical and cellular parameters, were clinically relevant improvements observed. Researchers now understand that asthma is heterogeneous and, particularly for strategies targeting specific mediators, careful selection of patients is necessary to fully understand the therapeutic potential of new drugs.

Recent approaches to the treatment of asthma [121] include the following:

- Cytokine inhibition—for example, anti-IL5 (mepolizumab), anti-tumor necrosis factor alpha (TNFα) (etanercept, soluble TNFR), anti-Interleukin 13 (IL13) (lebrikizumab, tralokinumab)
- Chemokine receptor antagonists—for example, chemokine (CXC motif) receptor 2 (CXCR2) (SCH527123)
- Signaling pathway inhibitors with anti-inflammatory effects—for example, targeting p38 MAPK (SD-282), PDE4 (roflumilast)

The specific targeting of single mediators is unlikely to provide a therapeutic option for asthma in its broadest definition. However, targeting specific subpopulations has shown clinical efficacy. Very recently, a study investigating a human IL13-neutralizing monoclonal antibody (tralokinumab) used a carefully balanced population of atopic and nonatopic asthmatics, with exclusions for additional respiratory pathology, cigarette smoking ≥10 pack-years, recent infection, or treatment with immunosuppressive medication, in a randomized double-blind study [122]. Here, tralokinumab was associated with improved lung function based on an increase in FEV_1 and a decrease in daily β_2-adrenergic receptor–agonist use [122]. These studies overall demonstrate that careful selection of asthma subjects, in this case based on phenotype, is critical in asthma drug development.

As novel asthma genes are identified, it is paramount that their evaluation as potential drug targets, particularly in the context of Phase II trials, takes into account pharmacogenetic factors. Preliminary data support genetic testing in Phase II trials of newer compounds, as shown in a recent report on a IL4/IL13 dual antagonist (pitrikinra). Polymorphic variation in the target receptor for this antagonist (i.e., IL4Rα) significantly influenced outcomes in allergic asthma subjects [123]. Pitrikinra is a recombinant form of IL4 differing at two amino acid residues (i.e., a mutein, R121D/Y124D). This has been shown to reduce late-phase antigen responses (LAR) to inhaled antigen as defined by changes in lung function (FEV_1) over 4–10 hours post-antigen exposure.

In one study, subjects had been following a four-week period of twice daily active treatment of nebulized pitrikinra or placebo, with an increased LAR ratio correlating with a reduced FEV_1 [124]. Stratification of subjects (pitrikinra n = 15, placebo n = 14) into genotype groups for the nonsynonomous *IL4RA* SNP rs1801275 (Gln576Arg) identified Arg/Arg carriers as having an attenuated LAR ($P < 0.0001$) following pitrikinra treatment compared to Gln/Gln or Gln/Arg genotypes. Similarly, stratification based on rs1805011 (Glu400Ala) showed an attenuated LAR in the Glu/Ala group but not the Glu/Glu group [123]. Interestingly, the Arg576 variant (when in combination with Val75) was shown to be a risk factor for allergic asthma and to lead to enhanced IL4Rα signaling post IL4 stimulation [125].

These preliminary data suggest that selecting a subgroup of patients with a particular genotype when it is anticipated that the receptor/pathway may have a more dominant role in that individual's asthma is critical to interpreting Phase II clinical trials.

28.6.1 Screening, Stratification, Personalization

Approaches to further define asthma subphenotypes (e.g., using cluster analyses) have been useful and further confirm this heterogeneity in clinical presentation. While current medications have been extremely successful in asthma management (e.g., ICS), it is clear that individual responses to these medications and to therapies in development are heterogeneous, with large variation in clinical benefits and/or detrimental effects. The stratification of asthma treatment using clinical and/or genetic approaches therefore shows great potential for maximizing clinical outcomes and minimizing adverse effects, leading to improvement in the management of asthma.

There has been excellent progress in this area of research over the last five to ten years with the introduction of anti-IgE (omalizumab) therapy into mainstay asthma treatment, but only for those patients with clinical indications (i.e., severe allergic asthma) with an elevated serum IgE level. This stratification in prescribing for anti-IgE shows proof-of-concept by targeting this expensive biologic to those patients most likely to show clinical benefit. Similarly, there is accumulating evidence that stratification of patients in Phase II trials of newer therapies—for example, anti-IL5 (mepoluzimab) and anti-IL13 (lebrikizumab), again based on clinical and cellular patient profiles, is essential to adequately evaluate these therapies and will be important if these therapies are introduced into clinical practice.

Clear progress in asthma pharmacogenetics has come with completion of newer studies that interrogate multiple SNPs in large prospective cohorts. To date, predominantly candidate gene/pathway approaches have been used, but several genetic variants have now been identified with confidence (e.g., *ALOX5* and leukotriene modifier response; *FCER2* and glucocorticoid response). Importantly, these studies show independent replication (the gold standard in genetic studies, including specific SNPs and direction of effect).

Also importantly, several GWASs have now been completed that provide integration of common variation spanning the entire genome (typically testing 500,000 SNPs) identifying novel gene variants in a hypothesis-free approach (e.g., the collagen (*COL22A1*) locus and *SPATS2L* and response to albuterol/salbutamol). These more recent findings still need further replication and validation; however, they potentially pave the way for a "responder" and "nonresponder" profile based on multiple SNPs in multiple genes, all measured on the same platform. A key question is the relative contribution of common variation (measured on these platforms) and rare variation (not currently measured to these outcomes).

Another remaining question relates to the magnitude of changes in clinical measures between genotype groups in asthma patients (e.g., FEV_1). Data so far suggests that these differences can be considered clinically relevant; however, further work with larger populations is required to accurately estimate effect sizes. Similarly, the genetic variation identified to date accounts only for a modest proportion of the overall variation of the trait (e.g., a recent estimate suggests the hereditability of bronchodilator response at ~28.5%). It is likely that studies so far have been confounded by factors including SNP/haplotype analyses, gene–gene interactions, and the relative contribution of SNPs in different ethnic backgrounds. Therefore, while our knowledge has dramatically increased, there is a need for prospective trials of these current compounds that involve large numbers of subjects and hypothesis-free approaches including GWAS.

As with GWAS approaches to identifying disease susceptibility genes, "missing hereditability" will be an important issue in pharmacogenetics studies. This small proportion of hereditability currently assigned to identified loci (e.g., *CRHR1* < 3%) of corticosteroid response needs to be addressed because asthma medications cannot be successfully personalized unless we resolve a larger degree of genetic variability and/or environmental factors.

As with clinical/cellular approaches to stratifying Phase II trials of newer asthma therapies, it is clear that genetic stratification has a role to play. For example, the recent Phase II trials of the IL4/IL13 dual antagonist (pitrikinra) suggests patient selection is critical to evaluating the clinical efficacy of this compound, with specific IL4Rα genotypes identifying responder groups. More pharmacogenetic integration is required for Phase II trials, which represents a clear challenge for drug development pipelines.

As our understanding of the genetic basis of asthma increases other therapeutic targets for asthma will become apparent (e.g., IL33 receptor antagonists). It is clear that the genetic variation associated with asthma susceptibility in these genes will influence pathways targeting methods, as they essentially identify individuals in which the pathway may be particularly important. It is also likely that existing therapies may be influenced by the genetic factors that underlie asthma susceptibility, particularly therapies that have multiple targets (e.g., ICS).

The impact of our genetic knowledge on asthma management and prescribing practice is limited at this time, as there is a need to further define the complex genetic basis of responders and adverse effects in large prospective studies. However, preliminary "real-life" studies with related outcome measures (e.g., days from school) have provided proof of concept that genetic information can have important implications for disease management (e.g., informing second-line therapy in asthma using *ADRB2* Arg16) [98].

28.7 CONCLUSIONS AND FUTURE DIRECTIONS

There remain many unanswered questions regarding the potential of stratified approaches in the management of asthma. While progress has been made in identifying patient subgroups based on clinical measures, cell counts, or marker expression, more work is required using very large studies to extensively characterize asthma patients not only cross-sectionally, but also longitudinally over many years to identify the natural progression of the disease.

The field of genetics is rapidly progressing, with great technological developments moving at a dramatic pace, e.g., GWAS comprising a million common SNPs or several million rare SNPs, gene expression studies, and whole-exome or targeted resequencing. These approaches will allow the interrogation of genetic variation effect in patient subgroups. It is likely that a drug-specific genetic profile involving several genes (e.g., receptors, signaling mediators, transcription factors) will be a step toward personalized medicine in asthma, with associated benefits including avoidance of adverse side effects and adequate control of the disease. We anticipate that through these approaches many novel common variants/genes will be identified as underlying responses to current asthma medication. As the cost of genetic analyses continues to fall, the potential of a relatively simple test that will have an impact on asthma management costs becomes a real possibility.

If genetic or clinical information is going to influence clinical practice, there must be a simple, reproducible diagnostic test based on SNP combinations or simple clinical measures, with adequately high specificity and sensitivity that distinguishes responders and nonresponders. However, the introduction of routine genetic and/or clinical testing into practice will require a clear demonstration of health benefits and cost-effectiveness that outperforms the current stepwise approach to asthma management.

29.1 OVERVIEW

Rheumatoid arthritis (RA) is an inflammatory symmetric polyarthritis that left untreated can lead to erosions, joint space loss, and permanent destruction of the affected joints. RA is a chronic, disabling disease and can be associated with systemic manifestations.

29.1.1 Epidemiology

RA affects approximately 1% of the population worldwide and leads to significant morbidity and mortality. It increases in incidence with age and affects women about three times more often than men [1]. However, after the age of 60, RA affects both genders equally.

29.1.2 Immunologic Features

The genetic basis of RA remains incompletely understood, although an association with major histocompatibility complex (MHC) class II molecules is well known. Specifically, individuals with the "shared epitope," a unique sequence of amino acids in the hypervariable region of the HLA-DR β chain, are at increased risk of RA than are those without it. *HLA-DRB1* alleles that code the shared epitope (SE)—a 5 amino acid–sequence motif in residues 70–74 of the HLA-DRβ chain—confer a strong genetic risk for RA [2,3]. Although the exact mechanisms for this association remain unclear, glutamine or arginine in position 70 on the DRβ chain increases RA risk, while aspartic acid in that position confers protection [4]. Up to 20% of RA patients are SE-negative [2]. Noninherited maternal HLA antigens (NIMA) may confer RA risk in some individuals [5,6].

Many environmental factors, in particular cigarette smoking and periodontal disease, have been identified as risk factors for RA [1]. This risk is further increased in individuals who also have the shared epitope [7]. Supporting the role of cigarette smoking in the development of RA is some evidence showing that smoking cessation may help prevent its development [8].

Deimination of arginine to citrulline by peptidyl arginine deiminase (PADI) is a well-described post-translational protein modification in RA and has been implicated in RA's pathophysiology. Various citrullinated proteins have been demonstrated to be in the rheumatoid joint, including fibrinogen, collagen, and fibronectin. The process of citrullination involves conversion of arginine to citrulline by the enzymes peptidylarginine deiminases (PADIs). Of the four isoforms, PADI2 and PADI4 are most abundant in

Handbook of Pharmacogenomics and Stratified Medicine. http://dx.doi.org/10.1016/B978-0-12-386882-4.00029-3

the inflamed synovium. PADI4 polymorphisms may confer increased susceptibility to RA in Asians and Europeans [9]. In RA, increased citrullination occurs in the inflamed synovium, and antibodies directed against these citrullinated proteins (anticyclic citrullinated peptide [anti-CCP] antibodies [ACPA]) are produced by resident B cells. ACPA may be an important effector mechanism in RA disease pathogenesis [2].

29.1.3 Pathogenesis

Although the etiology of RA is still unknown, there have been major strides in understanding how the inflammatory process leads to joint destruction. Several processes contribute to joint destruction in RA, including synovial immune complex deposition, neutrophil infiltration, angiogenesis, and T-cell activation [10]. T-cell activation triggered by an unknown antigen leads to joint inflammation and destruction. Synovial membrane hyperplasia and increased vascularity lead to pannus formation. The pannus shows leukocytic infiltration, increased expression of adhesion molecules, proteolytic enzymes, and cytokines, including tumor necrosis factor (TNF)-α, and interleukins (IL)-1, 6, and 17 [11]. These cytokines provide potential targets for blockade and therapy. B lymphocytes can act as antigen-presenting cells in the synovium and also produce antibodies and secrete proinflammatory cytokines. B-cell depletion therapy has been shown to be beneficial in patients with RA [12]. The pannus begins to invade the joint cartilage and bone. Proliferation of the pannus leads to profound cartilage destruction, subchondral bone erosions, and periarticular ligament laxity. Cytokine-stimulated osteoclast activity also contributes to the erosions and periarticular osteoporosis seen in RA [13].

The search for specific immunologic mechanisms steered the discovery of autoantibodies in patients with RA. The role of these autoantibodies in RA pathogenesis is unclear. The long-recognized rheumatoid factor (RF), a polyclonal IgM directed against the Fc portion of IgG, is found in about two-thirds of RA patients. It binds to IgG-containing immune complexes and enhances immune responses. RF can be present in chronic infections such as hepatitis B and C and chronic inflammatory conditions. The sensitivity and specificity of RF for RA diagnosis are roughly 66% and 82%, respectively. The key autoantibodies associated with RA are those against citrullinated peptides (ACPA), as described before. The sensitivity of anti-CCP antibodies for the diagnosis of RA is 70%, but the specificity is 95%; thus, these antibodies are superior to RF in making a diagnosis of RA. Up to 35% of patients with a negative RF at presentation will test positive for anti-CCP antibodies. A small percentage of patients (10–15%) will remain seronegative (RF and CCP antibody–negative) throughout the course of the disease.

29.1.4 Diagnosis

The presentation and course of RA is variable. Typically, patients present with an insidious onset of symmetric joint pain, swelling, and morning stiffness worsening over several weeks. The severity and duration of morning stiffness often correlate with overall disease activity. Less common presentations include acute, rapidly progressive polyarthritis and, more rarely, monoarthritis. RA commonly involves the small joints of the hands (metacarpophalangeal [MCP] and proximal interphalangeal [PIP] joints), wrists, and feet (metatarsophalangeal [MTP] joints). Large joints can also be affected and include the shoulder, elbow, hip, knee, and ankle. Physical findings in RA involve the identification of symmetric joint inflammation early in the course of disease, as well as manifestations of joint destruction with chronic disease. Active synovitis is characterized by warmth, swelling, pain, and palpable effusions. Synovial proliferation is determined on physical examination by the presence of soft or rubbery tissue around the joint margins.

Severe RA can manifest with sequelae of systemic inflammation, especially in RF-positive patients. These include rheumatoid nodules and vasculitic skin ulcerations and ocular, pulmonary, cardiac, neurologic, and hematological abnormalities. Renal and gastrointestinal manifestations are rare. With early recognition and treatment of RA, the incidence of extra-articular manifestations diminishes. The American College of Rheumatology (ACR) classification criteria for the diagnosis of RA [14] were designed for inclusion of patients in clinical studies and not for clinical diagnosis. It is also pertinent to point out here that these criteria were formulated using data from hospitalized patients and thus are not very useful in the outpatient setting. Despite these caveats, these criteria are helpful to a physician unfamiliar with RA as a tool to evaluate a patient in the office. Most of the articular destruction occurs in the early years of disease, so it is important to diagnose and treat RA early [15,16].

29.1.5 Treatment

The goals of RA treatment are to alleviate pain, control inflammation, preserve and improve activities of daily living, and prevent progressive joint destruction. Medical treatment includes the use of nonsteroidal anti-inflammatory drugs (NSAIDs), disease-modifying antirheumatic drugs (DMARDs), and corticosteroids. Equally important in the management of RA is nonmedical treatment, including patient education, physical therapy, occupational therapy, orthotics, and, rarely, surgery.

DMARD therapy within three months of diagnosis is currently recommended because it can slow or arrest progression of the disease. DMARDs suppress immune-mediated inflammation by decreasing the activity of target cells (e.g., lymphocytes) or specifically targeting cytokine pathways [1]. Commonly used DMARDs include methotrexate, leflunomide, sulfasalazine, and hydroxychloroquine. When maximal dosing of one DMARD provides suboptimal disease control, the addition of other DMARDs often improves effectiveness [17,18]. Monitoring for RA disease activity and drug toxicity is important as well.

Biologic DMARDs targeting the inflammatory cytokine TNF-α include the fusion protein etanercept; the monoclonal antibodies infliximab, adalimumab, and golimumab; and the pegylated TNF receptor fusion protein certolizumab pegol. Other currently available biologic DMARDs include abatacept (a cytotoxic T-lymphocyte antigen 4 fusion protein that blocks T-cell costimulation by antigen-presenting cells); rituximab (a monoclonal antibody to CD20 that depletes B cells); the IL-1 receptor antagonist anakinra; and tocilizumab, a monoclonal antibody to the IL-6 receptor. Recently, an oral biologic, tofacitinib, which is a janus kinase 3 (JAK 3) inhibitor was approved for RA treatment.

Corticosteroids in low doses (e.g., prednisone, 5–10 mg) are extremely effective in promptly reducing the symptoms of RA and are useful in helping patients recover their previous functional status, but care should be taken to use the lowest effective dose. Corticosteroids are appropriate in patients with significant limitations in their activities of daily living or in an acute disease flare while awaiting the efficacy of the generally slower-acting DMARDs [1]. NSAIDs, including the selective cyclo-oxygenase (COX)-2 inhibitors, are commonly added to treatment regimens for pain relief and to decrease inflammation. NSAIDs do not prevent progression of bone and cartilage damage and should be used with caution because of their potential for gastrointestinal (GI) and renal toxicity and effects on cardiovascular risk, especially since RA patients may have an increased incidence of cardiovascular events [19].

29.1.6 Pharmacogenetics and Stratified Medicines in RA

The rapid development of biologic DMARDs has widened the choices of treatment for RA and have made therapy for it more effective but at the same time more expensive. Thus, in recent years there has been an interest in developing pharmacogenetic methods to predict an individual patient's response to a given DMARD.

This chapter highlights some of the major publications in the field of pharmacogenetics in RA and touches on the implications of this field for future research and clinical care. The pharmacogenetics of five major nonbiologic DMARDs—methotrexate, leflunomide, azathioprine, sulfasalazine, and hydroxychloroquine—and three biologic DMARDs—the tumor necrosis factor antagonists, rituximab, and tocilizumab—are reviewed in the following sections.

29.2 PHARMACOGENETICS OF NONBIOLOGIC DMARDS

29.2.1 Methotrexate

For over the past two decades, methotrexate (MTX) has been the first-line DMARD in RA because of its well-recognized efficacy and safety [20–22] However, the response among patients to it can be quite variable, ranging from 46 to 65% [23,24]. MTX's exact mechanism of action in RA remains unclear; however, current evidence suggests that it affects the intracellular folate and adenosine pathways.

MTX is actively transported into the cell by solute carrier 19A1 (SLC 19A1), also called the reduced folate carrier 1 (RFC1) (Figure 29.1). It is pumped out of the cell by members of the ATP-binding cassette (ABC) family of transporters, also known as multidrug-resistant transporters (MDRs), and multidrug resistance–associated proteins (MRPs) [25]. After entry into the cell, glutamate residues are added to MTX by folylpolyglutamyl synthase (FPGS); thus, MTX is polyglutamated ($MTXPG_n$). The enzyme gamma glutamyl hydrolase (GGH) can reverse this process. Polyglutamation keeps MTX within the cell, preventing drug efflux by the ABC transporters.

The ratio of GGH to FPGS has been suggested as a predictor of MTX treatment outcomes in human primary leukemia [26]. MTX-resistant cells show decreased FPGS activity [27–29]. MTXPGs inhibit dihydrofolate reductase (DHFR), which reduces dihydrofolate to tetrahydrofolate (THF) [30]. THF is converted to 5,10 methylene tetrahydrofolate (5,10-CH_2-THF) and subsequently to 5-methyl THF (5-CH_3-THF) by methylene tetrahydrofolate reductase (MTHFR). 5-methyl THF is a biologically active folate cofactor that functions as a 1-carbon donor for many important cellular reactions, including the conversion of homocysteine to methionine [31]. MTXPGs also inhibit thymidylate synthase (TYMS), which converts deoxyuridylate to deoxythymidylate in the de novo pyrimidine synthetic pathway [32].

MTX has numerous effects on the purine synthetic pathway. MTXPGs inhibit the enzyme aminoimidazole carboxamide ribonucleotide (AICAR) transformylase, which in turn results in intracellular accumulation of AICAR. AICAR and its metabolites can then inhibit two enzymes in the adenosine pathway—adenosine deaminase (ADA) and adenosine monophosphate (AMP) deaminase—which leads to intracellular accumulation of adenosine and adenine nucleotides. Subsequent dephosphorylation of these nucleotides results in increased extracellular concentrations of adenosine, which is a powerful anti-inflammatory agent [33].

Polymorphisms in genes encoding MTX transporters and enzymes in the folate and adenosine pathways inhibited by MTX have been studied in RA patients (Table 29.1).

29.2.1.1 Transporter Genes—RFC1/GGH/ABCB1

MTX is transported into the cell by RFC1. Polymorphisms in the *RFC1* gene, by altering gene expression, can modify MTX transport [52,53]. *RFC1* is a 27 kb gene located on chromosome 21 (21q22.3). An 80G>A polymorphism leading to substitution of arginine for histidine at codon 27 in the first transmembrane domain (TMD1) of the RFC1 protein and a 61- bp (base pair) repeat polymorphism in the *RFC1* promoter causing increased transcriptional activity of the gene have been described [54]. In a cross-sectional study conducted on 105 RA patients, the effect of the G80A single-nucleotide polymorphism (SNP) on response to MTX was examined. Patients in the top 25th percentile of MTX responders were identified using a visual analog scale (VAS) that measured the patients' and physicians' response to MTX. Patients homozygous for the *RFC* 80A/A genotype had a greater response to MTX compared to patients carrying the wild-type 80G/G. Patients homozygous for the A allele were three times more likely to be within the top 25th percentile of MTX responders (confidence intervals (CI) 1.3–8.4; $p<0.01$), compared to patients with the wild-type G allele. Thus, the *RFC* 80AA SNP may be a marker of amplified response to MTX in RA [55].

SNPs in the *GGH* promoter can impact both GGH expression [56] and MTX polyglutamation [50,57]. A 452C>T SNP leading to decreased GGH activity and accumulation of intracellular long-chain MTX polyglutamates [50] and a 401C>T promoter polymorphism also modifying intracellular MTXPG levels have been described [57].

There is also a *GGH*-16T>C polymorphism whose functional effects are unidentified. A Japanese study of patients with RA demonstrated that the presence of the *RFC* 80AA and *GGH*-401TT genotypes independently predicted MTXPG levels. Patients carrying the *RFC* 80AA genotype were 3.4-fold more likely to have MTXPG levels above the group median compared to patients with the 80GG or 80GA genotype (odds ratio (OR) 3.4, 95% CI 1.4–8.4; p = 0.007).

In contrast, patients with the *GGH*-401TT genotype were 4.8-fold (OR 4.8, 95% CI 1.8–13.0; p = 0.002) more likely to have MTXPG below the study median compared to those who carried the *GGH*-401CC or CT genotype [41]. Thus, both the *GGH*-401C>T and the *RFC* 80G>A SNPs influenced intracellular MTXPG levels and so may predict MTX response in RA [35,36,50,56].

29.2.1.2 *ABCB1*

ABCB1 is a 209 kb gene located on chromosome 7 (7q21.1). It codes for P-glycoprotein (P-gp), a membrane transporter important in the transport of a number of drugs, including MTX. SNPs in the *ABCB1* gene have been studied for their effects on P-gp expression [58]. The 3435C>T SNP is a synonymous SNP in exon 26 of the *ABCB1* gene. The 2677G>T SNP in exon 21, which results in substitution of alanine in position 893 by serine or threonine, is frequently linked to the 3435C>T SNP [59,60]. The impact of variations in *ABCB1* and/or P-gp expression on MTX efflux from the cell is uncertain. One study of human leukemic CCRF-CEM sublines suggested that higher P-gp expression may mediate MTX resistance [61]; however other studies did not support this [62,63].

In one study, genotyping was performed in 92 RA patients and 97 healthy controls for the 3435C>T polymorphism. Patients who had active RA (n = 62, nonresponders) after six months of treatment with MTX (7.5–15 mg/week) and prednisone (5–10 mg/day) and those who responded after six months of the same treatment (n = 30) were studied. The distribution of the *ABCB1* genotypes was similar between RA patients and controls. Patients with the 3435CC and 3435CT genotypes had active disease compared to patients with the 3435TT genotype (OR 2.89; CI 0.87–9.7; p < 0.05). Thus, the presence of the 3435T allele was associated with less active RA and a better response to MTX and prednisone [64].

29.2.1.3 *MTHFR/TYMS/DHFR*

MTHFR is a 19 kb gene located on chromosome 1 (1p36.3). Of several *MTHFR* polymorphisms that have been recognized, [65] two, 677C>T and 1298A>C, have been well studied for their influence on MTX's clinical properties. The 677C>T polymorphism leads to an alanine-to-valine substitution in the codon at nucleotide 677 of the *MTHFR* gene [66]. This change leads to the encoding of a thermolabile variant of MTHFR with resultant decreased enzyme activity. The 1298A>C polymorphism results in a glutamine-to-alanine substitution in the codon at nucleotide 1298. It leads to reduced MTHFR enzyme activity [67]. MTHFR is important in the generation of 5-methyl THF (see Figure 29.1). Because 5-methyl THF acts as the carbon donor for the remethylation of homocysteine to methionine, these two SNPs, by reducing MTHFR activity, can increase plasma homocysteine levels [68].

A number of studies have evaluated the effects of these SNPs on MTX response. One examined 105 patients with RA, 35 of whom were treated with MTX (7.5–15 mg/week), 34 with sulfasalazine (SSZ) (2–3 g/day), and 36 with MTX and SSZ. The 677C>T SNP was genotyped in all patients and their plasma homocysteine levels were measured. Patients on MTX had higher plasma homocysteine levels than those on SSZ alone, but those on both MTX and SSZ had the highest levels. Patients heterozygous for the 677C>T SNP had higher plasma homocysteine levels after one year than patients without the SNP. Patients homozygous for the SNP had a higher plasma homocysteine level at baseline, which did not change significantly. Elevated plasma homocysteine levels (17%, p < 0.05) were found in patients with GI side effects from MTX, such as nausea, abdominal pain, and discomfort compared to patients without side effects.

Combination therapy with MTX and SSZ led to the highest homocysteine levels and the most GI side effects. However, the presence of the C677T SNP was not directly associated with the occurrence of GI events. This suggests that MTX's toxic effects may be caused by elevated plasma homocysteine levels that may be exacerbated by the presence of the *MTHFR* 677C>T SNP [38].

In a Dutch study, 236 patients with RA on MTX were genotyped for the 677C>T SNP. MTX was initiated at 7.5 mg/week and titrated to a maximum dose of 25 mg/week. Patients were assessed for MTX toxicity and disease activity periodically. Of 236 patients, 122 (52%) did not have the SNP; 19 (8%) were homozygous; and 95 (40%) were heterozygous for the polymorphism. Patients who were homozygous and heterozygous for the 677C>T SNP had an increased risk of discontinuing MTX because of adverse events (relative risk (RR) 2.01; CI 1.09–3.70), particularly hepatotoxicity (RR 2.38; CI 1.06–5.34). Supplementation with folic or folinic acid reduced the risk of toxicity-related discontinuation of MTX both in patients with and without the SNP. The 677C>T SNP was not associated with MTX efficacy [39].

Berkun et al genotyped 93 RA patients treated with MTX (average dose 11.9 mg/week) and 377 healthy controls for the 677C>T and 1298A>C polymorphisms in a cross sectional study and assessed patients for RA disease activity and MTX toxicity. Serum folate and plasma homocysteine levels were measured. The prevalence of the 1298CC genotype (24.7%) was higher in RA patients than controls

(12.8%) and this was significant ($p < 0.001$). There were no associations between the 1298A>C SNP and MTX efficacy. Homozygotes for the 1298C allele appeared to be protected from MTX toxicity; 33% did not experience toxicity, only 9.1% had adverse reactions ($p = 0.035$). In contrast, patients with the 1298AA genotype were five times more likely to develop toxicities than those with the CC genotype (OR 5.24; CI 1.38–20). Also, patients carrying the C allele had higher plasma homocysteine levels than patients with the AA or AC genotype, and this was not influenced by serum folate levels. Because the 677C>T polymorphism had no effect on MTX toxicity or efficacy in this study, homozygosity for the 1298C allele may increase susceptibility to RA, but also may protect from MTX toxicity presumably via a homocysteine-dependent mechanism [43].

In another study, 106 RA patients who had been treated with MTX were assessed retrospectively for MTX efficacy and toxicity. The dose ranged from 2.5 mg/week to 12.5 mg/week. All patients were genotyped for the 677C>T and 1298A>C SNPs. Direct assessment of MTX efficacy (as measured by disease activity scores) was not possible because of the retrospective design. However, patients carrying the 1298A>C polymorphism (homozygous or heterozygous) were more likely to be on lower doses of MTX compared to those without the polymorphism (RR 2.18; CI 1.17–4.06; $p < 0.05$). Patients carrying this polymorphism also showed improvement in their inflammatory markers such as erythrocyte sedimentation rate (ESR) and C reactive protein (CRP), suggesting an increased clinical efficacy of MTX ($p < 0.05$). However, the presence of the 677C>T polymorphism was associated with increased MTX toxicity (RR 1.25; CI 1.05–1.49; $p < 0.05$) but not with MTX efficacy. Thus, the 677C>T polymorphism appeared to be a marker for MTX toxicity and the *1298A>C* polymorphism for MTX efficacy [40].

More recent studies have yielded varied results. Three confirmed an effect of the 677C>T polymorphism on MTX efficacy. However, results from these studies were conflicting, with the T allele being a marker of both decreased and increased MTX efficacy in US [46] and Polish [69] cohorts, respectively, and the C allele being a marker of increased MTX efficacy in a Dutch cohort [41]. Eight recent studies showed an effect of the T allele on MTX toxicity. Four examined Asian patients, including Japanese, [40,70] Korean, [71] and Chinese; [72]; others included Dutch [73], US, [47,74], and Spanish [75] cohorts. Two meta-analyses have also yielded contrasting results. One found an association between the 677C>T polymorphism and MTX toxicity, but no such association for the 1298A>C variant [42]. However, another (which included 1514 patients with RA) found no association between either of these polymorphisms and MTX toxicity and efficacy [44].

TYMS is an important enzyme in the de novo synthesis of pyrimidines. It converts deoxyuridine monophosphate (dUMP) to deoxythymidine monophosphate (dTMP) and is a direct target of polyglutamated MTX. The *TYMS* gene is a 15 kb gene located on chromosome 18 (18p11.32). A polymorphic tandem 28-bp repeat sequence has been described in the 5′ untranslated region (TSER) of the *TYMS* gene, with a variable number of repeat elements [76]. *In vitro* studies have shown that TYMS mRNA expression and enzyme activity increases with an enhancing number of these repeat sequences [76–78]. Patients homozygous for the triple repeat allele (*TSER*3/*3* or *3R*) have higher TYMS mRNA expression compared to patients homozygous for the double repeat allele (*TSER*2/*2* or *2R*) [78,79]. An additional G to C substitution within the 3R allele further diversifies 3R into 3RC and 3RG; the C allele abolishes a critical residue in the upstream stimulatory factor (USF-) –binding site, lowering TYMS activity in 3RC carriers [80]. Deletion of a 6-bp sequence at nucleotide 1494 in the 3′ untranslated region (3′UTR) of TYMS has also been described and may be associated with decreased TYMS mRNA stability and expression [45,81].

In a retrospective study, 167 patients with RA, of whom 115 were treated with MTX, were genotyped for the following polymorphisms—*TYMS* 5′UTR enhancer repeat (*TSER*), 3′UTR deletion, *MTHFR* 677C>T, and 1298A>C. The mean weekly MTX dose in this study was 5.7+/-2.3 mg per week. Both MTX-treated and -untreated groups displayed similar frequencies of these SNPs. The *TYMS* and *MTHFR* polymorphisms were not associated with toxicity, although a significant percentage of patients (45%) on MTX experienced adverse events. Weekly MTX dose (rather than standardized disease activity measures) was used as a marker of efficacy in this study. A dose of >6 mg/week was considered indicative of less efficacy and <6 mg/week was considered indicative of greater efficacy. Homozygotes for the *TSER*2* allele (*TSER*2/*2*) required lower doses of MTX (i.e., had greater efficacy) than homozygotes for the *TSER*3* allele ($p = 0.033$). The *TYMS* 3′UTR deletion and *MTHFR* polymorphisms had no effects on MTX efficacy. The researchers speculated that the repeat enhancer *TSER*3* polymorphism may lead to decreased MTX efficacy by increasing TYMS mRNA expression. This study also put forward the idea that *MTHFR* polymorphisms may not influence MTX toxicity or efficacy [49].

DHFR reduces dihydrofolate to tetrahydrofolate in the intracellular folate pathway. It is directly inhibited by polyglutamated MTX and encoded by the *DHFR* gene, a 28 kb gene located on chromosome 5 (5q11.2–q13.2). Two hundred and five MTX-treated RA patients were studied for *DHFR* gene polymorphisms. MTX was started at 7.5 mg/week and increased to 15 mg/week (with folic acid supplementation) after four weeks based on response to the drug. MTX efficacy and toxicity were assessed from time to time. Genotyping for the *MTHFR* 677C>T, *MTHFR* 1298A>C, *DHFR* -473G>A, *DHFR*

35289G>A, and *RFC* 80 G>A SNPs was performed. At six months, patients carrying the *MTHFR* 1298AA and *MTHFR* 677CC (wild-type) genotypes showed a greater response to MTX compared to patients carrying the heterozygous or homogenous genotype (OR 2.3; CI 1.18–4.41 and OR 2.73; CI 1.03–7.26, respectively). Haplotype analysis for the *MTHFR* 1298A and 677C SNPs revealed that patients with two copies of the haplotype had greater improvement than those with one or no copies (OR 3.0; CI 1.4–6.4). Patients homozygous and heterozygous for the *MTHFR* 1298 A>C SNP (*MTHFR* 1298AC+CC) had an increased number of overall adverse drug events at three and six months (OR 2.55; CI 1.20–5.41 and OR 2.5; CI 1.32–4.72, respectively). Because the *RFC* and *DHFR* SNPs were not associated with MTX toxicity or efficacy, patients with the wild-type *MTHFR* alleles (*MTHFR* 1298AA and 677CC) responded better to MTX, while those with the 1298C allele had an increased risk for MTX toxicity [41].

Thus, based on the literature just cited (Table 29.1), the 677C>T SNP in *MTHFR* appears to have effects on MTX toxicity, presumably through its effects on homocysteine metabolism, and on MTX efficacy [41]. The effects of the 1298A>C polymorphism on MTX are inconsistent, with data suggesting that it may increase [40] or decrease [41] patients' response to MTX and possibly protect them from MTX toxicity [43]. This may stem from the fact that these SNPs perhaps have effects other than that on homocysteine metabolism that may influence response to MTX. The retrospective design of most of these studies may not have allowed an accurate assessment of MTX effects, especially adverse effects. Although one of the studies [49] concluded that *MTHFR* SNPs did not affect MTX efficacy or toxicity, it is worth pointing out that the doses of MTX used in this study were small (6 mg/week as opposed to standard doses of 15–20 mg/week), which may have influenced the study results. Also, standardized measures of disease activity were not used in this study, which may have further impacted the results.

29.2.1.4 ATIC /CCND1

AICAR transformylase (ATIC) converts AICAR to 10-formyl AICAR and is directly inhibited by MTX (see Figure 29.1). This leads to accumulation of AICAR and adenosine, a purine with anti-inflammatory properties. Adenosine may be an important mediator of the anti-inflammatory effects of MTX [82]. *ATIC* is a 37 kb gene located on chromosome 2 (2q35). The *ATIC* 347C>G SNP leads to a threonine-to-serine substitution in codon 2, which may cause a decrease in ATIC's enzymatic activity and affect AICAR accumulation and adenosine release. In 108 RA patients on MTX at a dose of 14 mg/week (range 5–25 mg/week), the combined effects of the *ATIC* 347C>G SNP, *TSER*2*, and the *RFC* 80G>A polymorphism on MTX efficacy was assessed. Red blood cell long-chain MTX polyglutamate (MTXPG) concentrations were measured and a pharmacogenetic index was calculated from the sum of homozygous variant genotypes (*RFC1* 80AA, *ATIC* 347GG, *TSER*2/*2*). The allelic frequency of the *ATIC* 347G variant was 37%. Patients were categorized as MTX responders or MTX nonresponders using a visual analog scale (VAS).

Eighteen patients who were carriers of the *ATIC* 347GG genotype had fewer swollen joints (1.9 ± 0.6 versus 4.5 ± 0.6 [p = 0.06]) and a lower score for physician's assessment of patients' response to MTX (1.8 ± 0.3 versus 2.8 ± 0.2 [p = 0.02]) compared to 90 patients who were carriers of the C allele (*ATIC* 347CC, n = 47; *ATIC* 347CG, n = 43) [36]. Among other studies, only one demonstrated the *ATIC* 347C allele to be associated with MTX efficacy in a Dutch cohort [41]. Four studies showed an association of the *ATIC* 347G allele with MTX toxicity in US [46,47], Dutch [41], and Slovenian cohorts [48].

G1/S-specific cyclin-D1 is a protein that in humans is encoded by the *CCND1* gene, whose activity is required for cell-cycle G1/S transition [83]. The 870A>G substitution resides at the mRNA splicing site [84]. The A allele preferentially encodes the transcript lacking exon 5, leading to increased levels and longer half-life of cyclin D1 [85]. Elevated levels or expression of cyclin D1 protein (coded by the A allele) have been found in a variety of cancers, including breast cancer, head and neck cancer, non-small-cell lung cancer, and mantle cell lymphomas [86]. In a human fibro sarcoma HT1080 cell line, CCND1 over expression modified sensitivity to MTX [86].

Jekic et al. genotyped 184 RA patients treated with MTX for selected polymorphisms in the *GGH* (−354G>T and 452C>T), *CCND1* (870A>G) and *TYMS* (variable number of tandem repeats, or VNTR, and G-to-C substitution of the triple repeat, 3R allele) genes. Based on the European League Against Rheumatism (EULAR) response criteria—a standardized measure of disease activity in RA—146 RA patients (79.3%) were classified as responders and 38 (20.7%) as nonresponders after six months of MTX therapy. There was no difference between MTX responders and nonresponders in the frequency of polymorphisms in the *GGH* and *CCND1* genes or *TYMS* VNTRs. However, when *TYMS* was analyzed with respect to VNTRs and the 3R G-to-C substitution, a higher frequency of the 3G/3G genotype (G allele) was found in MTX nonresponders when compared to other genotypes (p = 0.02, OR 5.4, 95% CI 1.0–21.1) [51]. Eight of 184 patients developed bone marrow toxicity, and all of those eight carried the *GGH*-354GG genotype. The -354 T allele has been shown to correlate with increased *GGH* gene expression [56]. For this reason, the investigators proposed that the -354 G allele possibly results in reduced GGH levels and higher cellular concentrations of MTXPG, leading to increased toxicity [51].

29.2.2 Pharmacogenetics of Leflunomide

Leflunomide is an isoxazole derivative used as a DMARD in the treatment of RA. It is a prodrug that is metabolized in the plasma and intestinal mucosa to an active, open-ring metabolite, teriflunomide (also known as A77 1726), that causes noncompetitive and reversible inhibition of dihydroorotate dehydrogenase (DHODH) [87]. DHODH is critical to de novo pyrimidine synthesis, and the effect of leflunomide treatment is a decrease in lymphocyte proliferation and thereby decreased inflammation (Figure 29.2). Polymorphisms that may affect the response to leflunomide are discussed in this section, and summarized in Table 29.2.

29.2.2.1 DHODH

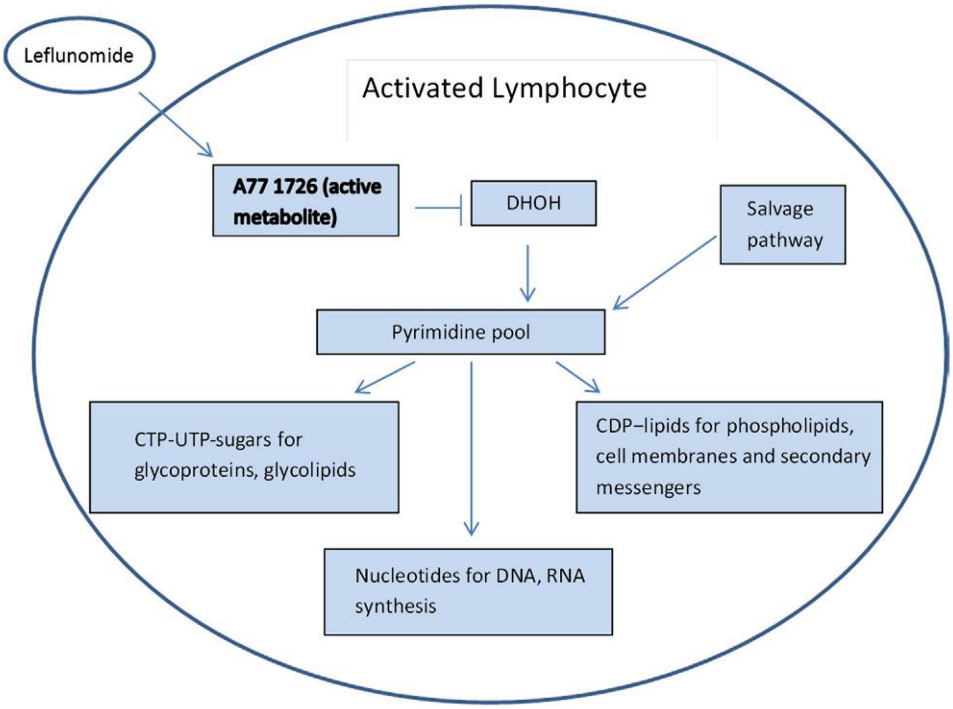
The human *DHODH* sequence frequently contains a missense polymorphism in the first exon (19A>C), which leads to a lysine-to-glutamine amino acid substitution in the N-terminal region of the polypeptide. This segment controls the insertion of the polypeptide into the mito chondrial inner membrane and thus influences the cellular effects of the enzyme [34].

Pawlik et al. [37] conducted a study on 147 patients (123 women, 24 men; mean age 52.8 ± 11.03 years and of Caucasian origin) diagnosed with RA and treated with leflunomide 20 mg/day. Genotyping was performed to analyze the 19C>A SNP in exon 1 of the *DHODH* gene. Remission was more frequent in patients who carried the C rather than the A allele, with no significant association between either of the alleles and adverse events. Conversely, in a retrospective study of 105 patients with RA, of whom 62 tolerated leflunomide treatment well, and 43 patients who discontinued treatment owing to leflunomide toxicity, this polymorphism was associated with a 6.8-fold increased risk of overall leflunomide-related adverse events, including GI, mucosal, and hepatic toxicity [88].

29.2.2.2 ABCG2

ATP-binding cassette subfamily G, member 2 (ABCG2) is a protein encoded by the *ABCG2* gene [89]. ABCG2 is involved in the disposition of various chemotherapeutic agents as an efflux transporter. It is highly expressed in the gastrointestinal tract and liver, and governs the absorption, distribution, and excretion of a wide variety of clinically important drugs, including leflunomide [90]. Two common *ABCG2* genetic variants are 34G>A and 421C>A.

Kim et al. [91] analyzed the pharmacokinetic characteristics of A771726, according to *ABCG2* genotypes, in 24 healthy study participants following a single leflunomide



Leflunomide
Activated Lymphocyte
A77 1726 (active metabolite)
DHOH
Salvage pathway
Pyrimidine pool
CTP-UTP-sugars for glycoproteins, glycolipids
CDP–lipids for phospholipids, cell membranes and secondary messengers
Nucleotides for DNA, RNA synthesis

FIGURE 29.2 Metabolism of leflunomide. The active metabolite of leflunomide (A77 1726), whose CYP enzyme–mediated production occurs in plasma and intestinal mucosa, is taken up by activated lymphocytes, wherein it inhibits the action of DHODH. De novo pyrimidine synthesis is thus inhibited, leading to decreased lymphocyte proliferation. Polymorphisms in DHODH and CYP enzyme genes are thought to affect leflunomide toxicity. CYP—cytochrome P450; DHODH—dihydroorotate dehydrogenase. *Source: Modified from Davila and Ranganathan et al.* [34].

TABLE 29.2 Pharmacogenetics of Leflunomide

Gene, Product, and Role	Polymorphism	Cellular Effects of Polymorphism	Clinical Effects (Reference)
DHODH, DHODH, key enzyme in de novo pyrimidine synthesis	19 C>A	Alters N-terminal region of DHODH, affecting insertion into mitochondrial membrane	Associated with increased efficacy [37]
			Associated with increased toxicity [88]
			Not associated with toxicity [97]
ABCG2, ABCG2, governs absorption, distribution, and excretion of drug	421C>A	Influences bioavailability and oral clearance	Associated with increased C_{max} and decreased oral clearance [91]
			Associated with increased toxicity [97]
ESR1, estrogen receptor, interferes with down-modulation of cytokines	rs9340799 AA rs2234693 TT	Alters estrogen receptor expression	Associated with increased efficacy [93]
CYP1A2, CYP enzyme, involved in activation of leflunomide	CYP1A2*1F CC	Increases formation of active metabolite, leading to higher drug levels	Associated with increased toxicity [95]
	CYP2C19*2		Increased oral clearance [96]
	CYP2C19		Associated with increased likelihood of discontinuing leflunomide [97]

Source: Modified from Davila and Ranganathan et al. [34].

dose of 20 mg. *ABCG2* 421C>A substantially influenced the pharmacokinetics of A771726. A771726 C_{max} was 30% higher, the area under the concentration-time curve (AUC) was 83% larger, and oral clearance was 41% lower in 421C>A carriers than in noncarriers.

29.2.2.3 Estrogen Receptor Polymorphisms

Because previous studies [92] indicated that women have a poorer response to leflunomide treatment than men, Dziedziejko et al. [93] looked at the effect of estrogen receptor polymorphisms on leflunomide therapy. Two estrogen receptors—α and β—are known, and the genes *ESR1* and *ESR2* that encode them are responsible for transducing extracellular signals into transcriptional responses. In this prospective study, common SNPs in *ESR1* (rs9340799A>G, rs2234693T>C) and *ESR2* (rs4986938G>A, rs1256049G>A) were examined in 115 women with RA, mean age 54.1 ± 11.0 years, treated with leflunomide (20 mg/day). The *ESR1* rs9340799 AA and rs2234693 TT genotypes were associated with a better response to leflunomide after 12 months of therapy—improvement of ESR, patient's global assessment of disease activity on VAS and DAS28 (disease activity score, a standardized measure of disease activity in RA) values. There was no such association with *ESR2* genotypes and haplotypes [93]. A possible explanation for this association is that these polymorphisms may influence estrogen receptor expression and thus alter response to leflunomide.

29.2.2.4 Cytochrome P450 System

The cytochrome P450 (CYP) system, particularly the enzyme encoded by *CYP1A2*, converts leflunomide to its active metabolite [94] A prospective study from central Europe of 105 patients with RA identified an association between the *CYP1A2*1F* polymorphism and leflunomide toxicity [95]. Another prospective study by the same group, of 67 patients with RA and 4 with polyarthritis resembling RA and psoriasis treated with leflunomide, investigated the association of SNPs in *CYP1A2* and *CYP2C19* with A77 1726 pharmacokinetics. The oral clearance of A77 1726 was found to be 71% higher in carriers of the *CYP2C19*2* 681G>A polymorphism compared with noncarriers. There was no impact of steady-state plasma concentrations of A77 1726 on the occurrence of adverse events from the drug [96].

In a recent retrospective study from Australia, 78 RA patients on leflunomide for at least 12 months were genotyped for the following SNPs: *CYP2C19*2* (rs4244285), *CYP2C19*17* (rs12248560), *ABCG2*421C>A (rs2231142), *CYP1A2*1F* (rs762551), and *DHODH*19C>A (rs3213422). Polymorphisms were chosen based on the potential importance of encoded proteins on steady-state teriflunomide blood levels via an effect on leflunomide metabolism (*CYP2C19*2* [*CYP2C19* 681G>A, rs4244285] and *CYP2C19*17* [*CYP2C19*, 608C>T, rs12248560]) or on biliary secretion of teriflunomide (*ABCG2*421C>A, rs2231142) [91].

Polymorphisms previously linked to leflunomide toxicity—*CYP1A2*1F* (*CYP1A2* 163C>A, rs762551) [95,96] and *DHODH* (*DHODH* 19C>A, rs3213422) [88]—were also studied. *CYP2C19*2* is the loss-of-function allele, while *CYP2C19*17* is the gain-of-function allele. Poor metabolizers of leflunomide carry two loss-of-function alleles, intermediate metabolizers carry one loss-of-function and one wild-type allele, extensive metabolizers carry two wild-type alleles, and ultrarapid metabolizers carry either one or two gain-of-function alleles and no loss-of-function alleles.

After adjusting for current leflunomide dose, triple therapy (with methotrexate, sulfasalazine, and hydroxychloroquine), and positive rheumatoid factor status at diagnosis, the *CYP2C19* genotype was significantly associated with the likelihood of discontinuing leflunomide, with poor and intermediate metabolizers discontinuing it more frequently (adjusted hazard ratio = 0.43 for each incremental change in genotype, 95%; CI 0.24–0.79; p = 0.006) [97]. Previously observed associations between *CYP1A2* [95] and *DHODH* genotypes and toxicity [88] were not apparent, but there was a trend for the *ABCG2* SNP to be associated with drug cessation due to diarrhea.

29.2.3 Pharmacogenetics of Azathioprine

Azathioprine (AZA) is used in the treatment of several rheumatic diseases, particularly systemic lupus erythematous (SLE) and RA. About 10–30% of RA patients discontinue AZA because of side effects [98]. AZA is a prodrug that after oral intake is converted into 6-mercaptopurine (6-MP), an active purine antimetabolite that affects the purine de novo synthetic and salvage pathways (Figure 29.3). 6-MP is converted by hypoxanthine phosphoribosyl transferase (HPRT) to cytotoxic thioguanine nucleotides (6-TGN) via the intermediary metabolite, 6-thio-inosine monophosphate (6-TIMP). Inosine monophosphate is phosphorylated to inosine triphosphate (ITP), a toxic metabolite, and this process can be reversed by inosine triphosphate pyrophosphatase (ITPase, encoded by *ITPA*). ITPase deficiency can result in the accumulation of toxic ITP. ITPase-deficient individuals treated with AZA can develop toxicity because of accumulation of thio-ITP [99]. By a parallel pathway, 6-MP can be deactivated by thiopurine methyltransferase (TPMT) to 6-methylmercaptopurine (6-MMP) or by xanthine oxidase (XO) to thiouric acid (TU). Thus, a relative or absolute deficiency of TPMT leads to accumulation of cytotoxic TGN and significantly increased AZA toxicity.

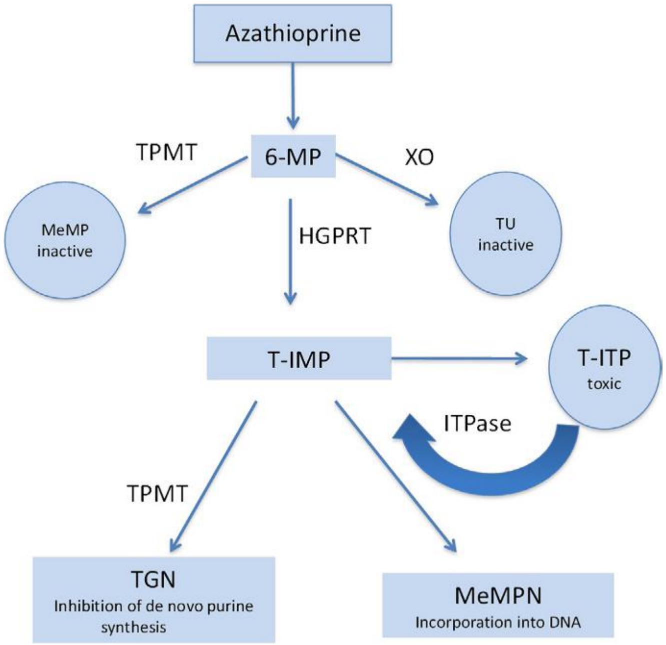


FIGURE 29.3 **Thiopurine drug metabolism.** TPMT—thiopurine methyltransferase; XO—xanthine oxidase; HPRT—hypoxanthine phosphoribosyl transferase; 6-TIMP—6-thiosine monophosphate; 6-MMP—6-methylmercaptopurine; 6-TGN—6-thioguanine nucleotides. *Source: Modified from Davila and Ranganathan et al.* [34].

The most common adverse effects of AZA are hematologic and gastrointestinal.

29.2.3.1 TPMT

The *TPMT* gene is a 26 kb gene located on chromosome 6 (6p22.3). TPMT activity in erythrocytes varies between high, intermediate, and low or none and is controlled by the gene's allelic variants. Population studies have shown that approximately 90% of the population has high activity, 10% has intermediate activity, and 0.3% has little to no activity [100].

One of three common allelic variants of the *TPMT* gene—*TPMT*2*, *TPMT*3A*, or *TPMT*3C*—is found in 80–95% of patients with low TPMT activity [101–103]. Ethnicity seems to influence the frequencies of these allelic variants [104,105]. Patients with low TPMT activity require lower AZA doses to avoid toxicities, as standard doses may lead to significant toxicities [106].

Sixty-eight patients with rheumatic disease on AZA (2–3 mg/kg/day) were genotyped for *TPMT*2* and *TPMT*3A* alleles. All patients were assessed for side effects from AZA, such as leucopenia, liver function abnormalities, and GI intolerance. Six (9%) were heterozygous for *TPMT*3A*; five of those discontinued AZA within four weeks of starting the medication because of hematologic toxicity [107]. In another study 40 RA patients on AZA were genotyped for the *TPMT* alleles. AZA dose varied from 0.7 mg/kg to 1.4 mg/kg/day. Six out of 40 patients discontinued AZA because of toxicity. Three of the six with severe GI toxicity were heterozygous for the *TPMT*3A* allele, while the remainder possessed the wild-type *TPMT* allele. The association between the *TPMT* allele and AZA toxicity was significant ($p=0.018$). The positive predictive value for toxicity in a *TPMT* polymorphism carrier was 60% in this particular study [108].

One case report described a SLE patient who presented with pancytopenia, sepsis, typhlitis, and disseminated intravascular coagulopathy after a short period of AZA therapy. The patient had low TPMT activity due to the *TPMT*3C* genotype [109]. A meta-analysis of 67 studies examined whether patients with intermediate TPMT activity were at increased risk of myelosuppression when taking thiopurine medications. It included all primary studies of patients on a thiopurine medication with either genotypic or phenotypic testing for TPMT activity, and reported cases of hematological adverse reactions. The search was not restricted to a specific disease or condition. Patients with two *TPMT* variant alleles who were TPMT-deficient had a substantial increase in their risk of myelotoxicity (86% of deficient patients developed myelosuppression). Patients heterozygous (i.e., with one variant allele) for any of the *TPMT* variant alleles that lead to intermediate TPMT activity were also at high risk for drug-induced myelosuppression compared to those with wild-type alleles (OR 4.19; 95% CI 3.20−5.48) [110].

29.2.3.2 ITPA

AZA is frequently used to treat inflammatory bowel disease. As mentioned earlier, ITPase deficiency can result in the accumulation of toxic ITP. In a prospective study of patients with Crohn's disease taking AZA, dropouts during the first two weeks because of adverse events were more frequent carriers of the *ITPA* 94C>A allele [111]. In a more recent study of patients with inflammatory bowel disease, 40 of 160 on AZA were found to have decreased ITPA activity (below the lower limit of the reference range <122 μmol/(gHb·h)). ITPA activity was measured in erythrocyte lysates by a high-performance liquid chromatography procedure based on conversion of ITP to IMP; it was expressed as micromoles of IMP formed per gram of Hb per hour (μmol/(gHb·h)). Patients with decreased ITPA activity were separated into quartiles, resulting in three additional thresholds (37.3, 59.9, and 89.2 μmol/(gHb·h)). Adverse events were reported for 88 of the 160 patients (55%). Patients with ITPA activity <89.2 μmol/(gHb·h) developed leukopenia more often than did patients with higher enzyme activity (OR 3.27; 95% CI 1.21−8.82), whereas individuals with very low ITPA activity (<37.3 μmol/(gHb·h)) had elevated liver enzymes more frequently compared with those with ITPA activity >37.3 μmol/(gHb·h) (OR 5.0; 95% CI 1.35−18.57). The only significant genotyping association was seen for the *ITPA* 94C>A polymorphism and leukopenia [112].

In contrast, an earlier study by Gearry et al. failed to demonstrate a significant association between the presence of *ITPA* alleles and AZA-related toxicity. In this study, genotyping was performed for the 94C>A missense mutation in *ITPA*, *TPMT*2*, and *TPMT*3* in 147 patients with inflammatory bowel disease. About 50% of patients had adverse events from AZA. There was no significant difference in the frequency of the *ITPA* alleles between patients who had an adverse event versus those who did not (16/146 versus 16/148, $p=0.56$). The *ITPA* 94C>A polymorphism was not found to be associated with adverse events such as rash or pancreatitis or flu-like symptoms [113].

29.2.3.3 GST

The conversion of AZA to the active metabolite 6-MP was considered to be a nonenzymatic reaction until recently. Studies in the last few years have shown that glutathione S transferases (GSTs) may be involved in this conversion [114,115]. One recent study demonstrated that patients with inflammatory bowel disease who carried the *GST-M1* null genotype required a lower AZA dose to generate 6-TGN compared to those with the *GST-M1* wild-type genotype. Other *GST* genotypes did not show a substantial effect on AZA metabolism [116].

29.2.3.4 Other Purine Pathway Enzymes

Some studies have looked at the association between the activity of enzymes other than TPMT in the purine pathway and AZA toxicity. In one study, TPMT, HPRT, 5′-nucleotidase, and purine nucleoside phosphorylase activity in the red blood cells (RBC) of 33 RA patients on AZA (≈2 mg/kg/day) and 66 controls was measured. Fourteen RA patients with low ($p = 0.004$) and seven patients with intermediate TPMT activity ((RR 3.1) developed AZA toxicity when compared to patients with normal TPMT activity [98]. Another study measured TPMT activity in three RA patients who had experienced AZA-induced hematologic toxicity and 16 RA patients without AZA toxicity. Two patients with AZA-induced hematologic toxicity were TPMT-deficient, one partial and the other complete. In the third patient, 5′-nucleotidase activity was found to be well below the lowest level observed in the control subject [117]. It should be pointed out that the sample sizes in these studies were small and genotyping was not done.

Both *TPMT* genotyping and measurement of TPMT activity in RBC have been studied in predicting and preventing AZA toxicity. Current evidence supports that TPMT deficiency, either partial or complete, can cause increased toxicities from AZA. Clearly, large prospective studies are needed to confirm the observations from the smaller studies just described (Table 29.3). There is some evidence for *ITPA* variants influencing AZA toxicity in inflammatory bowel disease, but there are no studies to date on this polymorphism in RA. Of note, *TPMT* genotyping is available to clinicians to screen patients prior to initiation of AZA, and it is the first commercially available assay for pharmacogenetic testing in rheumatology.

29.2.4 Sulfasalazine

Sulfasalazine (SSZ) is another DMARD often used in the treatment of RA. It is estimated that 20–30% of RA patients on SSZ report adverse drug reactions. The major adverse drug events of SSZ are gastrointestinal and hematologic.

29.2.4.1 NAT2

SSZ is a combination of sulfapyridine and 5-aminosalicylic acid (5-ASA). After ingestion, SSZ is split into these two compounds by the colonic bacteria. 5-ASA remains in the large bowel, while most of the sulfapyridine is completely absorbed and undergoes acetylation, hydroxylation, and glucoronidation in the liver. The enzyme N-acetyltransferase 2 (NAT2) acetylates sulfapyridine into N-acetylsulfapyridine (Figure 29.4). *NAT2* is a 9 kb gene located on chromosome 8 (8p22). Its polymorphisms may modify the acetylator phenotype of an individual (slow versus fast) and thus have effects on an individual's vulnerability to SSZ toxicity. SSZ toxicities such as abdominal discomfort, nausea, rash, and headaches are found more commonly in slow than in fast acetylators [118,119].

A few studies have evaluated the effects of *NAT2* polymorphisms on SSZ toxicity in RA patients. One retrospective study evaluated 144 RA patients on SSZ at a dose range of 500–1500 mg/day. *NAT2* genotyping was carried out in all patients. Slow acetylators lacking the wild-type *NAT2*4* allele had a higher frequency of adverse events (63%) compared to fast acetylators with at least one *NAT2*4* allele (8%). The association between the *NAT2* genotype and SSZ toxicity was significant (OR 7.73; CI 3.54–16.86;

TABLE 29.3 Pharmacogenetics of Azathioprine

Polymorphism	Amino Acid Change in Enzyme	Population Prevalence	Effect on Enzyme Activity	Biochemical Effect	Clinical Effects	Reference
*TPMT*2* 238G>C	Alanine to proline	0.2–0.5%	Low to intermediate due to enhanced degradation of enzyme	Decreased methylation of drug to inactive compounds	Hematologic and GI toxicity	[107]
*TPMT*3A* 460G>A, 71A>9G	Alanine to threonine and tyrosine to cystine, respectively	3.2–5.7%	As above	As above	Hematologic toxicity	[107,108]
*TPMT*3C* 719A>G	Tyrosine to cystine	0.2–0.8%	As above	As above	Hematologic toxicity	[109]

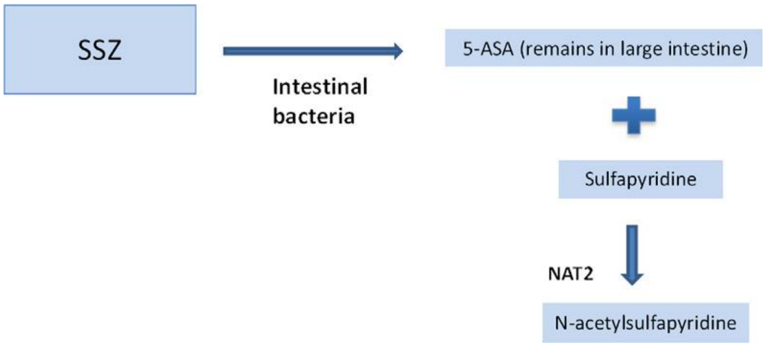

FIGURE 29.4 **Sulfasalazine metabolism.** SSZ—sulfasalazine; 5-ASA—5-aminosalicylic acid; NAT 2—N-acetyltransferase 2 NAT2 acetylates sulfapyridine into 5-acetylsulfapyridine. *Source*: *Modified from Davila and Ranganathan et al.* [34].

$p < 0.001$). In fact, 25% of the slow acetylators had to be hospitalized for their toxicities [120]. In another study, 114 patients with inflammatory bowel or joint disease treated with SSZ (mean dose 2 gm/day) were genotyped for 5 allelic variants—*NAT2*5A*, *NAT2*5B*, *NAT2*5C*, *NAT2*6*, and *NAT2*7* (encoding slow acetylator status) and the wild-type *NAT2*4* allele (encoding rapid acetylator status). Twenty-seven of 39 patients (69%) who developed agranulocytosis within three months of starting treatment with SSZ were slow acetylators compared to 34 of 75 patients (45%) who received SSZ without a hematological adverse event (OR 2.7; $p = 0.002$). *NAT2*6* alleles were found to be more frequent among patients who had agranulocytosis (36%) compared to patients without it (23%) ($p = 0.033$) [121].

In a more recent investigation, researchers performed two bioavailability studies under comparable conditions with 24 healthy subjects. Plasma levels of sulfapyridine and acetylsulfapyridine were determined after oral intake of enteric-coated formulations of sulfasalazine (500 mg and 1000 mg, respectively). The *NAT2* genotype was analyzed in parallel for all subjects. The terminal elimination half-life of sulfapyridine as well as of acetylsulfapyridine was prolonged in those with the slow acetylator genotype. A *NAT2* 341T>C polymorphism seemed to contribute the strongest functional effect on *NAT2* activity in slow acetylators [122].

Thus, the acetylator status of a patient as determined by the *NAT2* genotype appears to be an important determinant of the risk for SSZ toxicity based on the limited data published so far (Table 29.4). While more studies and data are clearly needed, the data from the studies discussed suggest that prospective screening of patients for the *NAT2* genotype prior to initiation of SSZ may be a useful tool to prevent SSZ toxicity.

29.2.5 Pharmacogenetics of Hydroxychloroquine

Antimalarials such as hydroxychloroquine (HCQ) are effective treatments for RA and SLE. Pharmacogenetic data are available for this drug in SLE but not in RA. HCQ is rapidly

TABLE 29.4 Pharmacogenetics of Sulfasalazine

Polymorphism	Effect	Associated Biochemical Changes	Clinical Effects	Reference

absorbed from the gut after oral administration and is metabolized in the liver by cytochrome P450 (CYP) enzymes to its active metabolite, N-desethylhydroxychloroquine [34] (Figure 29.5). N-desethylhydroxychloroquine is a weak base that accumulates in acidic vesicles, such as cellular endosomes and lysosomes, increasing the pH of these compartments [123]. Consequently, its presence inhibits the action of acidic proteases involved in multiple cellular functions, particularly intracellular protein processing.

Subsequent downstream effects include interference in antigen presentation and production of proinflammatory and anti-inflammatory cytokines such as tumor necrosis factor (TNF) and interleukin (IL)-10 [124,125] Antimalarials may also have negative effects on the production of a variety of proinflammatory cytokines besides TNF, such as IL-1, IL-6, and IFNγ, although such effects have been shown only *in vitro* [126]. The lysomotropic properties of antimalarials may also inhibit the interaction between intracellular toll-like receptors (TLRs), especially TLR 9, and extracellular nucleic acid motifs in SLE [127].

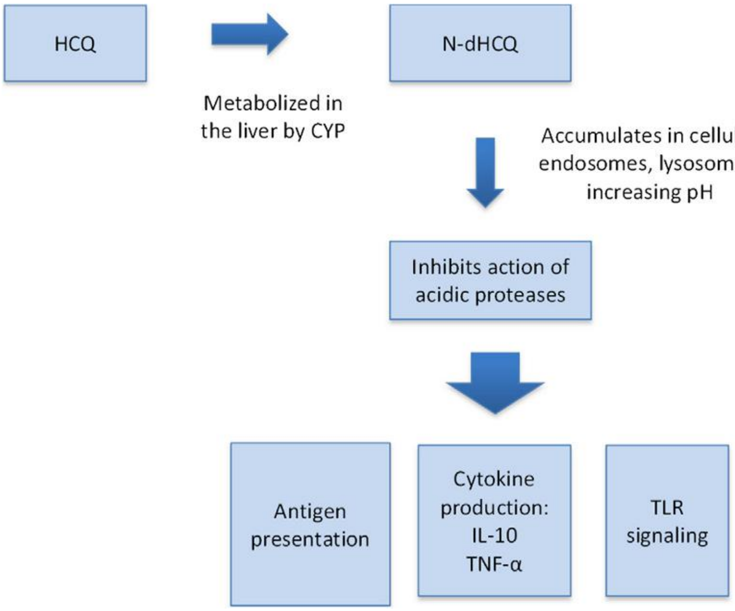
29.2.5.1 CYP

Low serum levels of HCQ have been associated with high disease activity and higher risk of disease exacerbation in SLE. Variants in the genes encoding the CYP enzymes that metabolize hydroxychloroquine may influence the efficacy or toxicity of the drug. CYP2C8, CYP3A4, and CYP2D6 are the major enzymes responsible for chloroquine metabolism in human liver microsomes, [128,129], with CYP2C8 being the most important. The metabolism of the antimalarial amodiaquine (structurally related to chloroquine) appears to be impaired in individuals with *CYP2C8* polymorphisms [130].

A few studies have looked at the influence of CYP polymorphisms on HCQ metabolism. Wahie et al studied a cohort of 200 patients with discoid lupus erythematosus (DLE) treated with HCQ. They found no association between *CYP2C8* and *2D6* variants and response to HCQ (OR for *CYP2C8* 1.55 (0.82–2.96); for *CYP2D6*, 1.20 (0.67–2.18)). However, there was a trend for *CYP2C8* variants to be associated with a greater response to HCQ (although not statistically significant), as these variants may lead to a slower metabolism of antimalarials [131].

29.2.5.2 TNF/IL-10

Polymorphisms in certain cytokine genes such as *TNF* and *IL-10* have been studied for their ability to predict response to HCQ in patients with SLE. An *IL10* –1082A>G polymorphism, along with two others (*IL10*–819C>T and –592C>A), all in the *IL10* promoter region, influence basal and induced IL-10 production, with the GCC/GCC haplotype conferring the highest level of IL-10 production [132–134]. The *TNF*-308A allele is associated with increased transcription and synthesis and high serum levels of TNF as compared to the *TNF*-308G allele [135,136]. (This variant is discussed further in Section 29.3.) In a case-control study from Spain, serum TNF levels were quantified in 171 SLE patients and 215 healthy controls by ELISA techniques,



HCQ

together with genotyping for the *IL10* –1082A>G and *TNF* –308A>G promoter gene polymorphisms in 192 patients with SLE and 343 matched healthy controls [137]. Among the 192 patients who were genotyped for SNPs in both cytokine genes, 40 (20.8%) were good responders to antimalarial therapy whereas 74 (38.5%) required the addition of corticosteroids or other immunosuppressive drugs for an optimal response. Patients with SLE had higher serum TNF levels compared with healthy controls, but patients with SLE treated with antimalarials had lower serum TNF levels.

In this study, there was a significant association between carriage of the high TNF producer genotype (AA/GA) and a good response to antimalarial drugs (OR 2.25; 95% CI 1.11–4.58; $p = 0.024$), whereas the *IL-10* genotype by itself did not show any significant association. However, patients who carried both genotypes, which translated into low IL-10 and high TNF production (that is, *IL10* 1082 AA/AG and *TNF*-308 AA/GA), had the best response to HCQ (OR 3.13; 95% CI 1.41–6.92; $p = 0.005$) [137].

Thus, despite the widespread use of HCQ in RA and SLE, pharmacogenetic data that could guide the optimum use of HCQ are currently sparse and available only for SLE (Table 29.5). Further studies of possibly similar SNPs in RA and larger cohorts of SLE patients are needed to replicate and confirm the findings described.

29.3 PHARMACOGENETICS OF BIOLOGIC DMARDS

29.3.1 Tumor Necrosis Factor Antagonists

Over the past decade, tumor necrosis factor alpha (TNF-α) antagonists have become the mainstay of treatment for severe RA. Anti-TNF agents are very effective in slowing down and even halting the radiographic progression of the disease; this benefit is evident even in patients who may not have a complete clinical response [138,139]. However, anti-TNF agents fail in about 20–40% of RA patients, and while lack of response is drug-specific in some patients, it may be class-specific (anti-TNF class) in others [140,141].

Currently approved anti-TNF agents include etanercept (ETN), infliximab (INF), adalimumab (ADA), golimumab (GOL), and certolizumab pegol (CZP). INF, ADA, and GOL are all monoclonal antibodies to TNF-α; INF is a chimeric mouse protein antibody, while ADA and GOL are fully humanized antibodies. ETN, the first anti-TNF agent to be used in RA, is a fusion protein of the Fc portion of human IgG1 attached to two identical chains of the p75 portion of the TNF receptor; it binds to soluble TNF-α. CZP is a human anti-TNF Fab fragment that is conjugated with polyethylene glycol to increase its half-life.

Anti-TNF agents are expensive and have significant side effects, including an increased risk of infections. At present, there are no means to predict which individual patient may benefit from a certain drug. Over the past few years, several studies have attempted to define pharmacogenetic markers to predict RA response to anti-TNF therapy. Various genes in the TNF pathway have been evaluated using a candidate gene approach. Polymorphisms in genes for TNF-α, TNF receptors, signaling pathways downstream of the TNF receptors, Fc receptor genes, and risk variants for RA have been studied. We review these studies as well as genome-wide association studies (GWASs) of anti-TNF therapy in RA in the following sections (Table 29.6).

29.3.1.1 TNF Gene Polymorphisms

The TNF family consists of the cytokines TNF-α and lymphotoxins A (LTA) and B (LTB). The TNF locus, consisting of genes for TNF, LTA, and LTB, is on chromosome 6 and in close proximity to the HLA B and MHC III DR regions (Figure 29.6).

The promoter region polymorphism in the *TNF* gene, *TNF*-308A>G is probably the most significant and best studied of the *TNF* gene polymorphisms. The *TNF*-308A

TABLE 29.6 Pharmacogenetics of TNF Antagonists

Genes/Polymorphisms	Postulated Effect of Gene/Polymorphism	Clinical Effects	Reference
TNF promoter-308A> G	May increase transcription of TNF-α gene	Increased response to INF	[135,144]
	May increase circulating TNF-α levels	No effect on response to INF	[142,143]
TNF promoter-238G>A	May increase transcription of TNF-α gene	No effect on response to ETN	[145]
TNF +489 G/G	Intronic polymorphism—function unknown	No effect on response to ETN	[146]
TNFRSF1A-609, -580, -383	May affect ligand binding	No effect on response to ETN	[147]
TNFRSF1B 196 T>G	May affect receptor shedding and ligand binding; may increase synthesis of IL-6	Increased response to INF, ETN	[146]
		No effect on response to ETN	[147]
TNFRSF1B 676T>G	May affect membrane receptor shedding	Increased response to anti-TNF therapy	[148]
TNF microsatellites a, b, c, d, e	May influence production of TNF by PBMC, linked to TNF-308 SNP, increased susceptibility to RA	Specific *TNFa/b* haplotype associated with response to INF	[149]
		No effect on response to ETN	[147]
HLA DR, DQ alleles	May increase susceptibility to and severity of RA, close proximity to TNF locus	No effect on response to INF	[149]
		Specific individual *HLA DRB1* alleles and haplotype markers of increased response to ETN	[147]
MHC class I chain-related gene A transmembrane polymorphism	As above	No effect on response to INF	[149]
HLA microsatellites *BAT2, D6S273, D6S2223*	Haplotype may carry "response gene"	*BAT2-D6S273* haplotype associated with increased response to INF	[149]
FcγRIIIA 158FF	Low affinity for IgG, affects antibody clearance	Increased response to anti-TNF therapy	[150–152]
FCγRIIA-131RR	Low affinity for IgG, affects antibody clearance	Increased response to IFN	[151]
PTPRC rs10919563	RA susceptibility marker	Associated with good response to anti-TNF therapy	[153,154]
Polymorphisms in *MAP* kinase pathways *MAP3K1* rs96844, *MAP3K14* rs4792847, *MAP2K6* rs11656130	Affect signaling pathways in RA	Associated with good response to anti-TNF therapy	[155,156]
AFF3 SNPs rs10865035, rs1160542	RA susceptibility markers	Associated with good response to anti-TNF therapy	[157]
CD226 SNP rs763361	T and NK cell cytotoxicity	Associated with good response to anti-TNF therapy	[157]
IL-10 promoter microsatellite polymorphism R3	Associated with IL-10 secretion	Good response to ETN	[158]
-1087G>A in *IL-10* in combination with -308TNF	Associated with IL-10 secretion	Good response to ETN	[159]
IL-6 -174GG	Associated with IL-6 levels	Good response to ETN	[160]

allele is associated with increased transcription and higher levels of TNF-α as compared to the *TNF*-308G allele. In an early study of 59 RA patients, those without the A allele had a better response to INF by disease activity score (DAS), than those with the A allele (42%) ($p = 0.0009$) [135]. The poor response associated with the A allele is likely related to higher TNF-α levels in patients carrying it. Cuchacovich et al. [136] genotyped 132 patients with RA for the *TNF*-308 promoter polymorphism. Of these, ten patients with *TNF*-308 G/A and 10 with *TNF* -308 G/G were given INF. INF therapy caused elevation in TNF-α in both groups, which had a similar response to treatment. Although both groups showed a similar response, the increase in TNF-α levels correlated with the ACR50 response, another standardized measure of disease activity in RA, only in patients with the G/A polymorphism ($p < 0.03$). The researchers postulated that the *TNF*-308 polymorphism influences response to INF by its effects on circulating TNF-α levels.

Subsequently, several studies looked at the effects of *TNF*-308 on response to anti-TNF therapy in RA, arriving at mixed results. Three recent meta-analyses analyzed these studies but also yielded mixed results. Two meta-analyses by Lee et al. and Pavy et al. did not find any significant association between the *TNF*-308 polymorphism and response to anti-TNF therapy in RA [142,143]. Another, by Zeng et al., which evaluated 15 studies with a total of 2127 patients with RA, did find the *TNF*-308G allele to be associated with an improved response to anti-TNF agents [144].

Another SNP in the promoter region, *TNF*-238G>A (rs361525), also has possible effects on TNF-α production. In a study by Maxwell et al. [146], the *TNF*-238G>A genotype predicted a poor response to INF but not to ETN ($p = 0.028$, $n = 40$) [145]. Other *TNF* polymorphisms of possible significance include the promoter region SNP −857C>T and the intronic SNP +489, which are known to be associated with severe RA. However, no conclusive data exist regarding their association with response to anti-TNF therapy.

29.3.1.2 TNF Receptor Polymorphisms

Soluble TNF-α binds to two transmembrane receptors: the p55 receptor, also known as TNF receptor type 1 (TNFRSF1A); and the p75 receptor, also known as TNF receptor type 2 (TNFRSF1B). Production and regulation of soluble TNFRs modulate TNF-α activity in RA joints. Therefore, polymorphisms in the TNF-α receptors have been of interest in determining response to anti-TNF therapy. The *TNFRSF1B* gene is located on chromosome 1 and has 10 exons and 9 introns [161]. The SNP *TNFRSF1B* 196T>G in exon 6 leads to an amino acid substitution of methionine to arginine [162]. This polymorphism was studied in 175 RA patients, 66 of whom were treated with either ETN or INF, and their response to treatment was assessed using the DAS. Of those receiving TNF antagonist therapy, 38 had the TT, 22 had the TG, and 6 had the GG genotypes. The GG genotype was more prevalent in patients with severe RA (6.4%) as compared to the mild or moderate group (3.1%). The TT genotype was predictive of a better response to therapy over 24 weeks compared to the TG or GG genotypes. The greatest difference in response based on the genotype was seen at 12 weeks (OR 5.1; CI 1.3–19.96; $p = 0.03$) [146].

Another polymorphism in exon 6 of the *TNFRSF1B* gene, 676T>G, also results in an amino acid change from methionine to arginine. In a different study, the 676TT genotype predicted a better response to anti-TNF therapy as compared to the 676TG genotype at 3 months (OR 3.78; 95% CI 1.07–13.31) and 12 months (OR 4.30; 95% CI 1.16–15.99) [148]. In some studies, this association was only seen in patients who were anti-CCP-positive [148,163]. A larger study by Criswell et al. genotyped 457 RA patients for the 676T>G polymorphism, but could not confirm any association with anti-TNF therapy [147].

29.3.1.3 MHC Gene Polymorphisms, TNF, and MHC Microsatellites

The "*TNF locus*," *HLA B*, and *HLA DR* genes (*MHC* genes) are all arranged in tandem on chromosome 6. As described earlier, there is a strong link between specific HLA DRB1 alleles (also called the shared epitope alleles) and susceptibility to RA and its severity [164]. This makes it likely that *MHC* gene polymorphisms may affect the response to anti-TNF agents. Microsatellite haplotypes were previously associated with susceptibility to RA and certain *TNF* promoter region SNPs [165,166]. In a study by Martinez et al., 78 RA patients on INF therapy were genotyped for *HLA-DRB1*, *HLA-DQA1*, *HLA-DQB1*, *MHC* class I chain-related gene A (*MICA*) transmembrane polymorphism alleles, microsatellites *TNFa-e*, *D6S273*, HLA-B associated transcript 2 (*BATS2*), and *D6S2223*. Some interesting associations were observed between certain microsatellite haplotypes and response. Among the microsatellite haplotypes, the *D6S273_4/BAT2_2* pair was a marker of the INF responder group, both among patients and when compared to controls (46% versus 11% in nonresponders, $p = 0.001$; 46% in responders versus 17% in controls, $p = 0.00002$), indicating that this microsatellite pair may occur on the haplotype that carries the "response gene," or each microsatellite allele may be a marker of a "response gene" in proximity. The frequency of one of the *TNFa/b* haplotypes was increased in responders compared to nonresponders (41% versus 16% in nonresponders, $p = 0.01$). None of the *MHC* alleles influenced response to INF. Thus some microsatellite haplotypes were associated with response to INF in this study; single alleles did not reveal similar associations [149].

In a second study, patients were genotyped for the "shared epitope" specific *HLA-DRB1* alleles. Genotyping was carried out on 457 patients with active RA of ≤3 years duration, who were categorized as having 0, 1, or 2 copies of the SE. Patients were treated with MTX or ETN for one year, and response to therapy was measured by ACR50. SNPs at positions −308, −238, and +488 of the *TNF* gene; +249, +365, and +720 of the *LTA* gene were also examined. (These 6 *LTA-TNF* SNPs mark haplotypes spanning the "TNF locus" region). Five *TNF* microsatellites (*TNF a–e*), SNPs in *TNFRSF1A* at positions −609, −580, and −383, and the 196T/G polymorphism in *TNFRSF1B* were also examined.

As the Fc receptor (FcR) pathway appears important in the degradation of ETN-TNF complexes, three *FcR* polymorphisms were also examined in this study. Response to treatment was associated with a higher number of *HLA-DRB1* (SE) alleles. Patients with 2 copies of the SE alleles had a better response to ETN compared to those with 1 copy or none (OR 4.3; 95% CI 1.8–10.3). Haplotypes defined by the 6 *LTA—TNF* SNPs and *DRB1* alleles were deduced for the 16 most common *DRB1* alleles in a subset of 224 Caucasian patients. Among 448 haplotypes thus examined, two, *HLA-DRB1* *0101-GGGAGG and *HLA-DRB1* *0404-GGAAGG, strongly correlated with response (76 and 61% ACR50 response at 12 months, respectively). The number of copies of *HLA-DRB1* SE alleles inherited and specific haplotypes spanning the *HLA-DRB1* region and SNPs in the *LTA–TNF* region may therefore be associated with response to ETN, at least in Caucasians [147].

29.3.1.4 RA Risk Variants

Several risk alleles have been identified that are associated with increased susceptibility to RA [167]. Given this association, these alleles may also influence response to treatment. Some data suggest that the RA risk variant gene tyrosine phosphatase receptor type C (*PTPRC*) has a strong association with response to anti-TNF therapy. The *PTPRC* gene encodes a CD45 antigen. In a study by Cui et al. [153], a cohort of 1283 RA patients on TNF inhibitors were genotyped for SNPs in *PTPRC*. Patients with the rs10919563 SNP in the *PTPRC* gene had a better EULAR response as compared to patients without the polymorphism ($p = 0.0001$). Another large cohort of 1115 RA patients from the United Kingdom were tested for 29 SNPs known to be RA susceptibility variants. The rs10919563 SNP in the *PTPRC* gene was again associated with improved response to anti-TNF therapy (OR 0.62; 95% CI 0.40–0.95; $p = 0.03$) [154]. Despite the relatively strong association found in these studies, a subsequent study by Krintel et al. was unable to replicate these findings [168].

Mitogen-activated protein kinases (MAPKs), which are involved in several signaling pathways in RA, are also known RA risk variants. Studies evaluating polymorphisms in the MAPK pathways have yielded mixed results. In a UK cohort of 642 patients, the SNP rs96844 in *MAP3K1* and the SNP rs4792847 in *MAP3K14* were found to be nominally associated with response to anti-TNF therapy ($p < 0.05$). However, these associations could not be confirmed in a validation cohort of 428 patients with RA in the same study [155]. Coulthard et al. [156] studied polymorphisms in 11 genes in the MAPK pathway in a cohort of 1102 RA patients receiving TNF inhibitors. Seven polymorphisms were identified in five genes in the MAPK signaling pathways that were associated with an improved DAS28 response to IFN and ADA. However, no association was found with response to ETN. One polymorphism, rs11656130 in *MAP2K6*, was associated with a good EULAR response but not an improved response as measured by DAS28.

Two more SNPs in *AFF3* were identified as markers of response to anti-TNF therapy by Tan et al. [157] in 1012 RA patients. The G allele of two SNPs, rs10865035 and rs1160542, in *AFF3* were associated with response to anti-TNF therapy. The *AFF3* gene, which encodes nuclear transcription activators in lymphoid tissue, is a known RA susceptibility marker. Another SNP rs763361 in the *CD226* gene results in a substitution of serine for glycine. This SNP was also associated with response to anti-TNF therapy [169]. CD226, a membrane protein on the surface of hematopoietic cells, is involved in T and NK cell cytotoxicity and has been described as a RA risk variant [170].

29.3.1.5 Cytokines, Toll-Like Receptors, and Signaling Pathways

Multiple cytokines are implicated in RA pathogenesis. Polymorphisms in the interleukin (*IL)-1β*, IL-1 receptor antagonist (*ILRA*), *IL-6*, *IL-10*, and tumor growth factor (*TGF*) β genes have been studied in relation to anti-TNF therapy. So far, no polymorphisms in individual cytokine genes have been associated with response [171]. According to Padyukov et al. [159], a −1087G>A SNP in the *IL10* gene, in combination with the −308 SNP in the *TNF* gene, were associated with a good response to ETN. Another combination, the A2 allele in intron 2 of the *ILRA* gene and a rare +915C allele in codon 25 of the *TGFB1* gene, was associated with a poor response to ETN therapy. The +915C allele was found significantly more often in combination with the A2 allele in the *ILRA* gene in nonresponders to ETN ($p<0.05$) [159]. Schotte et al. [158] reported that the *IL-10* microsatellite polymorphisms—the R3 allele and the R3-G9 haplotype in the promoter region—were associated with a good response, whereas the G13 allele and the haplotype R2-G13 were associated with moderate to no response [158].

Jancic et al. [160] genotyped 77 RA patients for the 174G>C*IL-6* gene polymorphism, which is known to influence IL-6 levels. These patients were treated for 12 months with ETN. More patients with the *IL-6*-174GG (95.7%) genotype had an improvement in disease activity by DAS as compared to those with the GC (75.6%) or CC (44.4%) genotypes ($p=0.006$). Potter et al. [172] examined SNPs in the NFkB (or nuclear factor kappa B, a transcription factor) and TLR (toll-like receptor) pathways. Among 187 SNPs genotyped in 909 RA patients, 12 in 9 genes showed a nominal association with response to anti-TNF therapy.

29.3.1.6 Fcγ Receptor Variants

Most anti-TNF agents are antibodies and therefore have a Fc component to them (except CZB, which is a pegylated Fab fragment). The Fc component attaches to the Fc gamma receptor (FcγR) on various cells and serves as a mechanism for antibody clearance. Polymorphisms in the *FcγR* gene affect the avidity and strength of Fc–FcγR binding and thereby may potentially influence the clearance and thus the efficacy of TNF antagonist drugs. For example, in the *FcγRIIIA* receptor polymorphism F158V, the FF genotype has a lower affinity for IgG1. In a small study of 30 patients with RA, the 158 FF variant was found in greater frequency among patients who had a very good response to anti-TNF agents, presumably because of lower drug clearance rates [150]. In another study of 98 RA patients treated with IFN, both ACR50 and EULAR responses at week 6 were better in those who were homozygous for the low-affinity *FCγRIIIA* 158FF genotype. Another affinity variant, *FCγRIIA* 131RR, was a marker of better ACR20 responses at week 30 of INF treatment in the same study [151]. These findings were replicated in a Japanese study with 33 patients, [152], but they could not be replicated in a subsequent larger Swedish study of 282 patients treated with INF or ETN [173].

29.3.1.7 GWASs

Genome-wide association studies (GWAS) represent another methodology used to evaluate the association of genetic polymorphisms with response to anti-TNF therapy. While they are a powerful way to look at a multitude of SNPs, higher numbers of patients are required to achieve significant results. Also, while the SNPs may not be significant in themselves, they may point to a genetic locus of significance. Liu et al. [174] reported the first GWAS in this area using 89 patients; there was an association of 16 SNPs in nine genes with response to anti-TNF therapy. These findings were not replicated in larger subsequent studies.

In a larger cohort of 566 patients, Plant et al. [175] found seven loci of significance by multistage GWAS. The first SNP, rs17301249, mapped to the eyes-absent homolog 4 (*EYA4*) gene on chromosome 6, and showed a significant association with response. *EYA4* is a co-transcription factor for interferon β and CXCL10. A second SNP, rs1532269, mapped to the PDZ domain–containing protein 2 (*PDZD2*) gene, which is associated with insulin secretion. (*PDZ* is an acronym combining the first letters of three proteins—post-synaptic density protein, *Drosophila* disc large-tumor suppressor, and *Zonula occludens*-1 protein—which were first discovered to share a domain). The significance of this locus is unclear. The other five SNPs mapped to intergenic regions on chromosomes 1, 4, 11, and 12.

Another GWAS by Krintel et al. [167] analyzed 486,450 SNPs in 196 Danish patients with moderate to severe RA on IFN, ETN, or ADA therapy. The findings of the earlier GWASs by Lui et al. and Plant et al. could not be confirmed in this study, and despite the multitude of SNPs studied none achieved significance.

A recent GWAS by Umicevic Mirkov et al. [176] analyzed 2,557,253 SNPs in 882 Dutch patients from the Dutch Rheumatoid Arthritis Monitoring (DREAM) registry. Three, (rs1568885, rs1813443, and rs4411591) showed directional consistency, and eight genetic loci were suggestive of association. However, no individual SNP achieved significant association with response to anti-TNF treatment. Also, none of the associations found in earlier studies could be confirmed.

Cui et al. recently conducted a GWAS meta-analysis with 2706 RA patients from 13 different cohorts. More than 2 million SNPs were evaluated for association with response to anti-TNF therapy. The rs6427528 SNP was associated with a better response by DAS scores in patients treated with ETN; this may be mediated by higher CD84 gene expression in peripheral blood mononuclear cells in patients carrying this SNP. CD84 is a cell-surface receptor found on various immune cells and is thought to play a role in signaling T-cell activation and IFN-γ secretion [177,178]. The variant rs6427528 was not associated with response to therapy with either INF or ADA [179]. Acosta-Colman et al. [180] described the SNP rs3794271 in intron 4 of the *SLCO1C1* gene in a cohort of 315 RA patients. This SNP was associated with a good EULAR response to anti-TNF therapy. *SLCO1C1* is a cell membrane transporter important in drug metabolism. The *SLCO1C1* locus is near the *PDE3A* gene (which codes for a phosphodiesterase). The aforementioned GWAS study by Krintel et al. had described an intergenic SNP, rs11045392, located between the 5′ end of *SLCO1C1* and the 3′ end of the *PDE3A* gene as a putative marker of response to anti-TNF therapy. The researchers speculated that these two SNPs, rs3794271 and rs11045392, may be in linkage disequilibrium and therefore that the *PDE3A-SLCO1C1* locus may be an important determinant of response to anti-TNF therapy [180].

29.3.2 Rituximab

Rituximab is an anti-CD20 chimeric antibody used in RA treatment. Several studies have looked at candidate genes for pharmacogenetic associations that affect response to rituximab therapy. Some of these genes had already been evaluated in patients with lymphoma, a condition for which rituximab has been in use for several years.

In a study of 63 RA patients, Daien et al. [181] analyzed 13 SNPs in nine genes, including *IL10, LTA*, *TGFβ1*, *TNF-α*, *TNFRSF1B*, *TRAF1-C5*, *STAT4*, *TNFAIP3*, and *PTPN22*. Some of these—rs2476601 in *PTPN22*, rs7574865 in *STAT4*, rs1081848 in *TRAF1-C5*, and rs6920220 in *TNFAIP3*—had been associated with RA susceptibility in prior studies [182,183].

In the *TGFβ1* gene, the CT genotype at SNP rs1800470 in codon 10 was associated with good treatment response to rituximab. The CT genotype, as compared to the TT genotype, was seen more often in responders (OR 1.6; 95% CI 1.2–2.3; $p = 0.002$), while the CC genotype was equally prevalent among responders and nonresponders. Another SNP, rs1800471 at codon 25 in the *TGFβ1* gene, was also associated with response to rituximab. Of patients with the GC genotype 100% were responders, while 63% with the GG genotype were responders (OR 1.6; 95% CI 1.3–1.9; $p = 0.025$) [181]. Rituximab was even more effective in patients who had both these polymorphisms—that is, SNP rs1800470 in codon 10 and SNP rs1800471 in codon 25 (OR 2.6; $p = 0.008$) [181]—which may be the result of lower TGFβ1 production in patients carrying these SNPs [184].

The B-lymphocyte–stimulating factor (BLyS) is essential for B-cell production and survival. As rituximab therapy causes depletion of B cells, it is also associated with a reflexive increase in BlyS levels that attempts to establish B-cell repopulation. Therefore, polymorphisms in BlyS may alter response to rituximab by altering B-cell repopulation after rituximab therapy. Ruyssen-Witrand et al. [185] studied the polymorphism −871C>T in the *BlyS* promoter region in 115 patients with RA. The 871CC genotype was associated with a better EULAR response to rituximab than the 871TT genotype (OR 6.9; 95% CI 1.6–29.6; $p = 0.03$), possibly mediated by a change in BlyS levels. This association of the −871C>T SNP with response to rituximab could not be validated in a subsequent study by Fabris et al. [186] in 155 Italian RA patients. In this study, four polymorphisms in the *BLyS* promoter region: −2841T>C, −2704T>C, −2701T>A, and −871C>T, in linkage disequilibrium, were examined. The haplotype TTTT was predictive of a good response to rituximab (OR 14.4; 95% CI 1.77–117.39; $p = 0.003$) in RA patients who were seropositive (positive for RF and/or CCP antibody) and had a prior poor response to anti-TNF agents. These findings were replicated in a validation cohort of 115 RA patients in the same study [186].

Because rituximab is a monoclonal antibody, its serum levels and rates of clearance are altered by Fc receptor polymorphisms. The F158V polymorphism in the *FcγRIIIA* gene (rs396991) has been associated with response to rituximab, although with variable results. In a study of 111 patients, Ruyssen-Witrand et al. [187] found that V allele carriage was associated with better response (91% of responders versus 70% of nonresponders (OR 4.6; 95% CI 1.5–13.6; $p = 0.006$). Another study of 212 RA patients reported similar findings: a good EULAR response was seen in 89.5% of patients with the VV genotype, in 66% with the VF genotype, and in 66.2% with the FF genotype ($p = 0.01$) [188]. Kastbom et al., however, found that heterozygotes carrying the 158VF genotype responded better than those homozygous for either 158VV or 158FF [189]. Sarsour et al. found no effects of the F158V polymorphism on response to either rituximab or TNF inhibitors [190].

Fabris et al. studied the −174G>C polymorphism in *IL-6* and the D358A polymorphism in IL-6-receptor alpha (*IL-6Ra*) genes for associations with rituximab response; these polymorphisms influence expression of IL6 and

IL6Ra, respectively. IL6 is a growth and maturation factor for B cells. The *IL-6*-174CC genotype (rs1800795) was associated with a poor EULAR response (39.1%) as compared to the GC/CC genotypes (18.5%) (OR 2.83; 95% CI 1.10–7.27; p = 0.031). No association was found between the D358A polymorphism in *IL-6Ra* and response to rituximab [191].

29.3.3 Tocilizumab

Tocilizumab is a humanized monoclonal IL-6 receptor antagonist that was recently approved for RA therapy. Wang et al. conducted the first GWAS to demonstrate that genetic variants are associated with response to tocilizumab. They used pooled data from six studies of tocilizumab in RA and a total of 1683 patients. In the initial analysis, 534,053 markers were studied, and 253 variants showed an association with tocilizumab therapy. Seven of these variants (rs11052877, rs4910008, rs9594987, rs10108210, rs703297, rs703505, and rs1560011) achieved significance on conformational analysis. Eight putative genetic loci of interest were identified that were not previously known to be significant. Associations of these variants with response were found to be stronger in seropositive RA patients [192].

29.4 CONCLUSIONS AND FUTURE DIRECTIONS

As seen from the studies described in this chapter, the field of pharmacogenetics in RA is rapidly evolving. Variations in genes controlling drug-metabolizing enzymes, drug receptors, and drug targets play a role in determining an individual's response to a given drug. Nonetheless, several points need to be considered before pharmacogenetics can be brought to the clinic.

In many of the studies described, the strength of the association between genotype and phenotype may not be robust, for several reasons. Most of the studies suffered from underpowering and small sample sizes, and associations observed in one study could not be replicated in another. Some were retrospective in design, which prevented an accurate estimation of drug effects, particularly adverse ones. In addition, race may strongly impact pharmacogenetics, and genotype-phenotype associations observed in one racial population may not necessarily hold true in a different racial population. Our study examining the frequencies of SNPs in the MTX pathway in different racial groups demonstrated significant differences in the allele frequencies of several SNPs between Caucasians and African Americans with RA [193]. Another study, by Criswell et al., showed that certain *MHC/TNF* haplotypes were predictive of response to ETN in a Caucasian population; whether these associations will be valid in other populations remains in question [147].

Most drugs used in RA (e.g., MTX, TNF antagonists) influence several different cellular (and genetic) pathways. Thus, analysis of SNPs in different metabolic pathways rather than only one may be more helpful in predicting response [57]. Also, if a variant is only weakly associated with response, this may be because it occurs in tandem or in proximity to the actual marker of response. For these reasons, haplotype analyses may be better than single SNP analyses in predicting response [147,194]. Genome-wide association studies in pharmacogenetics are emerging, as described in this chapter, that may also help in this regard. Finally, the cost-effectiveness of pharmacogenetic testing needs to be examined before such testing can be brought into the clinical setting [195]. Drugs with a narrow therapeutic index and severe side effects, and for which there exists a firm association between a specific genotype and phenotype (usually toxicity), are best suited for pharmacogenetic testing in the clinic; a good example is *TPMT* testing prior to AZA use in clinical practice.

Despite these caveats, as genotyping becomes easily available and less expensive, and as major funding agencies continue to show a commitment to pharmacogenetic research—for example, the International HapMap Consortium (www.hapmap.org) and the the National Institutes of Health Pharmacogenetics Research Network (www.nigms.nih.gov/pharmacogenetics/), personalized medicine in RA will become a reachable goal in the not too distant future.

Chapter 30

Pharmacogenomics of Oral Antidiabetic Drugs

Vangelis G. Manolopoulos and Georgia Ragia
Laboratory of Pharmacology and Clinical Pharmacology, Medical School, Democritus University of Thrace, Alexandroupolis, Greece

Chapter Outline

30.1 Overview 683
30.2 Genetic Basis of Diabetes 683
30.3 Management of Diabetes 684
30.4 The Need for Pharmacogenomics and Stratified Medicine 685
30.5 Genetic Variants Associated with Response to Oral Hypoglycemic Agents 685
  30.5.1 Biguanides (Metformin) 685
  30.5.2 Sulfonylureas 703
  30.5.3 Nonsulfonylurea Insulin Secretagogues (Glinides) 706
  30.5.4 Thiazolidinediones 707
30.6 Stratified Oral Antidiabetic Medicine: Pharmacogenomics Application 709
30.7 Conclusions: Future Perspectives 710
Abbreviations 710
References 710

30.1 OVERVIEW

Diabetes is one of the most common chronic diseases and has been steadily gaining in prevalence worldwide in recent decades. According to the fifth edition of the *Diabetes Atlas* (2012 update) 371 million people have diabetes and 187 million are still to be diagnosed. This upward trend will continue (www.idf.org/diabetesatlas). Approximately 90−95% of all diabetic individuals present with type 2 diabetes mellitus (T2DM).

T2DM is characterized by hyperglycemia, relative impairment in insulin secretion by β-pancreatic cells, and decreased tissue responsiveness to insulin (insulin resistance). Most common T2DM complications due to long-term hyperglycemia are micro- and macrovascular and neuropathic complications, such as retinopathy, nephropathy, coronary artery disease, peripheral vascular disease, stroke, and neuropathy [1]. Because of these complications, T2DM has a tremendous impact on healthcare systems and constitutes a major cause of mortality in the Western world. It has been estimated that, by the end of 2012, 4.8 million people had died from diabetes-related complications and that half of these deaths were people under the age of 60.

T2DM is one of the most complicated diseases, implicating several pathophysiologic mechanisms: oxidative stress, endoplasmic reticulum stress (ER stress) in B cells, and tissue inflammation; more recently, autoimmune mediators that cause inflammation have been associated with decline in insulin secretion [2]. Furthermore, T2DM incidence is attributed to both demographic and lifestyle factors, such as obesity, aging, physical inactivity, and genetic factors.

30.2 GENETIC BASIS OF DIABETES

The genomics of T2DM is an evolving field. Accumulated data on T2DM genomics research highlight its polygenic origin. Several gene polymorphisms have been associated in case-control association studies with T2DM incidence [3]. Case-control association studies are in principle conducted on the basis of hypotheses about the involvement of specific biologic factors with T2DM pathogenesis; these may range from factors directly regulating B cell function [4] to components of other systems such as the serotonergic system [5].

In addition, more than 35 genome-wide association studies (GWASs) on T2DM have been published as of

Handbook of Pharmacogenomics and Stratified Medicine. http://dx.doi.org/10.1016/B978-0-12-386882-4.00030-X
© 2014 Elsevier Inc. All rights reserved.

mid-2013 and can be found at www.genome.gov/gwastudies/index.cfm?pageid=26525384#searchForm. These hypothesis-free tools have revealed the association of several gene polymorphisms with T2DM incidence. It should be noted that results from GWASs have identified polymorphisms with as yet unknown functions relating to gene regulation or protein function [6]. In any case, the common theme that has emerged from GWASs confirms what was already known about the polygenic origin of complex diseases—that is, multiple gene polymorphisms confer only a modest increase in T2DM risk.

The genetic imprint of T2DM is being gradually discovered as the association of several gene polymorphisms with T2DM incidence is being replicated in both GWASs and case-control studies. A description of these studies is out of the scope of this chapter; interested readers are referred to a recent comprehensive review on the subject [3]. The most replicated gene associated with T2DM encodes transcription factor 7-like 2 (*TCF7L2*) that is expressed in the mature and developing β-pancreatic cells. This transcription factor is involved in the canonical β-catenin-dependent Wnt signaling pathway, which in turn regulates cell differentiation, proliferation, migration and survival, and organ development. *TCF7L2* is commonly called the diabetes gene because of its consistent association with T2DM development. It plays an important role in several vital functions in the pancreatic islet, such as pancreas development, B cell mass, insulin processing, and the maintenance of secretory function in mature B cells [7].

The *TCF7L2* gene single-nucleotide polymorphism (SNP) rs7903146 (*C*>*T*) strongly predicts the incidence of T2DM in populations of different ancestry (European, Asian, and African), and it is nearly in complete linkage disequilibrium (LD) with other variants of *TCF7L2*, such as rs12255372 (*G*>*T*), that are also associated with T2DM. The association of each SNP with T2DM incidence correlates 92% of the time with the other. The *TCF7L2* rs7903146 (*C*>*T*) SNP is among the most highly replicated and consistent associations with a disease of multigenic origin; its association with T2DM derives from consistent results of GWASs and global meta-analyses on different quantitative glycemic traits such as fasting plasma glucose levels and glycated hemoglobin (HbA1c). The attributable risk in disease incidence is driven by the *TCF7L2* rs7903146 *T* allele and confers an odds ratio (OR) of 1.46 for developing T2DM—a value similar in all human populations tested for this variant allele [8].

Though *TCF7L2* harbors the variant with the strongest effect on T2DM, the molecular mechanism of variation in this gene which increases the risk of T2DM remains elusive. The genetic variation of *TCF7L2*, rs7903146, is located in a noncoding region and is assumed to alter gene expression. More recent data indicate that *TCF7L2* rs7903146 is located at an islet-selective open chromatin site and consequently alters enhancer activity [7]. Its predominant direct or indirect role in B cell function and possible stimulation of B cell proliferation have also been suggested. (Other gene polymorphisms associated with T2DM in GWASs can be found in detail at the website of the National Human Genome Research Institute, www.genome.gov/gwastudies/index.cfm?pageid=26525384#searchForm.). It is widely accepted that numerous genetic polymorphisms contribute to T2DM causality, and it is believed that combined analysis of polymorphic gene locus confers increased risk [3]. Although gene polymorphisms are crucial for understanding human biology, this static aspect of genomic information is limited for explaining interindividual differences in gene expression, disease susceptibility, and drug response.

In this era, in which the entire genome sequence has been decoded, there is still a gap in knowledge about the hereditability of multigenic diseases such as T2DM, which has led to broader research on the identification of T2DM predisposing factors beyond the genome. The nonplasticity of the genome in terms of nucleotide sequence has led to the molecular characterization of other nongenetic alterations that affect gene expression [9]. The dynamic complexity of the human genome, as well as that of the patterns of altered gene expression in target tissues due to endogenous modulators or environmental factors, has opened the way to a new field of research, *epigenomics*.

Epigenomics focuses on changes in gene function that derive not from changes in the DNA sequence, but from reversible regulation of transcriptional control that dictates how genes are expressed. The general concept of epigenomics lies in the molecular basis of DNA organization. Epigenetic patterns include modifications of DNA wrapping that rule out the availability of a gene for transcription, and therefore expression, and mainly consist of three distinct molecular mechanisms of gene transcription and translation regulation: methylation; acetylation; and microRNAs.

During the last ten years, intense research efforts have been devoted to the study of epigenetic modifications, the factors that promote them, and the challenges remaining in implementing them as prognostic markers or as novel therapeutic targets in T2DM. It should be noted that most suggested mechanisms and implications of epigenomic involvement in T2DM development and diabetic complications are still at the hypothesis level. However, studies of human tissues or cells are beginning to emerge and will provide a more solid basis for understanding the mechanisms involved. Discussion of these studies is beyond the scope of this chapter, and interested readers are directed to a recent comprehensive review on the subject [10].

30.3 MANAGEMENT OF DIABETES

Management of T2DM consists initially of lifestyle modifications (diet and exercise) and eventually of pharmacologic treatment, which sooner or later becomes essential in most T2DM patients. T2DM pharmacologic treatment aims at achieving specific glycemic goals to substantially reduce the risk of both vasculature complications and morbidity. Measurement of HbA1c levels primarily identifies the average plasma glucose concentration over prolonged periods of time and serves as a marker for average blood glucose levels over the months prior to measurement. Guidelines for T2DM management released by the American Diabetes Association (ADA) in 2009 required that HbA1c levels have to be maintained below 7% [11]. More recently, ADA and the European Association for the Study of Diabetes (EASD) updated the recommendations for antihyperglycemic therapy in T2DM adults, stressing the fact that the best available evidence on glycemic control should be incorporated in a patient-centered, multifactorial risk reduction framework [12].

The main classes of oral drugs that are currently available to treat T2DM include biguanide metformin, sulfonylureas, nonsulfonylurea insulin secretagogues (glinides), thiazolidinediones, α-glucosidase inhibitors, and dipeptidyl peptidase IV inhibitors. Newer drug classes such as bile acid resins and dopamine agonists have also gained U.S. Food and Drug Administration (FDA) approval for the treatment of diabetes. Combination therapies are a common approach in T2DM patients, since during disease progression, most patients may require more than one antidiabetic drug to achieve glycemic goals and restrict hyperglycemia [11]. However, despite major recent advances in diabetes care, a large proportion of patients remain in poor glycemic control.

Throughout the years, a consistent observation in antidiabetic drug treatment has been that significant variability exists in drug disposition, glycemic response, tolerability, and incidence of adverse effects, even in T2DM patients who have apparent requirements for antidiabetic regimens. Among other factors, interindividual variability in patient responses to antidiabetic drugs is affected by gene polymorphisms. Pharmacogenomics studies individual pharmacologic response based on genotype [13]. Clinical application of gene polymorphisms in components that affect the pharmacokinetics of antidiabetic drugs, that are involved in their therapeutic mechanisms, and/or that cause adverse effects has the potential to improve T2DM management by helping clinicians effectively prescribe these medications [10].

Pharmacogenomic analysis is an additional tool that can be used, together with HbA1c monitoring—the current gold standard for glycemic control—to improve the choice and dosing of oral antidiabetic treatment by individualizing drug therapy; it does not challenge HbA1c monitoring but rather functions in a complementary fashion because it is addressing a step prior to monitoring blood glucose levels.

30.4 THE NEED FOR PHARMACOGENOMICS AND STRATIFIED MEDICINE

The study of genetic variation in association with response to oral antidiabetic medications focuses on genes involved in drug pharmacokinetics and pharmacodynamics, as well as on genes that are involved in the underlying disease condition or insulin secretion pathway. Most available pharmacogenomic data on antidiabetic medications derive from studies on early drugs, including biguanide (metformin), sulfonylureas, nonsulfonylurea insulin secretagogues, and thiazolidinediones. To the best of our knowledge, pharmacogenetic studies are not yet available on the remaining drug classes used for T2DM treatment.

Information on all gene polymorphisms that have been studied in association with drug response—their chromosome location, effect on encoded protein, and the respective antidiabetic medication they affect—is presented in Table 30.1. To further help the reader in easily accessing the published studies, all currently available data on gene polymorphisms associated with antidiabetic drug response are briefly listed in three tables: Table 30.2 presents polymorphisms in genes mediating the metabolism of antidiabetic drugs; Table 30.3 (later in the chapter) presents polymorphisms in genes encoding drug receptors and drug transporters; Table 30.4 presents polymorphisms in genes of all other molecules involved in disease pathogenesis. Furthermore, given the significance of clinical trials assessing implementation of pharmacogenomics in routine clinical practice, completed and ongoing clinical trials on antidiabetic drug pharmacogenomics are listed in Table 30.5 (also see www.clinicaltrials.gov). All tables can be found in the Appendix.

30.5 GENETIC VARIANTS ASSOCIATED WITH RESPONSE TO ORAL HYPOGLYCEMIC AGENTS

30.5.1 Biguanides (Metformin)

Metformin is the only available biguanide currently in clinical use; the other one, phenformin, was discontinued because of adverse events. Metformin is well tolerated by the majority of patients and acts by inhibiting excessive hepatic glucose production (gluconeogenesis), and subsequently reduces intestinal glucose absorption and fasting glycemia, and improves insulin sensitivity and peripheral glucose uptake and utilization [14]. In T2DM management, metformin is recommended as a first-line treatment, except when contraindicated. Overall, metformin monotherapy lowers HbA1c by 1.5–3%; nonetheless, many patients require additional glucose control, and metformin is approved for use in combination with other oral antidiabetic agents such as sulfonylureas and thiazolidinediones.

TABLE 30.1 Summary of Genetic Loci and Gene Polymorphisms

Gene (Protein)	Genomic Locus	SNP[a]	SNP Gene Location	Amino Acid Substitution	Effect on Encoded Product	MAF	Association

[a] *As reported in the dbSNP Short Genetic Variations database (www.ncbi.nlm.nih.gov/projects/SNP/snp_ref.cgi?rs).*

Note: These loci/polymorphisms have been examined in association with oral antidiabetic drug response. The table summarizes their chromosome location, effect on encoded protein, MAF (minor allele frequency), and the respective antidiabetic drug they affect.

Metformin is not metabolized by CYP450 hepatic enzymes, nor does it bind to plasma proteins, but it is excreted unchanged in urine [14]. The drug is widely distributed in body tissues, including intestine, liver, and kidney, by at least two organic cation transporters (OCTs), OCT1 and OCT2, and it is also a substrate of human multidrug and toxin extrusion 1 (MATE1) [15]. OCT1 mediates hepatic uptake of metformin from the circulation, whereas OCT2 and MATE1 facilitate its renal secretion. There is much interindividual variability in metformin pharmacokinetics as measured by differences in trough steady-state metformin plasma concentration. Polymorphisms in both OCT1 and OCT2, encoded by the *SLC22A1* and *SLC22A2* genes, respectively, and in MATE1, encoded by the *SLCO47A1* gene, have been consistently associated with metformin pharmacokinetics and therapeutic response, whereas evidence exists that polymorphisms in other genes potentially modify response to therapy (Tables 30.3 and 30.4).

30.5.1.1 SLC22A1 Gene Polymorphisms and Metformin Response

The *SLC22A1* gene encodes for OCT1 and is located on chromosome 6q25.3; it consists of 11 exons spanning 37 kb [16]. Human *SLC22A1* is highly polymorphic and its numerous polymorphisms have been described in various populations (www.ncbi.nlm.nih.gov/SNP/snp_ref.cgi?locusId=6580). The most common polymorphisms, their minor allele frequency (MAF), and their effect on transporter activity are shown in Table 30.1.

Research on the association of OCT gene polymorphisms with metformin response began in 2007, when Shu et al. showed that, in $Oct1^{-/-}$ mice, the glucose-lowering effect of metformin was abolished [17]. In the same study, the effect of four variants of OCT1 (*R61C*, *G401S*, *M420del*, and *G465R*), which are associated with reduced metformin transport, was assessed in regard to therapeutic response to metformin in 20 healthy volunteers given two subsequent metformin doses (1000 mg in the evening and 850 mg in the morning). Defective variants were associated with significantly decreased glucose-lowering response to metformin [17] and, in a following study in the same cohort population, with significantly higher area under the concentration–time curve (AUC) and maximum plasma concentration after two oral doses [18].

In a subsequent study of 103 healthy male volunteers, the same OCT1 variants (*R61C*, *G401S*, *M420del*, and *G465R*) were associated with increased metformin renal clearance and decreased hepatic uptake, suggesting that renal OCT1 expression may be an important determinant of metformin response [19].

TABLE 30.2 Gene Polymorphisms of Cytochrome P450 Enzymes

Drug	Gene	Polymorphisms	Subject Population	Investigated Parameter	Primary Outcome	Reference
Metformin	Metformin not metabolized by CYP450 hepatic enzymes	—	—	—	—	—
Sulfonylureas	*CYP2C9*	*CYP2C9*2* and **3* compared with *CYP2C9*1/*1*	16 healthy volunteers	Plasma concentration of glyburide and glimepiride	*CYP2C9*3* carriers: • 280% higher glyburide plasma levels • 267% higher glimepiride plasma levels	[37]
			23 healthy volunteers: • Single 500 mg oral dose tolbutamide • Then 75 g oral glucose at 1, 4.5, and 8 hours after	Tolbutamide oral clearance	*CYP2C9*3/*3* individuals: • 6.5-fold lower tolbutamide oral clearance	[38]
			21 healthy volunteers: • Single 3.5 mg oral dose glyburide • Then 75 g glucose at 1, 4.5, and 8 hours after	Glyburide oral clearance	*CYP2C9*3/*3* individuals: • <50% lower glyburide oral clearance	[39]
			15 healthy volunteers: • Single 500 mg oral dose tolbutamide	• Concentration • Oral clearance	*CYP2C9*1/*2* individuals: • 1.5-fold increased tolbutamide concentration • 29%, greater reduction in tolbutamide oral clearance • 38%, greater reduction in tolbutamide formation clearance *CYP2C9*1/*3* individuals: • 1.9-fold increased tolbutamide concentration • 48%, greater reduction in tolbutamide oral clearance • 56%, greater reduction in tolbutamide formation clearance	[40]
			• T2DM patients • Tolbutamide-treated participants of Rotterdam study	• Fasting serum glucose levels • Required doses	*CYP2C9*3* carriers: • larger decrease in fasting serum glucose levels after therapy start • required lower doses	[42]
			Go-DARTs study: • 1073 sulfonylurea-treated T2DM patients	• HbA1C target • Glycemic goal achievement	*CYP2C9*2/2, CYP2C9*2/*3, CYP2C9*3/*3* individuals: • 3.4 times more likely to achieve HbA1C <7% • achieved glycemic goal more rapidly and persistently	[43]

TABLE 30.2 Continued

Drug	Gene	Polymorphisms	Subject Population	Investigated Parameter	Primary Outcome	Reference
			207 sulfonylurea-treated T2DM patients	Mean sulfonylurea stable dose	*CYP2C9*3* carriers: • trended to lower mean stable glimepiride dose	[44]
		*CYP2C9*2* and **3*: • Compared with *CYP2C9*1/*1* (known *CYP2C19* genotype)	Clinical trial NCT0080601318: • 18 healthy Chinese volunteers: • Single dose 5 mg glipizide	Glipizide plasma concentrations over 36 hours	Compared with *CYP2C9*1/*1* individuals, *CYP2C9*1/*3* individuals: • higher glipizide AUC (by 95.5%) • lower glipizide clearance (−51.1%)	[41]
		*CYP2C9*2* and **3:* • Compared with CYP2C9*1/*1	80 glibenclamide-treated T2DM patients	• Response to glibenclamide • Glibenclamide plasma levels	*CYP2C9*1/*2* or **1/*3* patients: • more likely to have controlled T2DM (fasting plasma glucose value <110 mg/dl) compared with *CYP2C9*1/*1* patients *CYP2C9*2* and **3* carriers: • relatively higher plasma levels of glibenclamide compared with *CYP2C9*1/*1* patients	[45]
			• 20 T2DM patients with severe hypoglycemia • 337 T2DM without history of severe hypoglycemia	Severe hypoglycemia	*CYP2C9*3/*3* and **2/*3* genotypes: • increased risk of severe hypoglycemia (OR 5.2)	[47]
			• 92 T2DM with mild hypoglycemia • 84 T2DM patients without hypoglycemia	Mild hypoglycemia	*CYP2C9*3* allele: • increased risk of mild hypoglycemia (OR 1.7)	[48]
			• 102 T2DM patients with severe hypoglycemia • 101 T2DM without history of severe hypoglycemia	Severe hypoglycemia	• No over-representation of CYP2C9 PM phenotypes (*CYP2C9*2/*2, *2/*3*, or **3/*3* genotypes) in case group • Mean sulfonylurea doses in CYP2C9 EM *CYP2C9*1/*1, *1/*2*), IM (*CYP2C9*1/*3*), PM (*CYP2C9*2/*2, *2/*3, *3/*3*): • significantly lower in nonhypoglycemic controls compared with hypoglycemic cases	[50]

Source: From www.clinicaltrials.gov/.

In another study, Becker et al. analyzed the association of 11 tagging SNPs of the OCT1 with HbA1c change in 102 metformin users. They found significant association of the rs622342*A>C* polymorphism with HbA1c reduction [20]. The association of OCT1 defective variants with metformin response has been replicated in three more recent pharmacogenomic studies. In 138 T2DM patients randomized to metformin 1000 mg/day for 4 weeks and afterward to 2000 mg/day, reduced-function diplotypes composed of the alleles *R61C*, *G401S*, *M420del*, and *G465R* in OCT1 were associated with a significant decrease in trough metformin steady-state concentration and a reduced absolute decrease in HbA1c [21].

A study of 96 healthy Korean male volunteers administered a single 500 mg dose of metformin found that the OCT1 *P341L* polymorphism was associated with increased AUC and altered metformin pharmacokinetics [22]. Beyond the association of OCT1 variants with metformin pharmacokinetics and drug response, the findings of a recent study of 246 T2DM patients on metformin treatment, of whom 53 experienced common gastrointestinal side effects, showed an association of two OCT1 defective alleles (*R61C* and *G465R*) with metformin intolerance [23]. The researchers suggested that metformin intolerance is induced by a local increase in metformin concentration in the intestinal tissue and that, since OCTs are also expressed in intestinal cells, altered OCT expression potentially mediates the experience of metformin-induced adverse events.

OCT1 gene polymorphisms are associated with metformin response with a high degree of reproducibility and may emerge as useful genetic markers in personalizing metformin treatment. However, currently only one clinical trial assessing the effect of OCT1 genetic variants on metformin response in T2DM patients (Table 30.5) is registered on the ClinicalTrials.gov website (www.clinicaltrials.gov/).

Results from prospective, randomized clinical trials on the association of OCT1 gene polymorphisms with metformin response will enable the clinical application of metformin pharmacogenomics in routine clinical practice.

30.5.1.2 OCT2: SLC22A2 Gene Polymorphisms and Metformin Response

The *SLC22A2* gene encodes for OCT2 and is located on chromosome 6q25.3; it consists of 11 exons spanning 42 kb. The human *SLC22A2* gene is highly polymorphic, and numerous polymorphisms have been described in various populations (www.ncbi.nlm.nih.gov/SNP/snp_ref.cgi?locusId=6582). The most common *OCT2* polymorphisms, their MAF, and their effect on transporter activity are presented in Table 30.1.

In several studies, OCT2 gene polymorphisms were analyzed in association with metformin response together with OCT1; however, no significant results [19,21,23,24] and little contribution to the clinical efficacy of metformin [15] were derived. Nevertheless, evidence on the association of OCT2 gene polymorphisms with metformin pharmacokinetics first appeared in studies on healthy volunteers, suggesting that a decrease in transport function associated with OCT2 variants results in reduced renal clearance of metformin and consequently leads to increased plasma concentrations. More specifically, in healthy participants, Song et al. showed that OCT2 *596C>T*, *602C>T*, and *808G>T* variants were associated with increased metformin AUC and decreased renal clearance [25], whereas Wang et al., demonstrated that the *808G>T* OCT2 gene polymorphism was associated with metformin renal tubular clearance [26]. In another study, controversial results were obtained, since the same variant (OCT2 *808G>T*) was correlated with higher mean renal clearance compared with individuals with the reference genotype (*808GG*) [27].

Four ongoing clinical trials assessing the effect of OCT2 gene polymorphisms on metformin response are registered on the ClinicalTrials.gov website (listed in Table 30.5). Clinical trial NCT01237522, assessing the effect of the OCT2 *A270S* polymorphism on metformin renal clearance, has been completed; however, the results have not yet been published. The effect of OCT2 genetic variants on metformin pharmacokinetics and response is currently being investigated in three clinical trials (NCT00780715, NCT01681680, and NCT01341795). As in the case of OCT1, it is expected that the results of ongoing clinical trials will shed light on metformin's pharmacogenomics.

30.5.1.3 MATE1: SLC47A1 Gene Polymorphisms and Metformin Response

The human MATE1 gene (*SLC47A1*) is located on chromosome 17p11.2 and encodes a protein of 570 amino acids [28]. MATE1 is mainly expressed in the liver and kidney and has an important role in the renal excretion of metformin. More than 70 polymorphisms have been identified in *SLC47A1* (www.ncbi.nlm.nih.gov/SNP/snp_ref.cgi?locusId=55244); however, only a few of them appear to have an association with metformin clearance and response (Table 30.1).

Results from studies with metformin-treated T2DM patients show a consistent association of two highly linked MATE1 variants (rs2289669*G>A* and rs8065082*C>T*) with HbA1c reduction and metformin response. In a study of 116 metformin-treated T2DM patients, each MATE1 rs2289669 *A* allele was associated with 0.30% increased reduction of HbA1c [29]. The same research group looked at whether there is an interaction between the OCT1 rs622342 *A>C* and the MATE1 rs2289669 *G>A* polymorphisms with respect to HbA1c reduction in 98 metformin users who were participants in the Rotterdam Study [30]. In accordance with previous results, each OCT1 rs622342 *A* allele and MATE1 rs2289669 *A* allele was associated with greater decrease in HbA1c levels. Especially in *AA* homozygotes for both genes, the average decrease in HbA1c was the largest (−0.91%), whereas in OCT1 rs622342 *CC* and MATE1 rs2289669 *GG* participants, HbA1c levels increased by 0.48% (Table 30.3) [30].

In another large study, involving 990 metformin-treated individuals who participated in the Diabetes Prevention Program (DPP), the MATE1 rs8065082 gene polymorphism, which is in tight LD with MATE1 rs2289669, was associated with suboptimal responses to metformin treatment [31]. More recently, the MATE1 rs2289669 *A* allele was associated with higher HbA1c reduction in 148 metformin-treated T2DM patients [24]. However, the association of MATE1 gene polymorphisms with metformin response was not replicated in all studies [21]. The association of *MATE1* genetic variations with metformin response is the subject of clinical trial NCT01681680 (Table 30.5), which will assess the effect of OCT2, MATE1, and MATE2-K genetic variations with metformin pharmacokinetics and metformin glucose-lowering response in healthy Caucasian and Asian volunteers.

30.5.1.4 Ataxia Telangiectasia Mutated: Gene Polymorphisms and Metformin Response

Ataxia telangiectasia mutated (*ATM*) is an important tumor suppressor gene with key roles in DNA repair and cell cycle control. *ATM* gene SNP rs11212617*C>A* was identified in a large GWAS as a significant mediator of metformin response. This GWAS, jointly conducted by the Genetics of Diabetes Audit and Research Tayside (GoDARTs) study group and the UK Prospective Diabetes Study (UKPDS) pharmacogenetics study group, included 1024 Scottish T2DM individuals (Table 30.4). Results were replicated in two cohorts that included 1783 Scottish individuals and 113 individuals from the UKPDS. In the combined meta-analysis of all patients, the *ATM* SNP rs11212617 *C* allele was associated with metformin treatment success, both in terms of achieving Hb1A1c values $\leq 7\%$ and in terms of a lowering of HbA1c when analyzed as a quantitative trait [32]. ATM is estimated to alter response to metformin through an upstream effect of AMP-activated protein kinase [32]. The UK study group attempted to replicate their original finding in three independent cohorts using a phenotypic definition identical to that used in the original discovery [33].

The UKPDS researchers included metformin-treated T2DM patients from Diabetes Care System West-Friesland (DCS), from the Rotterdam Study from the Netherlands, and from the multicenter UK Collaborative Atorvastatin Diabetes Study (CARDS) trial. Data were analyzed in the individual cohorts, separately, combined in a meta-analysis, and combined in an additional meta-analysis that included the GoDARTS and UKPDS stage 2 replication cohorts. According to UKPDS results, the original association of the *ATM* rs112112617 *C* allele with metformin response was replicated in the DCS cohort; also, a similar but nonsignificant trend was present in the Rotterdam Study; no association was found in the CARDS cohort [33]. In the meta-analysis of the three cohorts, *ATM* rs11212617 *C* was associated with increased metformin response in the entire group of patients (OR 1.24; $p=0.016$), as well as in T2DM patients starting metformin monotherapy (OR 1.38; $p=0.015$). In the combined meta-analysis of all five replication cohorts, the *C* allele was associated with an HbA1c decrease of -0.050 per allele copy. When HbA1c was analyzed as a quantitative trait, no significant effect of the *ATM* gene SNP on metformin response was observed.

In a more recent study of 988 metformin-treated T2DM patient participants in the DPP, this association was not replicated because the rs11212617 *C* allele conferred no detectable advantage on metformin recipients [34]. However, among other reasons that may explain the controversy in the results, metformin response is defined differently in a prediabetic cohort such as the DPP; therefore, the association of the *ATM* rs11212617 gene polymorphism with metformin response merits additional follow-up in independent cohorts.

The association of *ATM* gene polymorphisms with metformin response is a quite promising pharmacogenetic link to personalized metformin therapy. Currently, no clinical trials are registered at ClinicalTrials.gov on *ATM* genetic variations and metformin response; however, it is anticipated that such trials will be initiated soon.

30.5.2 Sulfonylureas

Sulfonylurea oral hypoglycemic agents are the oldest class of oral diabetes medication and have been a mainstay of T2DM pharmacotherapy for over 50 years. They are relatively cost-effective and well tolerated. Sulfonylureas—of both the first (tolbutamide, tolazamide, chlorpropamide, and acetohexamide) and the second generation (glibenclamide or glyburide, glipizide, gliclazide, and glimepiride)—act by blocking ATP-dependent potassium (K_{ATP}) channels in pancreatic B cells thereby mimicking the effect of glucose on the production of a triggering signal for insulin secretion in a glucose-independent manner. Sulfonylureas are among the most potent oral antidiabetic medications, having an HbA1c-lowering efficacy of 1–2%. Their major adverse effects are hypoglycemia and weight gain at initiation of therapy [11]. According to the ADA, sulfonylurea treatment is included in well-validated core therapies for T2DM to achieve and maintain HbA1c levels lower than 7% [11]; however, American Association of Clinical Endocrinologists (AACE)/American College of Endocrinology (ACE) algorithms have assigned a lower priority to sulfonylureas because they increase the risk of hypoglycemia [35].

Significant interindividual variability exists among patients who are on sulfonylurea treatment in terms of HbA1c decrease, secondary failure of therapy, and incidence of hypoglycemic events. It is widely accepted that response to sulfonylureas is genetically determined by genetic polymorphisms affecting their pharmacokinetics and pharmacodynamics, as well as by polymorphisms in genes that are associated with T2DM incidence.

30.5.2.1 Sulfonylurea Pharmacokinetics

Cytochrome P450 2C9 (CYP2C9)

All sulfonylureas are extensively metabolized in the liver, primarily by the cytochrome P450 2C9 isoenzyme (CYP2C9) [36]. Polymorphisms in the *CYP2C9* gene seriously affect the enzymatic activity of encoded CYP2C9. Based on phenotype, the population can be divided into extensive, intermediate, and poor metabolizers (EMs, IMs, and PMs, respectively). To date, more than 50 different allelic variants have been identified in the *CYP2C9* gene (www.cypalleles.ki.se/cyp2c9.htm). Among them, the most common are **2* (rs1799853, *430C>T*, Arg144Cys) and **3* (rs1057910, *1075A>C*, Ile359Leu) (Table 30.1), which allow for prediction of more than 85% of PMs in most populations, including Caucasians [36].

Altered pharmacokinetics of sulfonylureas due to polymorphisms in the *CYP2C9* gene may partially explain the differences in patient dose requirements and frequency of adverse reactions. The effect of these polymorphisms on sulfonylurea pharmacokinetics has been investigated in several studies in healthy volunteers (Table 30.2). In principle, the *CYP2C9 *2* and **3* alleles are associated with impaired metabolism and reduced oral clearance of sulfonylureas. Plasma concentration of glyburide and glimepiride has been shown to be higher in *CYP2C9*3* allele carriers (280% and 267%, respectively) than in *CYP2C9*1/*1* carriers [37]. Similarly, *CYP2C9*3/*3* individuals had a 6.5-fold lower oral clearance of tolbutamide and less than 50% lower oral clearance of glyburide compared with *CYP2C9*1/*1* individuals [38,39].

In a study of 15 healthy volunteers (5 per genotype group *CYP2C9*1/*1*, **1/*2*, and **1/*3*) receiving a single oral dose of 500 mg tolbutamide, both plasma levels and oral clearance were elevated in **1/*2* and **1/*3* individuals compared to **1/*1* individuals [40]. More recently, the effect of *CYP2C* polymorphisms on the pharmacokinetics of glipizide was assessed (Table 30.5) in a clinical trial (NCT00806013). Eighteen healthy Chinese subjects were divided into three groups (*CYP2C9*1/*1* and CYP2C19 EMs; *CYP2C9*1/*1* and CYP2C19 PMs; and *CYP2C9*1/*3* and CYP2C19 EMs) and were administered a single dose of glipizide (5 mg). Drug plasma concentrations were determined during a 36-h period. The results showed that *CYP2C9*1/*3* individuals had higher glipizide AUC (by 95.5%) and lower glipizide clearance (−51.1%) compared with *CYP2C9*1/*1* individuals [41].

Subsequent results from studies on T2DM patients treated with sulfonylureas suggest that there is a straight linear effect of *CYP2C9* gene polymorphisms on sulfonylurea pharmacokinetics and therapeutic response, estimated by fasting serum glucose and HbA1c decrease, dose requirement, or incidence of hypoglycemic events. Specifically, among T2DM patients treated with tolbutamide, *CYP2C9*3* carriers had a greater decrease in fasting serum glucose levels after the start of therapy and required lower doses compared with *CYP2C9*1/*1* individuals [42]. In terms of achieving HbA1c goals, results derived from a Go-DARTs study of 1073 sulfonylurea-treated T2DM patients showed that carriers of two each of the *CYP2C9*2* and/or *CYP2C9*3* alleles were 3.4 times more likely to achieve HbA1c levels below 7%, compared with *CYP2C9*1/*1* patients [43]. Furthermore, these carriers also achieved glycemic goals more rapidly and persistently compared with *CYP2C9*1/*1* patients.

In a study on sulfonylurea-treated T2DM patients, *CYP2C9*3* carriers trended toward a lower stable glimepiride dose compared with *CYP2C9*1/*1* patients; however, this difference was not statistically significant [44]. In another, more recent study of 80 T2DM patients treated with glibenclamide, it was shown that those with a *CYP2C9*1/*2* or **1/*3* genotype were more likely to have controlled T2DM (fasting plasma glucose value < 110 mg/dl) compared with *CYP2C9*1/*1* patients [45]. Also, carriers of *CYP2C9*2* and **3* had relatively higher plasma levels of glibenclamide compared with *CYP2C9*1/*1* patients; however this difference was not statistically significant.

Dose titration of sulfonylureas in carriers of *CYP2C9* defective alleles can serve as an important tool for the application of pharmacogenomics and should also be taken into account in studies assessing the effect of *CYP2C9* genotypes on glycemic response. Taken together, the results of pharmacogenomic studies on the pharmacokinetics of sulfonylureas suggest that the presence of defective *CYP2C9* alleles is correlated with increased sulfonylurea plasma levels and may lead to an improved therapeutic effect of these drugs for *CYP2C9* defective allele carriers.

Hypoglycemia is the major and most common sulfonylurea adverse event, and can have a profound impact on T2DM patients' quality of life of [46]. Among other factors, increased plasma concentrations of sulfonylureas, decreased clearance, and prolonged action due to diminished drug metabolism in *CYP2C9* defective allele carriers might also be associated with hypoglycemia. The results of several studies so far seem to support this hypothesis. Specifically, it has been shown that carriers of *CYP2C9*3* were at higher risk of experiencing either severe (OR 5.2) [47] or mild hypoglycemic events (OR 1.7) [48,49].

In a recent study, Holstein et al. prospectively examined *CYP2C9*2* and **3* in association with severe hypoglycemia [50]. They did not confirm their initial results on the association of CYP2C9 PMs with hypoglycemia; however, when they calculated mean doses among different *CYP2C9* genotypes between hypoglycemic cases and nonhypoglycemic controls, they found that patients in the nonhypoglycemic control group were on significantly lower mean sulfonylurea dose compared with those in the hypoglycemic case group. The authors concluded that their results, despite the lack of association, point to the benefit of individualized and pharmacogenetic-based dosing of sulfonylureas to avoid incidence of hypoglycemic events, because the absence of association of *CYP2C9* polymorphisms with severe hypoglycemia in this study could be due to dose titration (lower dose) of sulfonylureas in nonhypoglycemic controls [50].

As mentioned earlier, AACE/ACE algorithms have moved sulfonylureas to lower priority because of their increased risk of hypoglycemia, despite their unquestionable therapeutic efficacy [35]. Therefore, pharmacogenetic markers such as *CYP2C9* could serve as useful tools for identifying T2DM patients who are at increased risk of sulfonylurea-induced hypoglycemia, and could increase the overall therapeutic value of these drugs.

Currently two clinical trials on the association of *CYP2C9* gene polymorphisms with sulfonylurea pharmacokinetics and response are registered at ClinicalTrials.gov (see Table 30.5). The clinical trial NCT01242137 will assess the dose requirements of T2DM patients treated with sulfonylurea (glibenclamide) based on their *CYP2C9* genotype. In this trial, investigators will test the hypothesis that patients with less active alleles of the CYP2C9 enzyme have lower dose requirements for glycemic control when compared to patients homozygous for wild-type alleles. Another important factor that potentially affects response to sulfonylureas is inhibition of the CYP2C9 enzyme due to concomitant administration of other drugs. Drug–gene interactions are the subject of clinical trial NCT01061112, in which investigators will assess the extent of CYP2C9 inhibition in tolbutamide-treated individuals with the *CYP2C9*1/*1*, *CYP2C9*1/*3*, and *CYP2C9*3/*3* genotypes by fluconazole.

30.5.2.2 Pharmacodynamics: Sulfonylurea 1 Receptor—Inward Rectifier K^+ Channel Kir6.2

The K_{ATP} channel in pancreatic B cells is the pharmacologic target of sulfonylureas. It is made up of four subunits of the sulfonylurea 1 receptor (SUR1), encoded by the *ABCC8* gene, and four subunits of the inward rectifier K^+ channel Kir6.2, encoded by *KCNJ11*. SUR1 is believed to be the regulatory subunit of the K_{ATP} channel, whereas Kir6.2 is the inwardly rectifying ion channel forming the pore and confers ATP sensitivity to the channel complex [51]. Gene polymorphisms of both components of the K_{ATP} channel have been associated with response to sulfonylurea therapy (Table 30.3).

The most important polymorphisms in SUR1 and Kir6.2 are the *ABCC8 S1369A* (rs757110) and *KCNJ11 E23K* (rs5219) variants, respectively. These polymorphisms are in almost complete LD and are inherited in linkage in more than 99% of haplotypes [52]. *KCNJ11 23K* affects *in vitro* K_{ATP} channel properties, inducing spontaneous hyperactivity of pancreatic B cells via increased threshold ATP concentration for insulin release. However, in the presence of sulfonylureas, *23K* K_{ATP} channels have increased sensitivity compared to *23E* K_{ATP} channels. Nevertheless, molecular electrophysiological evidence shows that *ABCC8 S1369A*, rather than *KCNJ11 E23K*, is the functional variant in the *ABCC8-KCNJ11* region [53]. More recent data suggest that K_{ATP} channel sensitivity is likely dependent on administered sulfonylurea [54]. K_{ATP} channels containing the *K23/A1369* haplotype are significantly less sensitive to inhibition by tolbutamide, chlorpropamide, and glimepiride, whereas K_{ATP} channels containing the *K23/A1369* haplotype are significantly more sensitive to inhibition by gliclazide [54].

Several studies have shown the association of *ABCC8-KCNJ11* variants with sulfonylurea response. In gliclazide-treated T2DM patients, it was shown that carriage of the variant alleles *ABCC8 1369A* and *KCNJ11 23K* leads to prolonged closure of K_{ATP} channel and insulin secretion, and that carriers of these alleles are more sensitive to sulfonylureas and have more efficient blood glucose and a greater decrease in HbA1c [53]. The results of a study of 115 T2DM patients treated with gliclazide showed that carriers of *ABCC8 1369A* exhibited greater significant HbA1c decrease after treatment compared to noncarriers (−1.6% versus −0.76%; $p = 0.044$) [55].

The association of the *ABCC8 1369A* allele with favorable response to sulfonylureas was replicated in a pooled analysis of two independent cohorts of gliclazide-treated T2DM patients [56]. In this study, patients with *ABCC8 1369SA* and *1369AA* genotypes, compared to *ABCC8 1369SS* patients, had greater decreases in fasting plasma glucose (−2.8% and −7.7%, respectively), greater decreases in 2-h glucose after oral glucose tolerance testing (−10.8% and −11.9%, respectively), and a greater chance of responding to gliclazide therapy compared to *ABCC8 1369SS* patients (OR 1.4 and 2.2, respectively) [56]. A similar effect of *KCNJ11 23K* (linked to *ABCC8 1369S*) on sulfonylurea response was reported [57]. In 101 T2DM patients who failed to achieve glycemic goals while on metformin monotherapy and were administered sulfonylureas as an add-on treatment, carriers of the *KCNJ11 23K* allele had greater decreases in HbA1c compared with *EE* individuals after six months of treatment. Interestingly, in a recent study of 100 Egyptian T2DM patients, the *KCNJ11 23K* allele was associated not with a favorable response, but with secondary sulfonylurea failure, defined as HbA1c ≥ 8%, despite sulfonylurea therapy [58].

ABCC8 1369A and *KCNJ11 23K* alleles have been studied also in relation to incidence of severe or mild hypoglycemia induced by sulfonylureas. In three studies these variant alleles were not associated with this major adverse effect of sulfonylureas [59–61].

30.5.2.3 Disease-Associated Gene Polymorphisms

As has already been discussed, the *TCF7L2* gene SNP rs7903146 (*C>T*) is the strongest predictor of T2DM incidence in populations of different ancestry. Carriers of the *TCF7L2* rs7903146 *T* allele have decreased B cell function compared to noncarriers. Along with this association, research has focused on the pharmacogenomic impact of this genomic marker to sulfonylurea therapeutic response. Results of studies conducted so far support the hypothesis that T2DM patients with decreased B cell function due to *TCF7L2* rs7903146 *T* carriage are at increased risk of sulfonylurea treatment failure (Table 30.4). In 901 sulfonylurea-treated T2DM participants of the Go-DARTs study, 57% of the rs7903146*TT* homozygotes failed to reach the glycemic target of HbA1c <7% compared to 40% of wild-type individuals [62]. Similar results were reported in two recent studies. In 87 T2DM patients who were on sulfonylurea + metformin therapy for six months, carriers of rs7903146 *T* (genotypes *CT* + *TT*) saw significantly smaller reduction in HbA1c and fasting plasma glucose in response to six months of sulfonylurea treatment [63], while in 189 T2DM patients who were treated with sulfonylureas, the *TCF7L2* genotype was the only predictor of sulfonylurea treatment failure (OR 1.57) [64].

In an ongoing clinical trial (NCT 00738088), the underlying genetic cause of differential response to sulfonylureas (gliclazide) is being assessed by identifying participants with a certain genetic predisposition to diabetes due to changes in the *TCF7L2* gene, then looking at how well they respond to sulfonylurea medication (Table 30.5).

30.5.3 Nonsulfonylurea Insulin Secretagogues (Glinides)

Nonsulfonylurea insulin secretagogues (glinides) have properties similar to the pharmacokinetic and pharmacodynamic properties of sulfonylureas; however, they bind to a different site in the sulfonylurea receptor to promote insulin secretion. Those currently available are repaglinide and nateglinide. The typical reductions in HbA1c levels they cause range from 0.5% to 1.5% [11].

30.5.3.1 Pharmacokinetics

Cytochrome P450 2C8 (CYP2C8) and 2C9 (CYP2C9)

The P450 2C8 (CYP2C8) enzyme is the primary metabolizer of repaglinide, whereas the CYP3A4 enzyme has only a minor contribution to its metabolism [36]. Polymorphisms in the *CYP2C8* gene affect the enzymatic activity of the encoded CYP2C8 protein and are associated with altered repaglinide pharmacokinetics. To date, in the Human Cytochrome P450 (CYP) Allele Nomenclature Database, 14 allelic variants have been identified in *CYP2C8* (www.cypalleles.ki.se/cyp2c8.htm). Among these, *CYP2C8*3* has been extensively studied in association with repaglinide pharmacokinetics and response (Table 30.2). Nateglinide is structurally similar to repaglinide; however, it is primarily metabolized by CYP2C9 enzyme [36]. Like sulfonylureas, the *CYP2C9*2* and **3* variant alleles are expected to affect nateglinide pharmacokinetics (Table 30.2).

In pharmacogenetic studies assessing the effect of gene polymorphisms on repaglinide pharmacokinetics, *CYP2C8*1/*3* individuals had lower mean AUC of repaglinide (−45%) and lower peak plasma concentration (−39%) compared with *CYP2C8*1/*1* individuals [65]. The research group involved in these studies replicated this association in a another study of 56 healthy volunteers [66]. In the case of nateglinide, *CYP2C9*3* allele carriers had significantly reduced oral nateglinide clearance; *CYP2C9*2/*3* individuals had median total clearances of 5.8 L/h; *CYP2C9*3/*3* individuals, 4.1 L/h; and *CYP2C9*1/*1* individuals, 7.9 L/h [67].

Similar results were obtained in a randomized, open-label, two-period crossover study of 18 healthy volunteers administered a single 120 mg nateglinide dose alone or in combination with sulfinpyrazone, a potent CYP2C9 inhibitor [68]. Co-administration of nateglinide with sulfinpyrazone resulted in higher mean nateglinide AUC (+28%) [68]. More recently, in a study of 35 Chinese male healthy volunteers administered a single oral dose of 120 mg nateglinide, the *CYP2C9*3* allele was associated with nateglinide AUC and clearance; however, no significant association with changes in the blood glucose-lowering effect of nateglinide was found [69].

30.5.3.2 Organic Anion-Transporting Polypeptide 1B1 (OATP1B1, SLCO1B1)

The disposition of both repaglinide and nateglinide in the human body is highly dependent on the polymorphic organic anion-transporting polypeptide 1B1 (OATP1B1), encoded by the *SLCO1B1* gene [70]. More than 40 nonsynonymous variants have been identified in this gene. The two most studied are rs4149056*T>C* (*521T>C*, Val174Ala) and rs2306283*A>G* (*388A>G*, Asn130Asp) (Table 30.1). The combination of these two functional SNPs forms four distinct haplotypes: *SLCO1B1*1A* (*388A-521T*), which is the reference haplotype, **1B* (*388G-521T*), **5* (*388A-521C*), and **15* (*388G-521C*) [71]. *In vitro* studies have shown that the *SLCO1B1*5* and *SLCO1B1*15* haplotypes (carriers of the *521C* allele) are associated with reduced OATP1B1 transport activity in different cell lines, suggesting that the effect of *521T>C* dominates that of *388A>G*.

One study investigated the effect of *SLCO1B1* gene polymorphisms for association with response to both repaglinide and nateglinide (Table 30.3). In the case of repaglinide, after analyzing the effect of *CYP2C8*3* on drug pharmacokinetics [65], investigators also assessed the effect of *SLCO1B1 −11187G>A*, *521T>C*, and *ABCB1 2677G>T/A* on drug pharmacokinetics in 56 healthy volunteers also genotyped for *CYP2C8* [66]. In another study, they replicated the results of the association of *CYP2C8*3* with a lower mean AUC of repaglinide and additionally showed that *SLCO1B1 521CC* individuals had higher AUC than *SLCO1B1 521TC* and *521TT* individuals (107% and 188%, respectively). In the latter study, both the *SLCO1B1 521CC* genotype and the *CYP2C8*3* allele were found to be independent predictors of AUC and concentration of repaglinide [66].

In another dose-escalation repaglinide study involving 28 healthy individuals, the *SLCO1B1* genotype was significantly associated with the pharmacokinetics of repaglinide in all tested doses [72]. After ingestion of a 0.25, 0.5, 1, or 2 mg dose of repaglinide, its AUC was 82, 72, 56, or 108% larger in *SLCO1B1 521CC* individuals compared with *SLCO1B1 521TT* individuals, whereas the maximum concentration was 60−70% larger in *SLCO1B1 521CC* individuals compared with *SLCO1B1 521TT* individuals. This same study also found that the effect of the *SLCO1B1* genotype on repaglinide plasma concentration translated into a tendency toward greater lowering of blood glucose concentrations in *SLCO1B1 521CC* individuals compared with *SLCO1B1 521TT* individuals [72].

More recently, the same investigators showed that, in 32 *CYP2C8*1/*1* healthy volunteers receiving a single 0.5 mg dose of repaglinide, the *SLCO1B1 521CC* individuals had a higher AUC than *SLCO1B1 521TC* and *521TT* individuals (59% and 72%, respectively) and a higher maximum concentration (27% and 62%, respectively) [73]. Similarly, increased repaglinide concentration was translated into a tendency in *SLCO1B1 521CC* individuals toward a greater blood glucose-lowering effect [73]. The *SLCO1B1 521T>C* polymorphism attenuated repaglinide clearance in 22 healthy male Chinese individuals; however, no significant differences in this effect were observed [74]. Overall, it appears that *CYP2C8* and *SLCO1B1* polymorphisms affect repaglinide pharmacokinetics and response.

In the case of nateglinide, in a study of 17 healthy volunteers with different *SLCO1B1* genotypes (11 individuals *521TT*, 4 individuals *521TC*, and 2 individuals *521CC*) administered an oral dose of 90 mg nateglinide, both maximum concentration and AUC were shown to be higher in *SLCO1B1 521CC* individuals (76% and 108%, respectively) and in *SLCO1B1 521TC* individuals (83% and 82%, respectively), compared with *SLCO1B1 521TT* individuals [75]. However, this finding was not replicated in another study [73]. In a more recent study involving 35 Chinese male healthy volunteers administered a single oral dose of 120 mg nateglinide, the association of not only *CYP2C9*3,* but also of *SLCO1B1 521 T>C* with AUC and clearance was demonstrated [69].

30.5.3.3 Pharmacodynamics: Sulfonylurea 1 Receptor—Inward Rectifier K$^+$ Channel Kir6.2 (KCNJ11)

Because both nonsulfonylurea insulin secretagogues, repaglinide and nateglinide, stimulate insulin secretion through bonding to the sulfonylurea receptor (SUR1, *ABCC8*) in B pancreatic cells, *ABCC8 S1370A* and inward rectifier K$^+$ channel Kir6.2 (*KCNJ11*) *E23K* polymorphisms have become attractive candidates that may affect response to these drugs. In a study of 100 Chinese patients newly diagnosed with T2DM and treated with repaglinide for 24 weeks, it was found that *KCNJ11 23K* is associated with better therapeutic effect (greater HbA1c decrease in *KCNJ11 23EK* and *23KK* individuals); the *ABCC8* exon/intron *16-3CC* homozygous genotype was associated with better insulin sensitivity [76]. Of 40 T2DM patients randomly selected to undergo an 8-week repaglinide treatment regimen, carriers of the *23E* allele had higher HbA1c levels compared to those of *23KK* patients [77]. Results on the association of the *ABCC8/KCNJ11* gene polymorphisms with nateglinide response are lacking. One possible explanation is that the inhibitory profile of the drug in K_{ATP} channels is similar irrespective of the variant haplotype [54].

Although genetic variants affecting repaglinide and nateglinide pharmacokinetics and pharmacodynamics are associated with drug response, we have not been able to find any ongoing or completed clinical trial assessing the impact of genetic polymorphism(s) on the therapeutic response of diabetic patients to these drugs.

30.5.4 Thiazolidinediones

Thiazolidinediones (or glitazones) are peroxisome-proliferator-activated receptor γ (PPARγ) agonists. PPARγ regulates fatty acid storage and glucose metabolism through modulation of various genes. The genes activated by it stimulate lipid uptake and adipogenesis by fat cells. Thiazolidinediones are the strongest ligands of PPARγ and are insulin sensitizers because they increase the sensitivity of muscles, fat, and liver to exogenous insulin. They lower HbA1c by 0.5−1.4% and appear to have a more durable effect on glycemic control compared to other oral antidiabetic drugs [11]. Originally, the clinically used thiazolidinediones comprised three drugs—namely, pioglitazone, rosiglitazone, and troglitazone. However, troglitazone was withdrawn from the market over a decade ago because of an idiosyncratic reaction leading to drug-induced hepatitis; more recently, rosiglitazone and its combination product with metformin were also officially withdrawn both by FDA and the European Medicines Agency (EMA) because of an apparent increase in cardiovascular risk. Pioglitazone is thus the only thiazolidinedione currently available in the market. However, pharmacogenomic studies have been conducted for all three thiazolidinediones and are included and discussed in the following sections (see also Tables 30.2–30.4, which summarize the pharmacogenomic studies on thiazolidinedione disposition and therapeutic response).

30.5.4.1 Pharmacokinetics: Cytochrome P450 2C8 (CYP2C8)

Thiazolidinediones are extensively metabolized by CYP450 enzymes. Pioglitazone is mainly metabolized by CYP2C8, whereas CYP3A4/5 and CYP1A1 contribute to a lesser extent [78]. Prior to pioglitazone's withdrawal, there had been only one study on the association of *CYP2C8* gene polymorphisms with pioglitazone pharmacokinetics. In this study, 16 healthy volunteers received the CYP2C8 strong inhibitor trimethoprim [79]. All received a single oral dose of 15 mg of pioglitazone while being treated either with placebo or with 160 mg of trimethoprim twice daily. Carriage of *CYP2C8*3* in the placebo arm was shown to lead to lower pioglitazone mean plasma concentrations, shorter pioglitazone half-life (higher metabolic ratio), and lower AUC. The AUC was 34% lower in *CYP2C8*3/*3* individuals and 26% lower in *CYP2C8*1/*3* individuals, compared to *CYP2C8*1/*1* individuals [79]. The association of trimethoprim with increased plasma concentrations of pioglitazone was also shown, although the *CYP2C8* genotype was not associated with it [79]. In 2013, three studies dealing with the pioglitazone–*CYP2C8* association were published. In 31 healthy volunteers who received a single 15 mg dose of pioglitazone followed by a 48-h sampling period, it was shown that *CYP2C8*3* had a significant effect on central compartment clearance [80].

In another two-armed study, 30 healthy Caucasian volunteers received either a single 15 mg dose of pioglitazone or 600 mg of the potent CYP2C8 inhibitor gemfibrozil twice daily for 4 days; they also received a single 15 mg dose of pioglitazone on the morning of day 3. It was shown that, when pioglitazone was administered alone, the mean AUC in *CYP2C8*3* carriers was 29.7% lower compared with that in *CYP2C8*1/*1* carriers [81]. When pioglitazone was coadministered with gemfibrozil, *CYP2C8*3* carriers had a 5.2-fold mean increase in AUC compared with a 3.3-fold mean AUC increase in *CYP2C8*1/*1* carriers. A similar effect was shown for the *CYP2C8*2* allele. A study of 17 healthy African-American volunteers (9 genotyped *CYP2C8*1/*1*, 7 genotyped *CYP2C8*1/*2*, and 1 genotyped *CYP2C8*2/*2*) demonstrated that the keto-pioglitazone metabolite–AUC ratio was significantly lower in *CYP2C8*2* carriers than in *CYP2C8*1/*1* carriers [82].

Rosiglitazone is mainly metabolized by CYP2C8, with a minor contribution from CYP2C9 [83]. In a seminal randomized, crossover study investigating the effect of trimethoprim, a selective CYP2C8 inhibitor, on the CYP2C8-mediated metabolism of rosiglitazone, eight healthy individuals received a single 8 mg dose of the drug in the presence or absence of trimethoprim [84]. The study showed that trimethoprim inhibited rosiglitazone metabolism both *in vitro* and *in vivo*. However, in contrast with the previously described pioglitazone, the *CYP2C8* genotype (**2* or **3* allele) did not appear to affect rosiglitazone metabolism, although there was a trend toward a higher AUC in *CYP2C8*1/*1* carriers compared with carriers of *CYP2C8*2* or **3* [84]. Similarly, in a two-phase, open-label, crossover trial involving 23 healthy volunteers, aimed at determining the effect of *CYP2C8* and of fluvoxamine (a CYP2C8 inhibitor) on the pharmacokinetics of rosiglitazone, even though fluvoxamine caused a significant increase in AUC, no effect of *CYP2C8* in rosiglitazone metabolism was found [85].

In a larger clinical study of 31 healthy volunteers genotyped for *CYP2C8* and receiving a single dose of rosiglitazone (8 mg), carriers of *CYP2C8*3* showed higher *in vivo* metabolic capacity compared to *CYP2C8*1/*1* carriers. The study population consisted of 14 *CYP2C8*1/*1* individuals, 13 *CYP2C8*1/*3* individuals, and 4 *CYP2C8*3/*3* individuals. Researchers found that mean total rosiglitazone and desmethylrosiglitazone clearance was higher in *CYP2C8*3* carriers (*CYP2C8*1/*3* and *CYP2C8*3/*3*), whereas, accordingly, rosiglitazone elimination half-lives were lower in *CYP2C8*1/*3* and *CYP2C8*3/*3*, compared with *CYP2C8*1/*1* individuals [86]. However, no differences were observed between the glucose-lowering effect of rosiglitazone and the *CYP2C8* genotype [86]. In a subsequent study of 26 healthy Caucasian volunteers, subjects with the *CYP2C8*1/*3* genotype had significantly lower rosiglitazone AUC and significantly higher rosiglitazone oral clearance compared with *CYP2C8*1/*1* individuals [87].

In a more recent study of 187 rosiglitazone-treated patient participants in the South Danish Diabetes Study, carriers of the *CYP2C8*3* allele had lower plasma levels of rosiglitazone and reduced therapeutic response [88]. In the same study, *CYP2C8*3* carriers also had a lower risk of developing edema during treatment with rosiglitazone. Apart from the *CYP2C8*2* and **3* alleles, a novel allele, *CYP2C8*11*, was also found to be associated with rosiglitazone plasma concentration in 9 healthy volunteers of Asian origin treated with a single 4 mg dose of rosiglitazone [89].

30.5.4.2 Organic Anion-Transporting Polypeptide 1B1 (OATP1B1, SLCO1B1)

Pioglitazone and rosiglitazone are possible substrates of organic anion-transporting polypeptide 1B1, or OATP1B1 [90]. In a study of 32 healthy volunteers receiving a single 15 mg dose of pioglitazone, lack of association between the *SLCO1B1 521T>C* polymorphism and pioglitazone pharmacokinetics was the main finding [91]. In the same study, it was shown that, similarly to pioglitazone, no association was found between *SLCO1B1 521T>C* and rosiglitazone pharmacokinetics volunteers receiving a single 4 mg dose of rosiglitazone [91]. This is in agreement with another study showing a lack of association between *SLCO1B1 521T>C*, *−11187G>A*, *−10499A>C*, and *388A>G* and rosiglitazone pharmacokinetics in 26 healthy Caucasian volunteers with known *CYP2C8* genotype [87].

30.5.4.3 Pharmacodynamics: Peroxisome-Proliferator-Activated Receptor γ

Since thiazolidinediones are ligands of PPARγ, *PPARγ* gene polymorphisms are attractive candidates for uncovering novel pharmacogenetic markers related to interindividual variability in glitazone drug response. *PPARγ* is a transcription factor that, upon activation, heterodimerizes with the retinoid X receptor and binds to specific PPAR-responsive elements of DNA to promote transcription of numerous target genes [92]. A number of genetic variants in the *PPARγ* gene have been identified; the most promising association between *PPARγ* gene polymorphisms and thiazolidinediones response is with *PPARγ Pro12Ala*. The *12Ale* allele leads to reduced binding to the *PPARγ*-responsive DNA elements and indicates reduced transcriptional activity of *PPARγ* [92].

In the case of pioglitazone, Ramirez-Salazar et al. assessed the influence of *PPARγ Pro12Ala* on metabolic and hormonal response to pioglitazone treatment in 83 obese postmenopausal women treated with 15 mg/day of pioglitazone for 15 days [93]. The researchers were able to show that the *PPARγ 12ProAla* genotype is associated with a greater decrease in serum glucose levels compared with the *12ProPro* genotype (−15 mg/dL versus −7 mg/dL, p = 0.003). Therefore, it was concluded that obese women carrying the *12Ala* allele may benefit more from pioglitazone treatment [93].

The beneficial effect of the *PPARγ 12Ala* allele was also shown in a subsequent study of 250 T2DM Chinese patients treated with 30 mg of pioglitazone for 24 weeks. The *PPARγ 12Ala* allele (*12ProAla* and *12AlaAla* genotypes) was associated with improved therapeutic response to pioglitazone [94]. Carriers of *PPARγ 12Ala* were more likely to be pioglitazone responders than noncarriers. In the same study, carriers of the *12Ala* allele had significantly greater decrease in HbA1c and fasting glucose plasma levels compared with noncarriers after 24 weeks of pioglitazone treatment [94].

In another study of 101 Iranian T2DM patients treated with pioglitazone 15 mg/day for 12 weeks, carriers of the *12Ala* variant appeared to have a better therapeutic response than *12ProPro* individuals, although the difference between groups did not reach statistical significance [95]. In a more recent study of 67 Chinese T2DM patients receiving pioglitazone 30 mg/day for 3 months, carriers of the *12Ala* allele showed significantly higher differential values of postprandial plasma glucose and serum triglyceride compared with *12ProPro* carriers [96]. However, in another study of 30 T2DM patients of Asian Indian origin receiving pioglitazone monotherapy, the *PPARγ Pro12Ala* polymorphism was not associated with glycemic target or primary pioglitazone therapy failure [97].

Only one study is available for the association of *PPARγ Pro12Ala* polymorphism with rosiglitazone response. As with pioglitazone, in a study of 198 T2DM patients treated with 4 mg/day of rosiglitazone for 12 weeks, the *12Ala* allele was associated with a greater decrease both in fasting plasma glucose levels and in HbA1c levels [98].

Before troglitazone was withdrawn, two randomized clinical trials—Troglitazone in the Prevention of Diabetes (TRIPOD) and DPP—assessed its effect on the prevention of diabetes. Participants of both trials were genotyped for *PPARγ* variants. Interestingly, the results from both cohorts revealed the *PPARγ Pro12Ala* polymorphism to be a major determinant for troglitazone therapeutic response [99,100]. Consistently, *12Ala* carriers appeared more likely to benefit from troglitazone therapy [99,100]. This finding strengthens the hypothesis that *PPARγ Pro12Ala* and other genetic variants of the *PPARγ* gene are associated with therapeutic response to thiazolidinediones, and thus might be useful genetic markers for identifying individuals who can benefit from therapy with the currently available thiazolidinedione, pioglitazone; however, it cannot resolve safety concerns about troglitazone's association with hepatotoxicity, or that of rosiglitazone with cardiovascular events.

A clinical trial aiming at determining genetic predictors of response to pioglitazone (NCT01135394) is currently recruiting patients (Table 30.5). T2DM patients will receive 30 mg pioglitazone once daily for 4 weeks and 45 mg once daily for an additional 8 weeks. Among the trial's outcome measures are the identification of genes correlated to pioglitazone response and polymorphisms and haplotypes in candidate genes that influence this response (Table 30.5). Given the heavy risk profile of thiazolidinediones, the availability of pharmacogenetic markers that could be used to stratify patients and predict response to thiazolidinediones, especially pioglitazone, which is the only thiazolidinedione currently available, is essential to improve and guide antidiabetic therapeutics with this drug.

30.6 STRATIFIED ORAL ANTIDIABETIC MEDICINE: PHARMACOGENOMICS APPLICATION

According to clinical guidelines, lifestyle modifications followed by pharmacotherapy with metformin are appropriate initial treatments for most individuals diagnosed with T2DM. When glycemic goals are not achieved, addition of a further antidiabetic agent, including a sulfonylurea, a meglitinide, or pioglitazone is often the second step. The use of intensive glucose-lowering therapy needs to be tailored to individual patient needs and risks. Maintaining effective glycemic control is linked to a diminished risk of microvascular complications. Currently, the choice of antidiabetic regimen relies on demographic and clinical characteristics of T2DM patients, whereas HbA1c monitoring directs the required therapy modifications.

Several of the genetic markers described in this chapter show an association with therapeutic response and/or adverse effects of oral antidiabetic drugs, and they point toward the utility of pharmacogenomics in personalizing and optimizing oral antidiabetic therapy. The pharmacogenomics of oral antidiabetic medications has the potential to improve clinical practice in terms of choosing the most appropriate oral hypoglycemic agent at the optimal dose based on individual genetic profiles. Genotyping of a panel of gene polymorphisms associated with response to metformin, sulfonylureas, nonsulfonylurea secretagogues, and pioglitazone can lead to instant diabetes control and reduced incidence of adverse events. Use of oral antidiabetic medication pharmacogenomics at the initiation of pharmacotherapy can also help in long-term reduction of micro- and macrovascular complications and in cardiovascular risk reduction. Ultimately, a pharmacogenomic-guided treatment approach will not only increase overall efficacy and the likelihood of a patient adherence, but may also improve patient well-being and quality of life.

Currently, pharmacogenomic information is not incorporated in antidiabetic drug inserts. Two main limitations of oral antidiabetic pharmacogenomics in routine clinical practice are the lack of large prospective clinical trials showing the benefits of pharmacogenomics at therapy initiation and the availability of many different pharmacologic compounds that enable clinicians to switch among different therapies. Although achieving and maintaining glycemic goals in T2DM patients is crucial for disease control, it should be acknowledged that no initial therapy failure has the devastating results seen in other life-threatening diseases such as cancer. Physicians appear content with the current empirical approach of starting and adjusting antidiabetic therapy as necessary, using established nongenetic indicators. However, it may become increasingly difficult to continue with this approach as more evidence leads to the era of personalized medicine.

30.7 CONCLUSIONS: FUTURE PERSPECTIVES

It is anticipated that the results of ongoing clinical trials assessing the pharmacogenomic dimension of oral antidiabetic drugs, as summarized in Table 30.5, will strengthen currently available evidence on the usefulness of oral antidiabetic pharmacogenomics and help persuade physicians to start using this tool. Of course, several more trials will be necessary to consolidate any favorable findings of completed trials. The ultimate trials will be those testing algorithms that incorporate pharmacogenetic information provided by patient genotype, along with other nongenomic stratification parameters, and that produce specific dose instructions that give tangible clinical benefit to patients. These trials should lead to the incorporation of relevant pharmacogenetic information in antidiabetic drug inserts and in therapeutic guidelines of medical associations. Ultimately, to get to the clinic, the single most important step necessary, in our opinion, will be the education of clinicians in using these tools in their everyday routine practice. For that, we still have a long, uphill way to go.

Chapter 31

Genomics and Pharmacogenomics of Lipid-Lowering Therapies

Kieran F. Docherty and Sandosh Padmanabhan
BHF Glasgow Cardiovascular Research Centre, Institute of Cardiovascular and Medical Sciences, UK

Chapter Outline

31.1 Overview 715
31.2 Lipid Metabolism 716
  31.2.1 Cholesterol Synthesis 716
  31.2.2 Lipoproteins 717
  31.2.3 Exogenous Pathway 717
  31.2.4 Endogenous Pathway 718
  31.2.5 Reverse Cholesterol Transport 718
31.3 Lipids and CVD Risk, Epidemiology, and Public Health Impact 718
  31.3.1 Total Cholesterol and Low-Density Lipoprotein Cholesterol 719
  31.3.2 HDL-Cholesterol 721
31.4 Genetic Basis of Lipid Disorders and Lipid Levels 722
  31.4.1 Primary Dyslipidemias 722
  31.4.2 Common Genetic Variants and Lipid Levels 727
  31.4.3 Pharmacological Management of Lipids and Pharmacogenomics 728
  31.4.4 HDL-C 738
31.5 Conclusion and Future Directions 741
References 742

31.1 OVERVIEW

Lipids are molecules integral to the body's structure and important substrates for energy metabolism. All the principal blood lipid fractions (total cholesterol, low-density lipoprotein cholesterol (LDL-C), high-density lipoprotein cholesterol (HDL-C), and triglycerides (TG)) have both environmental and genetic determinants, with heritabilities of 40–70% [1]. The strong, independent, continuous, and graded relationship between total cholesterol levels, or low-density lipoprotein level, and the risk of coronary artery disease events has been clearly demonstrated worldwide in men and women in all age groups. A causal role for cholesterol was established from observations of individuals with the rare familial hypercholesterolemia (FH), who develop cardiovascular disease (CVD) before the age of 30 in the homozygous state, and from substantive randomized control trials of cholesterol-lowering drug (statins), which showed benefit in terms of reduced CVD and total mortality. The mechanism by which cholesterol increases cardiovascular risk is the process of atherogenesis.

The public health importance of cardiovascular disease is reflected in the Global Burden of Disease survey projections showing that over the next 20 years, the leading cause of death worldwide will be ischemic heart disease and cerebrovascular disease [2]. The mainstay of cardiovascular risk reduction strategies is lipid-lowering therapy, the overall aim of which is to reduce circulating levels of atherogenic lipids in order to slow, reverse, or ideally prevent the development of atherosclerotic plaques. However, like any other drug treatment, the magnitude of plasma lipid responses to drug therapies is subject to considerable interindividual variation. This variation may be due to the multiple genetic factors that affect the pharmacokinetics (absorption, distribution, metabolism, and excretion) or pharmacodynamics (drug targets) of lipid-lowering therapy as well as a multitude of environmental factors. Understanding the basis of

interindividual variability in drug response will enable the development of biomarkers that will tailor lipid-lowering therapy to maximize efficacy and reduce toxicity.

In this chapter, an overview of lipid metabolism and the genetic basis of dyslipidemia is provided, along with a detailed review of pharmacogenomic advances in lipid-lowering therapy.

31.2 LIPID METABOLISM

Lipids serve as an important energy substrate, building block, and signaling molecule for the human body. They constitute a group of molecules that include sterols, fatty acids, triglycerides, fat-soluble vitamins (A, D, E, and K), and phospholipids among others. Because these molecules are hydrophobic, they must be packaged into particles known as lipoproteins—macromolecular complexes that play a vital role in the absorption and transport of lipids to and from the liver and peripheral tissues.

31.2.1 Cholesterol Synthesis

Cholesterol is an integral component of cell membrane structure and serves as a precursor for bile acids, steroid hormones, and vitamin D. It can be obtained from the diet, but is also endogenously produced. Endogenous production of cholesterol takes place mainly in the liver, with the intestine, adrenal cortex, and gonads contributing to a lesser degree.

The endogenous production of cholesterol, resulting in around 1 gram of cholesterol per day, is a 37-step process with acetyl-CoA as the initial building block. Acetyl-CoA is converted to mevalonate in a three-step process, with the action of HMG-CoA reductase as the rate-limiting step. Three molecules of mevalonate are then decarboxylated to form isopentenyl pyrophosphate, three molecules of which are subsequently condensed by the action of farnesyl synthase to form the intermediary geranyl pyrophosphate and then farnesyl pyrophosphate. The condensation of two molecules of farnesyl pyrophosphate takes place in the endoplasmic reticulum and is catalyzed by squalene synthase to form squalene. The oxidation of squalane by oxidosqualene cyclase, which also occurs in the endoplasmic reticulum, forms lanosterol. Lanosterol undergoes further reactions to produce the end product of a molecule of cholesterol. This process is detailed in Figure 31.1 and was a natural target in the search for drugs to reduce plasma cholesterol concentrations.

Endogenous cholesterol production is under the direct influence of the amount of dietary cholesterol absorbed, with a higher dietary intake resulting in decreased endogenous production. Intracellular cholesterol concentration is

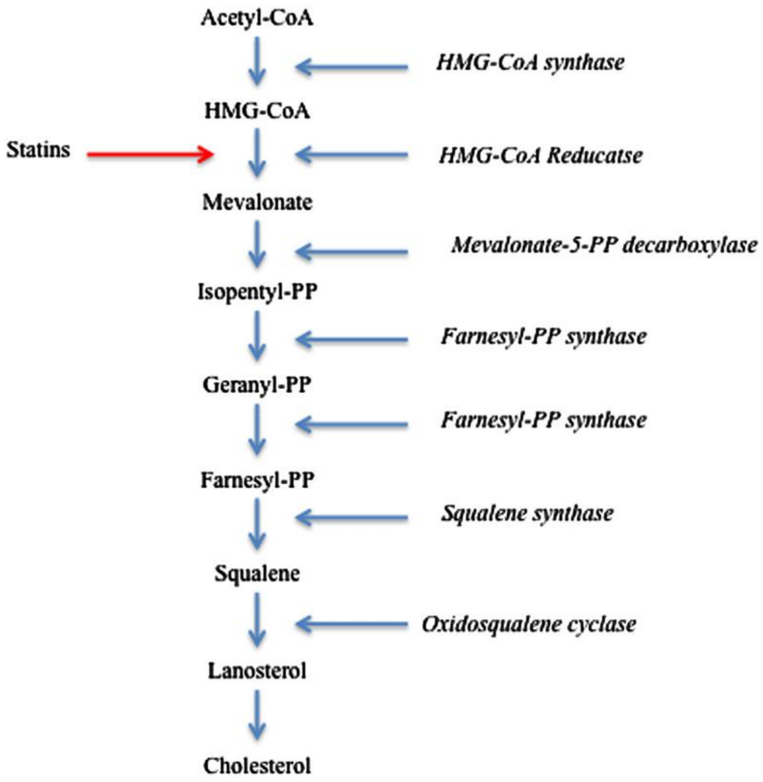

FIGURE 31.1 **Biosynthesis of cholesterol.** Statins act through inhibition of the rate-limiting step, the conversion of HMG-CoA to mevalonate by HMG-CoA reductase.

the main driver for the sterol regulatory element-binding protein (SREBP) pathway. SREBP is a transcription factor bound to the endoplasmic reticulum membrane, which when activated acts on promoter regions of the LDL receptor gene, the HMG-CoA reductase gene, and the HMG-CoA synthase gene. The end result of transcription of these target genes is to upregulate endogenous cholesterol production. Low intracellular cholesterol levels result in activation of the SREBP cleavage-activating protein (SCAP). In times of high intracellular cholesterol concentration, the SREBP-SCAP complex is reversibly bound to the membrane, along with a membrane protein, INSIG1. A decrease in intracellular cholesterol concentration allows dissociation of INSIG1 and the SREBP-SCAP complex. SCAP acts to release SREBP from the endoplasmic reticulum to allow it to travel to the nucleus by the proteolytic cleavage of its two sections by site-1 protease (S1P) and site-2 protease (S2P). When free to travel to the nucleus SREBP acts in the manner described earlier to upregulate endogenous cholesterol production.

31.2.2 Lipoproteins

Plasma lipoproteins consist of a hydrophobic core of cholesterol esters and triglycerides surrounded by an outer hydrophilic layer composed of ampipathic phospholipids, unesterified cholesterol, and apolipoproteins. The lipoproteins are categorized into five classes in a continuum of hydrated density. These are, in ascending order of density: chylomicrons, very-low-density lipoproteins (VLDLs), intermediate-density lipoproteins (IDLs), low-density lipoproteins (LDLs), and high-density lipoproteins (HDLs). Lipoprotein density is dependent on the concentration of triglycerides in the particle. Chylomicrons and VLDL, the largest and least dense lipoprotein particles, are responsible for the majority of the body's triglyceride transport. LDL and HDL are mainly responsible for the transport of the body's cholesterol, with very little of the triglycerides constituent in these particles.

The protein component of lipoprotein particles, apolipoproteins, is integral to the interaction of lipoproteins with cellular receptors, along with the activation and inhibition of enzymes involved in lipoprotein metabolism. Particular apolipoproteins are unique to certain lipoprotein classes. The main apolipoproteins and their characteristics are detailed in Table 31.1.

31.2.3 Exogenous Pathway

Dietary lipids are a vital source of energy to the human body. Triglycerides, which account for more than 95% of dietary lipids, are hydrolyzed by gastric and pancreatic lipases into monoacylglycerol, free fatty acids, and free glycerol. They are then emulsified with bile acids to form micelles, which transport them into the enterocytes of the intestine. The constituents are then repackaged into triglycerides and together with phospholipids, cholesteryl esters, rentinyl esters, cholesterol, and apo B-48 form chylomicrons. This process is driven by the microsomal triglyceride transfer protein (MTP). The newly formed chylomicrons are excreted by the enterocytes into the intestinal lymph system and into the plasma via the thoracic duct.

Chylomicrons travel through the systemic circulation and are significantly metabolized in the peripheral tissues, such as muscle and adipose tissue, before reaching the hepatic circulation and the liver. Circulating chylomicrons are hydrolyzed by lipoprotein lipase (LPL), which

TABLE 31.1 Apolipoproteins and Their Function

Apolipoprotein	Location	Activity
Apo A-I	HDL	Cofactor for LCAT
Apo A-II	HDL	Cofactor for LCAT
Apo A-IV	Chylomicrons	Activates LCAT/CETP
Apo A-V	Chylomicrons, VLDL, HDL	Activates LPL
Apo B-48	Chylomicrons	Ligand for LDLR
Apo B-100	VLDL, IDL, LDL	Ligand for LDLR
Apo C-I	HDL, VLDL	Inhibits CETP
Apo C-II	Chylomicrons, VLDL, HDL	Activates LPL
Apo C-III	Chylomicrons, VLDL, HDL	Inhibits LPL and HL
Apo E	Remnant particles (chylomicrons, VLDL, HDL)	Binds to LDLR

LCAT—lecithin-cholesterol acyltransferase; CETP—cholesterol ester transfer protein; LPL—lipoprotein lipase; HL—hepatic lipase; LDLR—LDL receptor.

is present on the endothelial surfaces of adipose tissue, heart, and skeletal muscle. The hydrolyzation of triglycerides into free fatty acids requires the activation of LPL by apo C-II, which is transferred from HDL to chylomicrons. The free fatty acids are then utilized by the surrounding tissues to generate energy through oxidative reactions, or they are stored as triglycerides.

The resulting chylomicron remnants are rich in cholesterol after the hydrolyzation of the hydrophobic triglyceride components, but also contain apo B-48 and apo E. Apo E is a necessary component in the uptake of chylomicron remnants into the liver by the LDL receptor (also known as the apoB/E receptor) or the LDL receptor-related protein (LRP).

31.2.4 Endogenous Pathway

In the liver, the esterification of fatty acids generates endogenously synthesized triglycerides. These are packaged, along with apo B-100, cholesterol, phospholipids, and vitamin E, to form VLDL particles in a process catalyzed by microsomal triglyceride protein (MTP). VLDL is then secreted into the plasma and undergoes a similar degradation to chylomicrons, driven by the action of LPL in adipose tissue, heart, and skeletal muscle. Prior to this, VLDL particles acquire apo E and apo C-II from HDL particles circulating in the plasma. VLDL particles contain an approximate 1:5 ratio of cholesterol to triglycerides, and subsequent to the action of LPL the resultant IDL particles contain similar amounts of cholesterol and triglycerides.

The liver takes up IDL particles by endocytosis driven by the binding of apo E to the LDL receptor. This accounts for around 40–60% of IDL particles, with the remainder forming LDL by the action of hepatic lipase (HL). The resulting LDL molecules retain apo B-100 and are the most cholesterol-rich of all the lipoproteins.

The majority of circulating LDL is cleared by the binding of apo B and the LDL receptor, resulting in endocytosis into the liver. The remainder is taken up in the peripheral tissues by a similar process. Once in the cells, LDL is degraded by lysosomes and the free cholesterol is esterified by sterol O-acyltransferase (SOAT); this process regulates the body's level of cholesterol through the SREBP pathway described previously.

31.2.5 Reverse Cholesterol Transport

The body cannot metabolize cholesterol, so any excess must be excreted as free sterol molecules via the liver or as bile acids in the gut. The system that drives this process is known as "reverse cholesterol transport" and is mediated by HDL molecules. This process is thought to reduce the risk of atherosclerotic cardiovascular disease by the removal of excess cholesterol in the peripheral tissues to the liver for excretion. (See Figure 31.2.)

HDL particles are synthesized in the intestine and liver as discoidal lipid-poor particles containing apo A-1, also known as pre-β1-HDL. During particle formation, apo A1 interacts with potentially atherogenic cholesterol containing cells expressing the membrane ATP-binding cassette protein A1 (ABCA1), leading to the nascent HDL particles acquiring phospholipids and free cholesterol to form pre-β2-HDL. Once circulating in the plasma, the HDL-associated enzyme lecithin-cholesterol acyltransferase (LCAT) esterifies the free cholesterol; the newly formed hydrophobic cholesterol esters then move to the core of the now mature HDL particle (α-HDL), making it spherical in shape. Further modeling of the HDL particles takes place in the plasma through the action of a variety of cell-surface and plasma enzymes, including hepatic (LIPC) and endothelial lipase (LIPG), the ABCG1 transporter, and the phospholipid transfer protein (PLTP).

Mature HDL particles can be removed from the circulation or transported to steroid-generating organs (adrenals, ovaries, and testes) through a direct or indirect pathway. Direct uptake is mediated by the cell-surface receptor known as scavenger receptor class B1 (SR-B1), which allows cellular uptake of cholesterol from mature HDL particles to form HDL particles that are free to reenter the cycle. The indirect pathway is mediated by cholesterol ester transfer protein (CETP), a plasma protein that facilitates the transfer of cholesterol esters from HDL to apo B-containing lipoproteins (VLDL, LDL) in exchange for a triglyceride particle. This allows cholesterol to be hepatically removed from the circulation through the LDL-R-mediated endocytosis of apo B-containing lipoproteins.

31.3 LIPIDS AND CVD RISK, EPIDEMIOLOGY, AND PUBLIC HEALTH IMPACT

Cardiovascular disease (CVD) is the leading cause of death worldwide and accounts for approximately 17 million deaths yearly—around 30% of total deaths [3]. It is predicted that by 2030 more than 23 million people will die from CVD annually. CVD results from the formation of atherosclerotic plaques in the arteries, leading to morbidity and mortality from coronary artery disease (CAD), peripheral vascular disease (PVD), and ischemic stroke. (See Figure 31.3.)

There are multiple risk factors for the development of CVD; they include modifiable factors—smoking, obesity, lack of exercise, diet, hypertension, diabetes mellitus, and plasma lipid abnormalities—as well as nonmodifiable factors—male gender and age. The relationship between plasma lipid abnormalities and CVD risk has been heavily investigated over the last 50 years, with large advances made in the estimation of cardiovascular risk and the management of dyslipidemias in a primary and secondary prevention setting. In the following section, we explore the individual plasma lipid parameters and their relationship to cardiovascular risk.

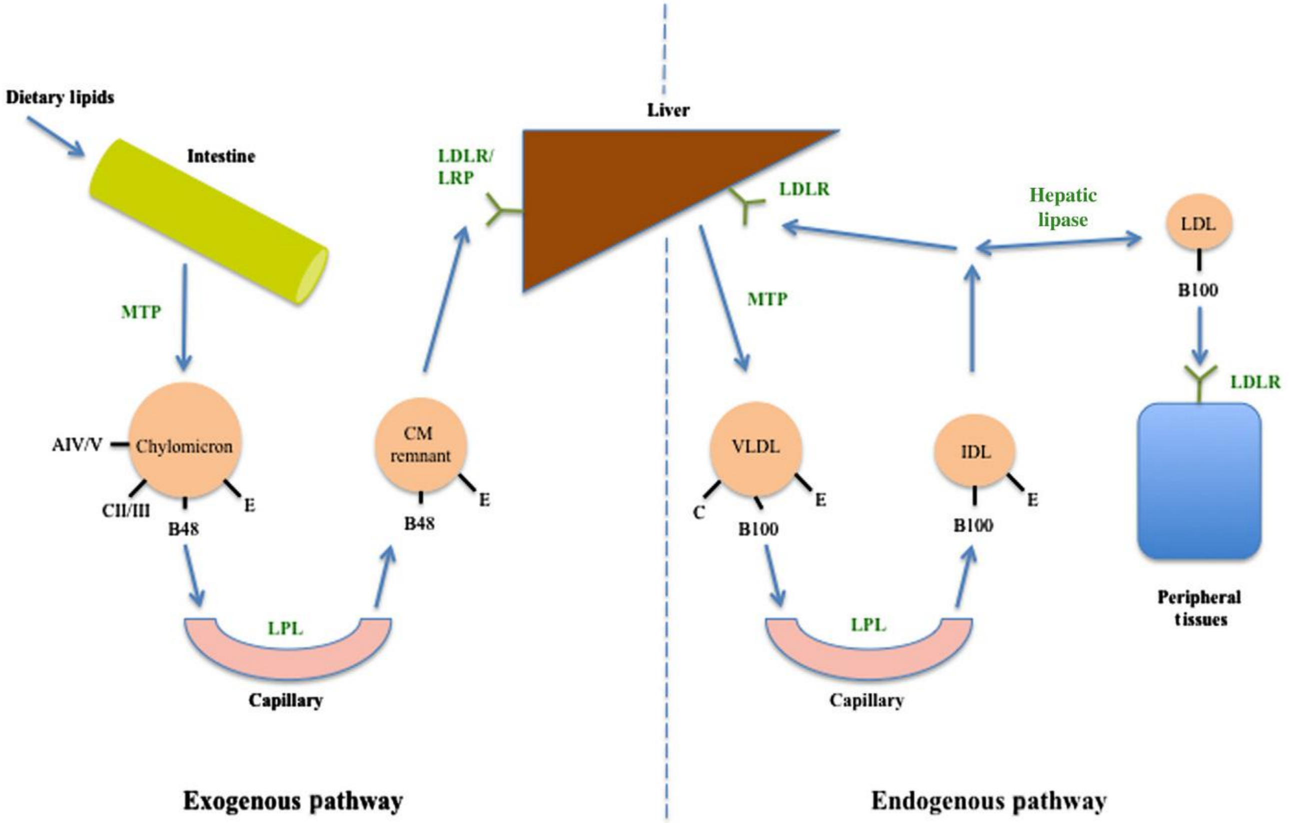

FIGURE 31.2 **Endogenous and exogenous pathways of cholesterol metabolism.** MTP—microsomal triglyceride protein; LPL—lipoprotein lipase; CM—chylomicron; LDLR—LDL receptor; LRP—LDL receptor-related protein; VLDL—very-low-density lipoprotein; IDL—intermediate-density lipoprotein; LDL—low-density lipoprotein.

31.3.1 Total Cholesterol and Low-Density Lipoprotein Cholesterol

The Framingham Heart study (1961) was one of the first observational trials to demonstrate a direct relationship between serum levels of total cholesterol and the development of cardiovascular disease [4,5]. The risk of mortality from coronary heart disease rose with increasing total plasma cholesterol, and these results were echoed in further observational trials, such as the Whitehall study, the Multiple Risk Factor Intervention Trial (MRFIT), and the INTERHEART study.

To investigate the relationship between blood pressure and cholesterol on cardiovascular mortality, a meta-analysis published in 2007 examined 61 prospective observational studies involving 892,000 subjects, an average follow-up of 13 years, and more than 55,000 deaths from a vascular cause [6]. It was demonstrated that a 1 mmol/l reduction in total plasma cholesterol in the age groups of 40–49, 50–69, and 70–89 years was associated with a significant reduction in cardiovascular events; hazard ratios were 0.44, 0.66, and 0.83, respectively.

The individual components of plasma cholesterol, such as LDL-C, HDL-C, and triglycerides, have also been examined in terms of their unique relationship to cardiovascular risk. It was discovered that increasing plasma levels of LDL-C, the major component of the plasma total cholesterol level, increases CVD risk.

As previously noted, elevated levels of total cholesterol and LDL-C are associated with an increased risk of CVD. It therefore follows that reducing levels of these lipid parameters should result in a lowering of this risk. The Scandinavian Simvastatin Survival Study (4S), a landmark trial published in 1994, heralded the role of HMG-CoA reductase inhibitors (statins) in lowering the risk of morbidity and mortality from coronary arterial disease.

A secondary prevention study, involving 4444 patients with established coronary arterial disease and a total cholesterol level of between 5.5 and 8.0 mmol/l, compared the effect of simvastatin versus placebo with a median follow-up of 5.4 years [7]. In the simvastatin arm of the trial, total cholesterol and LDL-C were reduced by 25% and 35%,

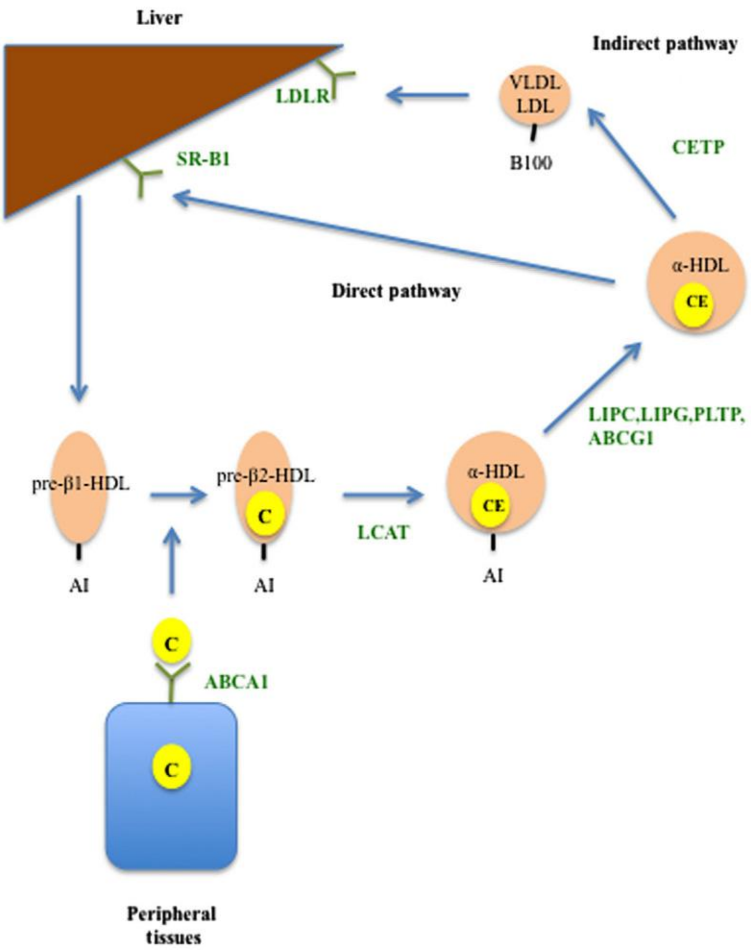

FIGURE 31.3 **Reverse cholesterol transport.** ABCA1—ATP-binding cassette protein A1; LCAT—lecithin-cholesterol acyltransferase; LIPC—hepatic lipase; LIPG—endothelial lipase; ABCG1—ATP-binding cassette protein G1; PLTP—phospholipid transfer protein; CETP—cholesterol ester transfer protein; LDLR—LDL receptor; SR-B1—scavenger receptor class BI.

respectively. This resulted in a statistically significant relative risk reduction of 0.66 for major coronary events (coronary death, myocardial infarction, or resuscitated cardiac arrest), and a reduced total mortality with a relative risk reduction of 0.70. These results indicated no difference in noncardiovascular death in the treatment and placebo groups.

The role of statins in secondary prevention was further confirmed by the results of the Cholesterol and Recurrent Events (CARE) trial, in which patients with a history of myocardial infarction and lower cholesterol levels than those in 4S (<6.2 mmol/l) showed a significant reduction in the incidence of coronary events compared to placebo [8].

The West of Scotland Coronary Prevention Study (WOSCOPS) trial was the first primary prevention trial to examine the role of plasma cholesterol reduction in hypercholesterolemic men with no history of coronary heart disease [9]. This was a high-risk population with average total plasma cholesterol levels of 7.03 mmol/l, one-third of the 6595 study group being smokers with an average body mass index (BMI) of 26. Participants were randomized to either pravastatin 40 mg once daily or placebo. In the treatment group, total cholesterol and LDL-C were reduced by 20% and 26%, respectively. The lowering of plasma cholesterol levels resulted in a reduced rate of coronary events by 31% and cardiovascular mortality by 32%. This study illustrated that statin-induced hypercholesterolaemia lowering, even in the absence of known coronary heart disease, had a positive effect on the rate of cardiovascular events and mortality.

The individual trials just discussed demonstrate a clinical benefit to the lowering of total plasma cholesterol and LDL-C as it relates to cardiovascular risk. In addition, there appears to be no threshold under which any further decrease in LDL-C does not result in lowered risk. These findings have been confirmed by a large meta-analysis by the Cholesterol Treatment Trialists' (CTT) Collaboration, where data from more than 90,000 patients with more than 14,000 vascular events were analyzed [10]. It was demonstrated that statin therapy, resulting in a lowering of LDL-C, reduces the risk of vascular events and death [8]. Each reduction in LDL-C by 1 mmol/L resulted in a reduction in mortality from CVD by around one-fifth. Further lowering also equated to further risk reduction. The results also suggest that the benefit incurred from reduction of LDL-C is the same irrespective of pretreatment LDL-C level. That is to say, benefit is accrued from the absolute reduction in LDL-C level, not from the particular level reached. The CTT meta-analysis included patients who had a history of CVD and those who did not.

Another meta-analysis, published in 2013, has shown benefit in LDL-C reduction with no excess of adverse effects in a selected patient subgroup with no history of CVD—that is, a group in which the risk of CVD is lower [11]. This finding echoed those of the CTT collaboration—that is, similar reduction of absolute risk by lowering LDL-C in patients at low risk of CVD and those at higher risk.

In conclusion, elevated plasma levels of total cholesterol and LDL-C are known to increase CVD risk; reducing those levels reduces that risk in both primary and secondary prevention settings.

31.3.2 HDL-Cholesterol

Lower LDL-C, as noted earlier, results in a lower cardiovascular risk. However, despite aggressive lowering, there still exists residual CVD risk. Data from the Framingham Heart Study and subsequent studies have shown low plasma levels of HDL-C to be an independent risk factor for CVD [12,13]. In the Framingham study, HDL-C levels were a more potent risk factor for CVD than plasma levels of LDL-C. In the Treating to New Targets (TNT) trial, where patients with known CAD were treated with statins to achieve an LDL-C level of <1.8 mmol/L, HDL-C level remained an independent risk factor when adjusted for other baseline risk factors [14]. A meta-analysis of four trials, adjusting for age, blood pressure, smoking, BMI, and LDL-C, found that an increase in HDL-C of 1 mg/dL (0.03 mmol/L) resulted in a decrease of 1.9–2.9% in risk [15]. These results suggest that increasing low levels of HDL-C should result in decreased CVD risk. However, there is limited data to support this hypothesis in trials using pharmacological methods to raise HDL-C using drugs such as nicotinic acid and CETP inhibitors. Given these disparate findings, the exact role of HDL-C as an independent factor in determining cardiovascular risk is still under debate.

31.3.2.1 Triglycerides

The potential association between elevated triglyceride levels and cardiovascular disease has been investigated for more than fifty years, with no conclusive evidence of an independent relationship as a risk factor. Several prospective studies have shown elevated plasma triglyceride levels to be a CVD risk factor. An analysis carried out on two prospective cohort studies, the Reykjavik study and the European Prospective Investigation of Cancer (EPIC) Norfolk study, along with a meta-analysis of 29 studies involving more than 10,000 CVD events in 262,525 individuals, calculated a combined odds ratio after adjustment for established CVD risk factors of around 1.7 in subjects with a triglyceride level in the highest tertile [16].

This finding, in a Western population, was very similar to that found in a previous analysis of an Asian-Pacific population [17]. A further meta-analysis in 2009 of more than 300,000 people, with 2.79 million person-years of follow-up, showed that the hazard ratio for CVD per 1 standard deviation higher triglyceride plasma concentration was 1.37 (95% CI 1.31–1.42) [18]. However, after adjustment for values of well-established risk factors, including non-HDL and HDL cholesterol, the hazard ratio was reduced to 0.99 (95% CI 0.94–1.05).

The results just discussed suggest a possible association between elevated triglyceride levels and CVD risk, which lessens after adjustment for well-established CVD risk factors, in particular plasma levels of HDL-C and LDL-C. A study published in 2010 aimed to clarify the role of triglyceride-mediated pathways in promoting CVD risk [19]. One of the most common genetic variants associated with triglyceride levels, rs662799 (−1131T>C) in the apolipoprotein A-5 (APOA5) gene, codes for the apolipoprotein associated with VLDL, a molecule rich in triglycerides. The authors examined the association between this genetic variant, elevated triglyceride levels, and the risk of coronary heart disease. They found that, for each minor C allele inherited, the mean triglyceride level was higher by 16% (0.25 mmol/L). There was no significant association between rs662799 and LDL-C concentration, and only a modest association with lower levels of HDL-C (mean difference of 3.5% per C allele inherited), lower apolipoprotein A1 (1.3%), and higher apolipoprotein B (3.2%).

Analysis findings equated to an odds ratio of coronary heart disease of 1.18 (95% CI 1.11–1.26) per inherited C allele. An additional finding was that the rs662799 polymorphism, and thus hypertriglyceridemia, was associated with higher VLDL plasma concentration and smaller HDL-C particles, thought to be potential pro-atherogenic precipitants of increased CVD risk. The authors concluded that there was a causal association between triglyceride-mediated pathways and coronary heart disease.

31.3.2.2 Apolipoproteins

Outside of the now standard measurements of LDL-C, HDL-C, and triglycerides in the estimation of cardiovascular disease risk, recent research has pointed toward the measurement of plasma apolipoprotein concentrations as potentially more accurate markers of CVD risk.

Apo B/Apo A-1

Apolipoprotein B is the major constituent of the atherogenic particles VLDL, IDL, and LDL. The plasma concentration of apolipoprotein B can be measured and has been examined for its function as a surrogate marker for cardiovascular risk. In addition to apo B, non-high-density lipoprotein cholesterol, the sum of VLDL, IDL, and LDL particles in the plasma (calculated as total cholesterol minus HDL-C) has been used in a similar manner [20].

Apolipoprotein A-1 is the major constituent of HDL-C and acts as a surrogate marker for HDL-C plasma concentration. Several prospective studies have shown measurement of apo-B or non-HDL-C to be at least as good as measurement of LDL-C in CVD risk reduction. The Emerging Risk Factors Collaboration (ERFC) found that CVD hazard ratios for non-HDL-C and HDL-C were almost identical to those found for apo B and apo A-1 in a meta-analysis of more than 300,000 subjects [18]. A later analysis, including the ERFC study set and totaling 233,455 subjects and 22,950 cardiovascular events, calculated apo B concentration to be a more powerful predictor of risk than non-HDL-C and LDL-C, with relative risk ratios of 1.43 (95% CI 1.35–1.51), 1.34 (95% CI 1.24–1.44), and 1.25 (95% CI 1.18–1.33), respectively [21].

With these results in mind, the authors calculated that measurement of apo B to predict risk and guide management could potentially, over a 10-year period, prevent 500,000 more cardiovascular events than a strategy based on non-HDL-C measurement. In comparison, the measurement of non-HDL-C was calculated to prevent 300,000 more events than a LDL-C measurement strategy.

Lipoprotein(a)

Lipoprotein(a) (Lp(a)) consists of an apolipoprotein B-100 particle attached to apolipoprotein A by a disulphide bridge. Recent research has shown elevated plasma concentrations of lipoprotein(a), in particular the apo A component, to be atherogenic, leading to increased levels of coronary artery disease. In an analysis of 36 prospective studies with more than 120,000 participants and 22,000 vascular events, there was a risk ratio of 1.13 (95% CI 1.09–1.18) per 1 standard deviation increase in Lp(a) for CVD, after adjustment for well-established CVD risk factors [22]. Genetic variants in Lp(a) have been identified, placing subjects with the genotypes at a higher risk; rs3798220 and rs10455872, which are associated with elevated plasma levels of Lp(a) and increased risk of CVD, are two SNPs that have been identified [23]. Current guidance does not recommend routine measurement of Lp(a) as part of risk estimation, but it may be considered in people with a high risk or strong family history of CVD [24].

31.4 GENETIC BASIS OF LIPID DISORDERS AND LIPID LEVELS

As detailed previously, the associations between plasma lipid abnormalities and increased risk of cardiovascular disease are well established. Recent advances in determining the genetic basis for plasma lipid levels have led to new insight into the pathogenetic basis of increased cardiovascular risk in certain individuals. Cardiovascular risk is a complex heterogeneous issue with no single etiological factor. It is well established that cardiovascular disease has a strong element of heritability, with a positive history in previous generations being a strong independent risk factor. However, the precise mode of inheritance is still unclear. In their individual components, lipid levels have been shown to have an element of heritability, with levels of correlation seen between family members against nonrelated individuals.

The association between lipid abnormalities and increased cardiovascular risk has long been established in Mendelian disorders, such as the primary dyslipidemias described next. The mapping of the human genome has led to the advent of genome-wide association studies (GWASs), with the aim of identifying common genetic variants that associate with lipid levels and consequently cardiovascular disease. The identification of functional genomic variants, which predispose to increased risk, has the potential to allow presymptomatic identification of those at high risk earlier than current practice, and allows early-targeted intervention to reduce risk. This is discussed later in the chapter.

31.4.1 Primary Dyslipidemias

Several monogenic disorders result in abnormalities of an individual's lipid profile, with varying corresponding levels of CVD risk. Table 31.2 outlines the most common of these disorders, their genetic basis, and their biochemical effect, along with their prevalence and distinguishing clinical features. We examine disorders affecting each aspect of the lipid profile in turn.

31.4.1.1 Primary LDL Abnormalities

Familial Hypercholesterolemia

The molecular defect causing familial hypercholesterolemia (FH) was first identified by Brown and Goldstein in their Nobel prize-winning work published in 1986 [25]. This discovery elucidated the role of LDL receptors in the uptake of cholesterol and the loss-of-function mutation in the LDLR gene located on chromosome 19p13.1–13.3, leading to the elevated LDL-C levels seen in FH. Two genotypic variants with an autosomal dominant pattern of inheritance exist, and these have differing clinical and biochemical presentations [26].

TABLE 31.2 Primary Monogenic Dyslipidemias

Genetic Basis Mode of Inheritance, Prevalence, and Distinguishing Clinical Features

Disorder	Genetic Defect	Lipid Defect	Inheritance	Prevalence	Clinical Findings
LDL-C					
Familial hypercholesterolemia	LDLR	↑ LDL	ACD	Heterozygous: 1/500	Heterozygous (TC: 7–13 mmol/L): tendon xanthomata, arcus senilis, premature CAD (age 30–50)
				Homozygous: 1/1,000,000	Homozygous (TC >13 mmol/L): plantar/tendon xanthomata, premature CAD (age <18)
Familial defective apoB-100	APOB (LDL receptor binding-region defect)	↑ LDL	AD	1/700	TC 7–13 mmol/L: tendon xanthomas, arcus senilis, premature CAD
Autosomal recessive hypercholesterolemia	LDLRAP1 (loss-of-function)	↑ LDL	AR	Very rare	Tendon xanthomas, arcus senilis, premature CAD
Autosomal dominant hypercholesterolemia 3	PCSK9 (gain-of-function)	↑ LDL	AD	Rare	Tendon xanthomas, arcus senilis, premature CAD
Sitosterolemia	ABCG5/8	↑ LDL	AR	Rare	Tendon xanthomas, premature CAD
Abetalipoproteinemia (Bassen-Kornzweig syndrome)	MTP (microsomal triglyceride transfer protein), Apo B-48/B-100	↓ LDL	AR	Rare	Fat malabsorption, spinocerebellar degeneration, retinopathy, acanthocytosis
Familial hypobetalipoproteinemia	APOB (↓ Apo B100)/PCSK9	↓ LDL	ACD	Very rare	Fat malabsorption, fatty liver, spinocerebellar degeneration, retinopathy
PCSK9 deficiency	PCSK9 (loss-of-function)	↓ LDL	ACD	Rare	Reduced CAD risk
HDL-C					
APOA-1 mutations	APOA1 (deletion/mutations)	↓ HDL	AD	Rare	HDL 15–30 mg/dL: corneal opacities, xanthomas, premature CAD
Familial LCAT deficiency	LCAT	↓ HDL	AR	Very rare	HDL-C <10 mg/dL: corneal opacities, hemolytic anemia, renal failure, hepatosplenomegaly

(*Continued*)

TABLE 31.2 Continued

Disorder	Genetic Defect	Lipid Defect	Inheritance	Prevalence	Clinical Findings
Fisheye disease (partial LCAT deficiency)	LCAT	↓ HDL	AR	Very rare	HDL-C: <10 mg/dL corneal opacities, hepatosplenomegaly
Tangier disease (analphalipoproteinemia)	ABCA1	↓ HDL	AR	Rare	HDL-C: <5 mg/dL premature CAD, peripheral neuropathy, hemolytic anemia, corneal opacities, hepatosplenomegaly, orange tonsils
CETP deficiency	CETP	↑ HDL	AR	Rare	Elevated HDL
Triglycerides					
LPL deficiency	LPL (endothelial LPL defect)	↑ Chylomicron	AR	Rare	TG: >8.5 mmol/L: infantile failure to thrive, eruptive xanthomas, hepatosplenomegaly, pancreatitis
Familial apolipoprotein C-II deficiency	APOCII (functional LPL deficiency)	↑ Chylomicron	AR	1/1,000,000	TG >8.5 mmol/L: pancreatitis, metabolic syndrome, eruptive xanthomas, hepatosplenomegaly
Familial hepatic lipase deficiency	LIPC	↑ VLDL remnants	AR	Very rare	Premature CAD
Familial dysbetalipoproteinemia	APOE	↑ Chylomicron and VLDL remnants	AD	1/10,000	TC 6.5–13.0 mmol/L; TG: 2.8–5.6 mmol/L: palmar/tuberoeruptive xanthomas, premature CAD

Heterozygous FH, where there is one mutated allele, is one of the most common genetic lipid disorders, with a prevalence of around 1 in 500. Affected individuals have elevated total cholesterol levels, typically between 7 and 13 mmol/L, resulting in an increased risk of atherosclerotic disease, which typically affects them starting at age 30.

Homozygous FH involves a mutation in both alleles coding for LDLR, resulting in markedly elevated total cholesterol levels, often more than 13 mmol/L. It is less common than heterozygous FH, with a prevalence of around 1 in a 1,000,000, and individuals are affected by an extremely early onset of atherosclerotic disease, often in adolescence. Given the extremely high LDL-C levels these individuals exhibit, treatment involves the use of high-dose statins and adjuncts such as cholesterol absorption inhibitors, bile acid sequestrants, nicotinic acid, or LDL apheresis in extreme cases.

During the early development of statins, Merck suspended a clinical trial of lovastatin because of concerns regarding potential toxicity; consequently, the future of the drug seemed extremely doubtful. This changed when small-scale studies in selected small groups of patients with severe heterozygous FH refractory to existing therapy showed dramatic reductions in LDL cholesterol with few adverse effects. Merck reinitiated its clinical development program in 1983 [27].

Familial Defective apo B-100

Familial defective apo B-100 is clinically indistinguishable from FH. However, it involves a different genetic basis with a mutation in the receptor-binding region of the apo B-100 gene, located on chromosome 2p24-p23 [28]. Several specific mutations have been identified, with the most common involving the substitution of glutamine for arginine at position 3500 in apo B-100. Elevated LDL-C levels result from the failure of the binding between circulating LDL-C in plasma and LDLR. This genetic defect is not as common as that of the LDLR, with a prevalence of around 1 in 700; it is treated in a similar manner to heterozygous FH.

Autosomal Recessive Hypercholesterolemia

Autosomal recessive hypercholesterolemia (ARH) is a rare cause of elevated LDL-C caused by a loss-of-function mutation in the LDLRAP1 gene, located on chromosome 1p36-35; it codes for the adaptor protein ARH [29,30]. This LDLRAP1 mutation results in the inability of hepatocytes to internalize the LDL-C ligand-receptor complex, resulting in elevated LDL-C plasma levels. Individuals with a heterozygous genotype often have normal cholesterol levels, unlike a homozygous genotype, where the clinical presentation is similar to that of homozygous FH.

Autosomal Dominant Hypercholesterolemia

Autosomal dominant hypercholesterolemia (ADH) can be caused by a defect in one of three genes, two of which were described in detail earlier: LDLR and APOB100. In 2003, a third causative mutation was identified in the proprotein convertase subtilisin/kexin type 9 (*PCSK9*) gene, located on chromosome 1p34.1-p32 [31]. PCSK9 is a protease enzyme that plays a vital role in cholesterol homeostasis by binding to the LDLR and enhancing its endosomal degradation, resulting in increased LDL catabolism. In the subtype of ADH caused by two possible gain-of-function mutations in the PCSK9 gene (HCHOLA3), there is increased PCSK9 protease-driven degradation of LDLR, resulting in decreased uptake of cholesterol into cells and subsequently elevated plasma levels. The impact of these mutations on cardiovascular disease are discussed later in the chapter, along with the ongoing efforts to establish the potential of PCSK9 as a pharmacological target with the aim of reducing levels of LDL-C and thus CVD risk.

Sitosterolemia

Sitosterolemia is an extremely rare autosomal recessively inherited condition caused by mutations to one of two genes, ABCG5 and ABCG8, located on chromosome 2p21, which encode for two adenosine triphosphate-binding cassette (ABC) transporter proteins, sterolin-1 and sterolin-2 [32]. The mutation leads to increased intestinal absorption and reduced biliary excretion of plant sterols with subsequent elevated plasma levels of sitosterol, which result in reduced hepatic LDLR expression, elevated LDL-C, and an associated increased risk of premature CVD.

Abetalipoproteinemia (Bassen-Kornzweig syndrome)

Abetalipoproteinemia (ABL) is a rare autosomal recessively inherited condition that results from a mutation in the gene located on chromosome 4q24 encoding for the microsomal transfer protein (MTP) [33]. This protein plays an important role in the assembly of lipoproteins in the endoplasmic reticulum. The failure of the transfer of lipids to lipoproteins containing apo B-48 and B-100 results in markedly reduced plasma levels of apo B-containing lipoproteins such as V-LDL and chylomicrons. This gives rise to very low plasma cholesterol levels and presents clinically with fat malabsorption, spinocerebellar degeneration, retinopathy, and acanthocytosis due to poor intestinal absorption of the fat-soluble vitamins A, D, K, and, in particular, E.

Familial Hypobetalipoproteinemia

Individuals with familial hypobetalipoproteinemia (FHBL) have LDL-C levels in the <5th percentile and an associated low risk of CVD. The genetic cause for this condition in the majority of cases is mutations in the APOB gene [34]. Multiple mutations have been identified, the majority of which result in truncated forms of Apo B with reduced plasma levels of apo B-100; these are thought to be inherited in an autosomal codominant manner. Heterozygotes can be asymptomatic or demonstrate fatty liver, intestinal fat malabsorption. Homozygotes present in a manner similar to that in patients with ABL. Some patients with the FHBL phenotype have been found to have no mutation in the *APOB* gene, and patients with the phenotype have been found to harbor mutations in *PCSK9*.

PCSK9 Deficiency

Similar to the gain-of-function mutations described, several loss-of-function mutations in PCSK9 have been discovered in individuals with low LDL-C plasma levels and low CVD risk [35].

31.4.1.2 Primary HDL Abnormalities

APOA-1 Mutations

A variety of genetic mutations to the *APO A-1* gene have been identified that lead to low HDL-C levels and to the development of atherosclerotic disease and premature coronary heart disease [36]. Individuals with a complete loss of apo A-1 have very low levels of HDL-C (<5 mg/dL) and correspondingly high-risk levels of premature CAD. Heterozygotes demonstrate no specific clinical symptoms; however, they do have HDL-C and apo A-1 levels around 50% of normal. Several missense or nonsense mutations of apo A-1 have been identified as causing low HDL-C levels and premature CAD. Thus, apo A-1, thought to be atheroprotective, has become a potential pharmacological target. An exception to these findings is the apo A-1_{Milano}

mutation, which, although causing reduced HDL-C levels, has actually been shown to result in reduced risk of cardiovascular events [37].

Analphalipoproteinemia (Tangier Disease)

Analphalipoproteinemia, or Tangier disease, is an extremely rare condition, resulting in decreased plasma HDL-C levels, that is inherited in an autosomal recessive manner [38,39]. It is caused by a loss-of-function mutation to the ABCA1 gene on chromosome 9q31, which encodes for the ATP-binding cassette transporter (ABCA1). ABCA1 is responsible for regulating the efflux of cholesterol and phospholipids to lipid-free apo A-1, forming nascent HDL-C. The mutation to the ABCA1 gene results in a lack of HDL-C in plasma and a toxic buildup of cholesterol in the cells, leading to impaired cellular function and cell death.

Tangier disease presents clinically with peripheral neuropathy, hemolytic anemia, corneal opacities, hepatosplenomegaly, and orange tonsils due to the accumulation of cholesterol in cells, in particular the reticuloendothelial system. The relationship between Tangier disease and CVD risk has not been fully elucidated, partly because of the rarity of the condition. However, it does not appear to cause as early an onset of CVD as that seen in diseases such as homozygous FH. This may be due to the low plasma levels of LDL-C seen in individuals with Tangier disease.

Familial LCAT Deficiency/Fisheye Disease (Partial LCAT Deficiency)

The lecithin-cholesterol acyltransferase (*LCAT*) gene, located on chromosome 16q22, is responsible for encoding the LCAT enzyme, which catalyzes the formation of cholesterol esters from free cholesterol in nascent HDL. This allows the HDL particles to mature. Homozygosity for loss-of-function mutations in the *LCAT* gene can present in two ways, with heterozygotes having HDL-C levels within the normal range [40]. Individuals with familial LCAT deficiency have a complete deficiency of LCAT and are unable to form mature HDL-C and esterify free plasma cholesterol. This presents clinically as HDL-C levels lower than 10 mg/dL with corneal opacification, hemolytic anemia, and progressive renal impairment, which in some cases results in end-stage renal failure. Fisheye disease is a variant with partial LCAT deficiency, where LCAT is active on LDL but not HDL, resulting in the same clinical picture apart from the fact that there is no effect on renal function. As with Tangier disease, no clear association between LCAT deficiency and CVD has been established.

CETP Deficiency

CETP deficiency is inherited in an autosomal recessive manner, in which affected individuals have loss-of-function mutations in both copies of the *CETP* gene. This results in elevated HDL-C levels and low LDL-C levels due to the failure of CETP-driven transfer of cholesterol esters from HDL to apo B-containing lipoproteins such as VLDL, IDL, and LDL. Several mutations have been identified, and data suggest that this genetic disorder is most prevalent in the Japanese population [41]. The two most common mutations are a G>A at +1 position on intron 14 and a D>G substitution at the 442 position on exon 15 (D442G), which are respectively present in approximately 2% and 7% of the Japanese population. Given that inhibition of CETP activity results in lower production of atherogenic lipoproteins, it has been suggested that CETP deficiency is associated with lower CVD risk [42]. To date, the evidence is conflicting, with some studies suggesting a low risk of CVD associated with CETP deficiency, and some showing equivocal results. This issue is further complicated by the current failure of pharmacological CETP inhibition to have any benefit on cardiovascular outcomes.

31.4.1.3 Primary Triglyceride Abnormalities

Familial Chylomicronemia Syndrome

Familial chylomicronemia syndrome (FCS)—that is, LPL deficiency and apo C-II deficiency—is a clinical syndrome of extreme hypertriglyceridemia presenting with eruptive xanthomas, lipemia retinalis, hepatosplenomegaly, and acute pancreatitis [43]. It is caused by homozygosity for one of two loss-of-function mutations in either the LPL or apo C-II genes. These mutations result in a failure of hydrolyzation of triglycerides by LPL and its cofactor, apo C-II, causing elevated plasma triglyceride chylomicron levels. There is no association between FCS and increased risk of atherosclerotic cardiovascular disease. Management involves reduction of dietary fat intake and avoidance of alcohol.

Familial Dysbetalipoproteinemia

Familial dysbetalipoproteinemia (FD), also known as type III hyperlipoproteinemia, arises from mutations in the gene coding for apo E [44]. APOE, normally expressed as the wild-type APOE3, acts as a ligand for the hepatic uptake of chylomicrons, IDL, and VLDL remnant particles. FD is seen in individuals homozygous for a common variant (rs7412) of APOE, known as APOE2, which results from a substitution of a cysteine for an arginine at position 158 on chromosome 19. The E2/E2 genotype has a prevalence of around 1 in 100. However, FD is only seen in around 1 in 10,000 individuals, suggesting that additional environmental, hormonal (estrogen deficiency), and genetic factors, in addition to the genotype, are required for disease development [45]. Individuals with FD have elevated levels of triglycerides and total cholesterol, and present clinically with palmar and tuberoeruptive xanthomata. An increased prevalence of early-onset CAD is also seen.

Hepatic Lipase Deficiency

Hepatic lipase deficiency is a very rare condition where deficiency in hepatic lipase results in elevated levels of total cholesterol, in particular HDL-C, and triglycerides. Various loss-of-function mutations have been identified in individual groups in the *LIPC* gene, which codes for hepatic lipase [46,47]. Although the rarity of this disease precludes definitive association, it is thought that the lipid profile of affected individuals results in increased CVD risk.

31.4.2 Common Genetic Variants and Lipid Levels

Research on the role of gene variants in determining plasma lipid levels has identified common genetic variants in more than 100 gene loci. The largest meta-analysis of GWASs to date examined 100,184 individuals of European ancestry and identified 95 loci demonstrating genome-wide significance ($p<5E\text{-}8$) with one or more of the traits of total cholesterol (TC), LDL-C, HDL-C, and TG [48]. The authors calculated that the loci identified accounted for 10–12% of total variance and 25–30% of genetic variance. This level of variance points toward the existence of other loci and unknown independent signals at already identified loci.

In analysis of the loci identified, 29 of 95 were associated with coronary artery disease, the majority being associated with elevated LDL-C, which supports the well-established causal relationship between elevated LDL-C and CAD risk. A further study performed in 2012, using a dense gene-centric approach in a meta-analysis of 32 studies (66,240 individuals of European ancestry), discovered additional loci associated with lipid levels [49]. The researchers discovered a further 21 novel loci and similar levels of variance as seen in the Tesslovich et al. study. These loci, taken on an individual basis, have relatively small “effect sizes,” and it is thought likely that an individual’s lipid profile is determined by a combination of environmental factors along with variants in multiple genes.

The question of genetic lipid level variance between different ethnic groups has arisen because of the known ethnic variation in lipid levels generally. This potential genetic basis for variance has been studied with known loci and in the search for novel loci as well. Tesslovich et al. confirmed that the majority of the 95 loci identified in their meta-analysis replicated their effect on lipid traits in South Asian, East Asian, and African-American groups.

The role that these common genetic variants potentially play in elevating CVD risk has also been examined. In an analysis of two prospective cohorts, the Whitehall II and British Women’s Heart and Health Study, investigators calculated lipid genetic scores based on subjects’ expression of SNPs known to be causal variants [50]. They found that individuals with high scores had higher levels of LDL-C, a higher chance to be deemed “high risk” by the Framingham risk calculator, and, most important, a higher odds ratio for cardiovascular events. Neither HDL-C nor triglyceride scores demonstrated a similar finding.

31.4.2.1 LDL-C

Variance in LDL-C levels is known to be due to genetic variants coding for Mendelian disorders, including LDLR, PCSK9, APOB, LDLRAP, and ABCG5/8, as described before. In addition, loci for HMGCR and NPC1L1 are known LDL-C lowering pharmacological targets for statins and ezetimibe, respectively. GWASs, such as that described earlier, have led to multiple novel loci being identified in association with variance in LDL-C levels. These include common variants at APOB, APOE, HMGCR, LDLR, and PCSK9 [48]. The 1p13 locus, coding for SORT1, has been identified as the strongest statistical association with LDL-C and CAD in the entire human genome, and homozygosity for the minor allele of 1p13 has been associated with a 40% reduction in risk of myocardial infarction [51–53].

In comparison, homozygotes of the minor allele have, on average, an LDL-C level that is 16 mg/dL lower than that in homozygotes for the major allele. This is a considerable effect size compared to other common variants. The exact role of SORT1 in LDL metabolism, and subsequent CVD risk, has not been clarified; several studies report disparate results in terms of the direction of effect of SORT1 expression [51,52,54]. Given the obvious pivotal role of SORT1 variance in LDL-C levels, it is hoped that the exact mechanism can be elucidated, and its possible role as a therapeutic target explored in the near future.

31.4.2.2 HDL-C

The heritability for HDL-C has been shown in twin studies to range from 40–60%; however, examination of common variants has shown a heritability of only 10–12% from these variants [55]. This suggests that our knowledge of the genetic basis of HDL-C levels is far from complete; this is in addition to the uncertainty surrounding the role of HDL-C in determining CVD risk. As with LDL-C, several monogenic disorders alter lipid levels. These include APOA1, ABCA1, LCAT, CETP, and LIPG. It should be noted, however, that Mendelian randomization studies of subjects with these genetic disorders have failed to show any association of genetically induced low HDL-C with CVD risk [56]. In addition, GWASs have uncovered several SNPs with an association with HDL-C level, including IRS1, ANKS1, KLF14, LPL, TRIB1, the ZNF259–APOA5–APOA4-APOC3–APOA1 gene cluster, and SH2B3 [57].

31.4.2.3 Triglycerides

Several monogenic determinants of hypertriglyceridemia have been identified, and the more common were explored earlier in the chapter. They include mutations at LPL, APOCII, and APOA5, along with rarer mutations at LMF1 (lipase maturation factor 1) and GPIHBP1. LMF1 is involved in the maturation and transport of lipoprotein lipase. Individuals with hypertriglyceridemia who lack mutations in the more common genes associated with elevated triglyceride levels have later been found to have loss-of-function mutations in LMF1 [58]. GPIHBP1 encodes for glycosylphosphatidylinositol-anchored HDL binding protein, which plays a key role in the processing of chylomicrons mediated by LPL. Homozygous mutations in GPIHBP1 have been identified in subjects with hypertriglyceridemia who lack more common mutations at other associated loci [59].

As with LDL-C and HDL-C, current studies have identified common genetic variants that account for around 10% of total population triglyceride variance, suggesting that our knowledge of the genetic determination of triglyceride levels is far from complete. Beyond monogenic disorders, it is thought that a combination of genetic variants is responsible for the variance seen. Loci most strongly associated with triglyceride levels in GWASs include APOA5, GCKR, LPL, and APOB, alongside other loci identified at TRIB1, ANGPLT3, MLXIPL, and KLHL8 [48,60].

31.4.3 Pharmacological Management of Lipids and Pharmacogenomics

We discussed earlier the role of the dyslipidemias in elevating CVD risk. Various pharmacological methods of managing dyslipidemia have been identified and investigated, with varying results in terms of their ability to reduce this risk. We examine each fraction of the lipid profile in turn and discuss the established and novel pharmaceutical methods available. The principle pharmaceutical agents currently available are detailed in Table 31.3 along with their individual effect on the plasma lipid profile.

31.4.3.1 LDL-C

Statins

As detailed earlier, statin therapy is currently universally accepted as the most effective pharmacological therapy for lowering total plasma cholesterol and LDL-C. A reduction in plasma levels leads to decreased CVD-associated morbidity and mortality. In addition to their effect on total cholesterol and LDL-C, statins, to a lesser extent, reduce triglyceride levels and effect an increase in HDL-C. This section of the chapter examines the pharmacology of statins, common side effects, and how common genetic variants can potentially alter individual patient response to therapy and increase the risk of certain side effects.

Statins are competitive inhibitors of hydroxymethylglutaryl-coenzyme A (HMG-CoA) reductase, the enzyme controlling the rate-limiting step (conversion of HMG-CoA to mevalonate) in cholesterol synthesis. In the drug development process, HMG-CoA reductase was an attractive target in contrast to other late-stage intermediates, not only because of its rate-limiting step but also because inhibition of HMG-CoA reductase does not result in buildup of toxic metabolites. Reduced endogenous cholesterol production results in SREBP activation, which upregulates LDLR gene expression, leading to increased plasma LDL-C uptake, thereby lowering LDL-C plasma levels. The role of statin therapy in lowering plasma levels of LDL-C and the concomitant benefit of reduced CVD risk in a primary and secondary prevention setting, has been examined in multiple trials, some of which were discussed earlier. In 2010, a large meta-analysis of 26 randomized control trials with statin therapy in more than 170,000 subjects showed reduced risk of major coronary events by 22% per mmol/L (40 mg/dl) reduction in LDL-C [61].

TABLE 31.3 Effect of Established Pharmacological Agents on Lipid Fractions

Agent	Lipid Fraction (%)		
	LDL-C	*HDL-C*	*TG*
Statins	18–55↓	5–15↑	7–30↓
Fibrates	5–20↓	10–20↑	20–50↓
Niacin	5–25↓	15–35↑	20–50↓
Bile acid sequestrants	15–30↓	3–5↑	No change
Ezetimibe	18–20↓	1–4↑	8↓

Several statins exist in different classes that vary according to pharmacology and metabolism, as summarized in Table 31.4, as well as in individual effect on the plasma lipid profile. Type 1 statins (lovastatin, simvastatin, and pravastatin) are produced from funghi such as *Aspergillus terreus* by fermentation. Type 2 statins (fluvastatin, atorvastatin and rosuvastatin) are synthetic molecules in which the butyryl group of type 1 statins is replaced with a fluorophenyl group, resulting in increased binding to HMG-CoA. Within this dichotomy, the individual statins differ in their pharmacokinetics depending on absorption/metabolism, lipophilic/hydrophilic rate, and form of administration. With the exception of lovastatin and simvastatin, the statins are administered orally as active hydroxyl acids. Lovastatin and simvastatin are administered as lactone prodrugs that must be hydrolyzed to the active hydroxyl form.

The statins also vary in their hydrophilicity/lipophilicity; pravastatin and rosuvastatin are the most hydrophilic of the statins; the others are lipophilic. Also, with the exception of pravastatin, they undergo phase 1 metabolism in the liver through the CYP450 enzymatic pathways. The particular enzymes responsible are CYP3A (lovastatin, atorvastatin, and simvastatin), CYP2D6 (fluvastatin, pitavastatin, and rosuvastatin), and CYP2C9 (pitavastatin and rosuvastatin). Pravastatin is different in that it is not acted on by the cytochrome P450 system and undergoes metabolism through sulfation and conjugation reactions. The various statin formulations most commonly used are described in Table 31.4 along with their individual pharmacological properties and effect on the plasma lipid profile.

Dosing and Statin Choice

The variety of statins available, and their individual dosing ranges, present a difficulty to prescribers: which statin and dose to choose for which patient? A large meta-analysis recently published compared the six available statins, and found atorvastatin, rosuvastatin, and simvastatin to be the most effective at lowering plasma levels of total cholesterol and LDL-C, with broad equivalence seen at high doses [62]. The study also confirmed the previously known dose–response relationship, whereby a higher dose of the same statin results in a greater reduction of LDL-C [63]. This relationship has been shown to be curvilinear, with a reduction in LDL-C of around 6% seen when the statin dose is doubled. The different statins and their dose-dependent LDL-C-lowering capabilities are detailed in Table 31.5.

Side Effects and Interactions

In general, statin therapy is well tolerated and serious adverse effects have rarely been noted in clinical trials. However, there are known associations with particular side effects, and also interactions with other pharmacological therapy, which prescribers should be aware of when administering statin therapy.

Myopathy

Muscle toxicity (myopathy) related to statin therapy can be a potentially dangerous side effect, as it can progress to rhabdomyolysis and potential renal failure. In the context of statin therapy, myopathy is generally defined as unexplained muscle pain or weakness accompanied by a grossly elevated creatine kinase concentration, >10 times the upper limit of normal. It was first reported in a cardiac transplant patient receiving the immunosuppressive cyclosporine, in addition to gemfibrozil, and, interestingly, was not detected during the original animal safety assessment studies [64].

In August 2001, cerivastatin, which had been introduced in 1998, was withdrawn from the market by its manufacturer

TABLE 31.4 Statins: Pharmacological Properties and Comparative Efficacy

Statin	Metabolism	Hydrophilic	Reduction in TC (%)	Reduction in LDL-C (%)	Increase in HDL-C (%)	Reduction in TG (%)

Simvastatin	20	1.54 (1.46–1.63)	32	80	2.01 (1.83–2.19)	42

because of a large number of reports of rhabdomyolysis, of which more than 50 cases were fatal [65]. For statins that are substrates for cytochrome P450 CYP3A4 (lovastatin, simvastatin, and atorvastatin), the risk of myopathy is increased by the concomitant administration of potent inhibitors of this enzyme [66].

Myopathy has an incidence of <1 in 1000 patients treated, and a study in 2004 found that in more than 250,000 patients treated with statins there were 24 cases of hospitalized rhabdomyolysis, with similar risks seen between the individual statins and an increased risk associated with concomitant fibrate therapy [60]. The exact mechanism of myopathy has not been fully elucidated. In rat models, it can be prevented by administering mevalonate, the product of the inhibited enzyme [67]. Myopathy risk is higher with advanced age, low body mass, higher doses, concomitant drug administration, and conditions that interfere with hepatic metabolism.

SLCO1B1 and Myopathy

A GWAS of 85 patients with myopathy and 90 matched controls from the 12,000-patient Study of the Effectiveness of Additional Reductions in Cholesterol and Homocysteine (SEARCH) trial identified an association with a common noncoding SNP (rs4149056) in the *SLCO1B1* gene [68]. rs4149056 is in tight LD with a nonsynonymous SNP ($r^2 = 0.97$) that encodes a valine-to-alanine substitution and confers a 4.5-fold increased risk of myopathy per copy of the minor C allele. This variant and others in this highly polymorphic gene have been demonstrated to reduce hepatic uptake and to increase serum statin levels [69]. Roughly 25% of the population carry the C allele, either alone or in combination with other SLCO1B1 variants, all of which appear to similarly affect most statin levels, although the effects are greatest for simvastatin [70]. Myopathy risk is also greatest for simvastatin.

Guidelines for managing simvastatin-induced myopathy risk in the context of SLCO1B1 genotyping were recently published [71]. Although genotyping is not currently required in conjunction with treatment, it is commercially available as a single assay or in combination with other pharmacokinetic variants. Following evidence accumulated on the SLCO1B1 521T>C polymorphism, in 2011 the FDA announced an update to its simvastatin product label recommendations. It is estimated that approximately 30 subjects need to be genotyped to avoid 1 ADR, which has led the Clinical Pharmacogenomics Implementation Consortium (CIPC) to recommend avoidance of the highest simvastatin dose (80 mg) regardless of genotype and use of a dose no higher than 20 mg, along with regular creatine kinase monitoring, in patients known to possess one or more copies of the C allele of rs4149056 (the 521CT or 521 CC genotype).

Hepatotoxicity

Hepatic damage arising from statin therapy has been demonstrated in relevant trials. Hepatotoxicity, defined by an elevation of AST/ALT three times above the upper limit of normal, is seen in around 1–2% of patients on statins, and occurs in a dose-dependent manner. Reversal is seen on dose reduction or cessation of statin therapy.

Diabetes

Results from several studies raised the question of statin therapy potentially having an effect on the incidence of diabetes. The JUPITER trial published results suggesting a causal link between statin therapy and increased incidence of diabetes in the statin arm of the trial, compared to placebo [72]. The opposite finding was reported in an analysis of the WOSCOPS cohort, where statin therapy was associated with reduced frequency of new cases of diabetes in participants receiving pravastatin therapy [73]. A meta-analysis of 13 trials and more than 91,000 participants aimed to resolve this issue, demonstrating a 9% increased risk in incidence of diabetes in patients on statin therapy and a higher risk in older participants [74]. The researchers concluded that this small absolute risk of developing incident diabetes was outweighed by the known cardiovascular benefit conferred by statin use. A prospective cohort study recently published demonstrated a similar risk, which was greater in patients receiving simvastatin, atorvastatin, and rosuvastatin, compared to the reference drug pravastatin [75].

Interactions

Certain drug interactions associated with statin therapy have been identified that increase the likelihood of statin-associated side effects. The majority of these interactions arise through enzyme induction or inhibition of the CYP isoenzymes responsible for statin metabolism, as detailed earlier. It should also be noted that statin therapy could be associated with altered metabolism of concomitant therapies through the same mechanism. A well-established example of this is the elevation of INR seen with statin therapy in patients on warfarin.

Inhibition of the cytochrome P450 isoenzymes can result in increased plasma levels of statins and increased risk of side effects, in particular myopathy and rhabdomyolysis. It is estimated that around a third of patients prescribed a statin are also prescribed a CYP3A4 inhibitor medication, with adverse effects secondary to drug interactions occurring in around 3% of patients [76]. The CYP3A4 isoform, responsible for the metabolism of lovastatin, simvastatin, and atorvastatin, is subject to inhibition by a wide variety of drugs, including macrolide antibiotics, azole antifungals, tricyclic antidepressants, immunosupressants, protease inhibitors, and calcium channel blockers among others. Inducers of the CYP3A4 isoenzyme, such as rifampicin, phenytoin, and St. John's Wort have been identified as reducing the lipid-lowering effect of statins through reduced plasma levels. Similar interactions are seen in statins metabolized by the CYP2C9 isoenzymes.

Outside of the cytochrome P450 system, drug transporters are important mechanisms by which drugs may interact with statin therapy. All statins undergo hepatic uptake through the organic anion-transporting polypeptide (OATP), and several drugs have been identified that either induce or inhibit this pathway. Additional transporters, including P-glycoprotein (P-gp), multidrug resistance-associated proteins (MDR1 and MDR2), breast cancer resistance protein (BCRP), and Na^+-dependent taurocholate cotransporting polypeptide (NTCP), are also subject to similar drug interactions. Several of the statins (atorvastatin, lovastatin, pravastatin, and simvastatin) require glucuronidation through the action of UDP-glucuronosyltransferase 1-1 (UGT-1A) as part of their metabolism, which transforms them into water-soluble products that can be excreted. Inhibitors and inducers of these metabolic pathways, and known statin interactions, are detailed in Table 31.6.

Genetic Variations in the Efficacy of Statins

As mentioned previously, HMG-CoA reductase inhibitors (statins) are associated with a lowering of LDL-C by up to 50%. Despite this, large interindividual variation exists in response to statin therapy. Genetic variations have been identified at various points in the pathways of statin metabolism, affecting the drug's pharmacokinetics and pharmacodynamics. The effect of individual genetic variations on response to statin therapy has been shown to be small and thus the impact on cardiovascular risk has been questioned. A study of the HPS cohort demonstrated an effect size of 0.5–3.0% per allele inherited in 10 common gene variants [77]. In addition, there was no demonstrable effect on cardiovascular risk reduction of statin therapy in association with expression of these common variants.

31.4.3.2 Pharmacokinetic Pharmacogenomics of Statins

As detailed earlier, the enzymes of the cytochrome P450 system are responsible for hepatic phase 1 statin metabolism. Altered pharmacokinetics as a result of genetic variation in the CYP enzymes can lead to altered drug exposure and potentially altered efficacy and increased risk of toxicity.

Various mutations in genes coding for the CYP-metabolizing enzymes have been identified, with varying effects on statin efficacy and toxicity. Polymorphisms in the CYP3A4 gene (rs2740574 and rs4986910), in association with atorvastatin therapy, have been found to have opposite effects on LDL-C [78]. In the case of rs2740574 (M445T variant), carriers of this variant allele at baseline had significantly lower LDL-C levels (−11.2%) relative to noncarriers, and this difference was more pronounced after treatment with atorvastatin (−17.6%). The SNP rs4986910 coded for the A290G variant in a CYP3A4 promotor gene, and homozygotes for this variant were found to have higher LDL-C levels (+12.6%) post-treatment than subjects with 1 or more wild-type allele.

Polymorphisms in the CYP3A5 gene, closely linked to CYP3A4, have been associated with interindividual differences in the efficacy of statin therapy. CYP3A5 is only

TABLE 31.6 Enzyme Inhibitors and Metabolic Pathway Inducers in Statin Metabolism

Metabolic Pathway	Statin	Inhibitors	Inducers
CYP Isoenzymes			
CYP3A4	Atorvastatin, lovastatin, simvastatin	Ketoconazole, itraconazole, fluconazole, macrolides, tricyclic antidepressants, nefazodone, venlafaxine, fluvoxamin, fluoxetine, sertraline, cyclosporin A, tacrolimus, mibefradil, amiodarone, danazol, diltiazem, verapamil, protease inhibitors, midazolam, corticosteroids, grapefruit juice, tamoxifen, sildenafil, warfarin	Phenytoin, phenobarbital, barbiturates, rifampicin, dexamethasone, cyclophosphamide, carbamazepine, omeprazole, St John's Wort
CYP2C9	Fluvastatin, rosuvastatin	Ketoconazole, fluconazole, sulfaphenazole, oxandrolone, amiodarone, dronedarone, warfarin	Rifampicin, phenobarbital, phenytoin

OATP1B1	All statins	Ciclosporin, rifampicin, gemfibrozil, macrolides, indinavir, ritonavir, saquinavir	
Uridine Diphosphate Glucuronyltransferase			
UGT-1A	Atorvastatin, lovastatin, pravastatin, simvastatin	Gemfibrozil, ciclosporin	Rifampicin

CYP—cytochrome P450; MDR—multidrug resistance-associated protein; P-gp—P-glycoprotein; OATP—organic anion–transporting polypeptide; UGT—Uridine 5′-diphospho-glucuronosyltransferase.

expressed in around 10% of Caucasian subjects, and it was postulated that individuals carrying at least one copy of the wild-type CYP3A5*1 allele would show increased statin metabolism, and therefore diminished lowering of LDL-C, relative to those homozygous for the CYP3A5*3 allele deemed nonexpressors of CYP3A5 [79]. In subjects expressing CYP3A5*1, LDL-C levels were higher by 24% than in those CYP3A5*3 homozygotes after one year on treatment with lovastatin, simvastatin, or atorvastatin. It was concluded that patients expressing the CYP3A5*1 allele may require increased doses of statins to achieve the desired hypolipidemic effect.

Genetic variation in CYP2D6 has been associated with variance in both statin efficacy and tolerance. Patients with polymorphisms in CYP2D6, resulting in a status of "poor metabolizers," have been shown to have enhanced lowering of total cholesterol with simvastatin therapy [80]. Unfortunately, decreased simvastatin metabolism resulting in increased drug efficacy also had the effect of increased toxicity, with more patients discontinuing treatment. In addition, a particular polymorphism, the CYP2D6*4 allele (rs3892097), was identified in a study on atorvastatin-induced myopathy as being present in 50% of those affected versus only 28% of controls [81].

CYP7A1 encodes for the 7α-hydroxylase enzyme, which is the catalyst for the rate-limiting step in the synthesis of bile acid from cholesterol. Carriers of the A-204C promoter variant have been shown to experience a significantly reduced efficacy of pravastatin therapy, with an LDL-C lowering effect of 24.3% versus 33.1% in noncarriers [82].

The polymorphisms just discussed are found in the proteins responsible for statin metabolism. The pharmacokinetics of statin therapy is also dictated by the uptake of the drug in a process governed by the membrane uptake transport proteins, in particular the organic anion-transporting polypeptides (OATPs) or the solute carrier organic anion transporters (SLCOs). The focus for much of the investigation surrounding these proteins is centered on the *SLCO1B1* gene, which codes for the OATP1B1 influx transporter and its role in statin-induced myopathy (see earlier).

31.4.3.3 Pharmacodynamic Pharmacogenomics of Statins

The genetic variations detailed earlier concern factors that dictate the pharmacokinetic properties of statins. This section examines variations that govern the pharmacodynamic properties of statins and, in turn, affect the extent to which statins reduce cardiovascular risk. (See Figure 31.4.)

The first step in cholesterol synthesis, and the pharmacological target for statins, is HMG-CoA reductase. It therefore follows that genetic variation in HMG-CoAR potentially leads to variability in statin therapy response. In a study of 1536 patients treated with pravastatin in the PRINCE cohort, two SNPs, 12 and 29 (rs17244841 and rs17238540), were identified with reduced response [83]. These SNPs are in tight linkage disequilibrium with each other. Subjects with one copy of the minor allele of either were found to have a 22% lower reduction in total cholesterol and 19% lower reduction in LDL-C relative to subjects homozygous for the major allele for one of them. A further study of rs17238540 confirmed reduced statin therapy efficacy in subjects expressing the less frequent G allele [84].

The ATP-binding cassette (ABC) transporters G5 and G8 play a role in the intestinal absorption, hepatic transportation, and excretion of cholesterol. The D19H variant (rs11887534) in the *ABCG5/8* gene has been shown to be associated with a greater LDL-C-lowering response with atorvastatin, than the wild-type variant [85].

Apolipoprotein E (Apo E) is present in triglyceride-rich lipoproteins and HDL, and interacts with the LDL receptor to promote lipoprotein clearance. The Apo E gene is polymorphic with three alleles, E2, E3, and E4, in order of increasing affinity for LDL-R. Various studies have shown how variations in Apo E alleles alter lipid levels and potentially CVD risk, as described earlier. Several studies have shown variance in response to statin therapy depending on the Apo E allele expressed, with the E2 allele being associated with an enhanced response and, conversely, the E4 allele being associated with an attenuated hypolipidemic response [86]. It should be noted, however, that results on this relationship are inconsistent and that certain studies have shown that the Apo E genotype loses significance for variable response to therapy when other factors such as BMI, age, and sex are adjusted for. The effect of Apo E polymorphisms and statin therapy on cardiovascular outcomes has also been investigated.

In an analysis of the 4S cohort, the E4 allele was associated with a nearly two-fold increase in mortality relative to noncarriers [87]. This excess risk was found to be almost entirely abolished by statin treatment. However, this finding was not replicated in a further study of the Regression Growth Evaluation Statin Study (REGRESS) cohort, where there were no improvements in angiographic parameters of CAD associated with the Apo E genotype [88]. It can be concluded that variants in the Apo E genotype are associated with varying response to statin therapy, but that the evidence for any effect on cardiovascular outcomes is equivocal.

The role of the cholesterol ester transfer protein (CETP) in lipid metabolism is described in detail elsewhere in this chapter. The most investigated CETP variant is the SNP rs708272, also known as the Taq1B variant. The B1 allele is associated with elevated CETP levels, resulting in lower plasma HDL-C levels, and subjects homozygous for the B1 allele have accelerated atherosclerosis compared to wild-type carriers. Interestingly, studies have shown that subjects with the B1B1 genotype have a more atherogenic lipid profile at baseline, but they respond well to statin therapy and thus incur lower mortality from cardiovascular events than subjects with the seemingly less atherogenic B2 genotype [89].

Statin therapy has an indirect effect, through proprotein convertase subtilisin/kexin type 9 (PCSK9), on LDL-C levels other than that mediated by HMG-CoAR, and polymorphisms in the PCSK9 gene may alter response to statin therapy. Statin-induced upregulation of the sterol regulatory element-binding protein-2 (SREBP-2) results in activation of the *PCSK9* gene, leading to increased plasma PCSK9 levels. It follows therefore that polymorphisms in the *PCSK9* gene result in varying statin response, depending on whether they are "loss-of-function" or "gain-of-function." The clinical consequences of this are described in a following section on PSCK9 as a pharmacological target.

Kinesin-like protein 6 (KIF6) is responsible for the intracellular transport of several molecules, including mRNA. Initial studies in large clinical-trial cohorts identified an association between the rs20455 SNP (Trp719 Arg), increased risk of CVD and increased statin efficacy [90]. In the WOSCOPS cohort, carriers of the 719Arg allele had an absolute CAD risk reduction of 5.5% from statin therapy, with noncarriers having a risk reduction of 0.1%. This benefit of the 719Arg polymorphism was echoed in an analysis of the PROSPER, CARE, and PROVE IT-TIMI 22 cohorts. However, these positive findings have not been replicated in further studies, and a large meta-analysis of 17,000 cases of CAD showed no association between the 719Arg allele and CAD risk compared to noncarriers [91]. This was also the case in the HPS study cohort, where no association between KIF6 polymorphisms and CVD risk or statin response was elicited [92].

FIGURE 31.4 **Statin pharmacokinetics.** Statins are oral inhibitors of HMG-CoA reductase. They enter the systemic circulation by intestinal absorption and transportation through the action of the ABC and SLC gene transporters. Metabolism is mainly hepatic and is driven by the CYP and UGT gene enzymes. Excretion occurs through the biliary route, mediated by the ABC transporters. *Source: Reproduced with permission from PharmGKB and Stanford University (copyright held by PharmGKB).*

Ezetimibe

Ezetimibe is a selective inhibitor of cholesterol absorption that has been shown to be an effective LDL-C lowering agent as monotherapy or in combination with statin therapy.

Ezetimibe is taken as a once-daily oral medication and binds to the intestinal cholesterol transporter Niemann-Pick C1-Like 1 (NPC1L1). The binding of ezetimibe to the transporter protein prevents the vesicular internalization of NPC1L1 and cholesterol into the small intestine, thereby inhibiting its absorption (Figure 31.5). In addition, decreased cholesterol absorption leads to upregulation of genes involved in LDL-C uptake and de novo sterol synthesis, in particular SREBP-2, LDL-R, and HMG-COAR, leading to increased cellular clearance of LDL-C from the plasma.

In monotherapy, ezetimibe was calculated to lower plasma levels of LDL-C, with a mean reduction of 18.58% compared to placebo, in a meta-analysis of eight trials

FIGURE 31.5 **Statin pharmacodynamics.** Statins affect plasma LDL-C levels through inhibition of HMG-CoA reductase, resulting in reduced endogenous production of cholesterol. Various genes affect the pharmacodynamics of statin therapy, and variations in these gene products can alter therapy efficacy and safety. *Source: Reproduced with permission from PharmGKB and Stanford University (copyright held by PharmGKB).*

involving 2722 people [93]. Several studies demonstrated a benefit in combination therapy of ezetimibe with a statin [94,95]. In patients with primary hypercholesterolemia, the addition of ezetimibe proffered an additional 12% reduction in LDL-C compared to monotherapy with atorvastatin, and this finding was echoed in a combination of ezetimibe with simvastatin, where an additional reduction in LDL-C of 13.8% was seen. In the setting of familial hypercholesterolemia, ezetimibe's effect on a surrogate end point of atherosclerosis, carotid-intima thickness (cIMT), was examined with unexpected findings [96]. Despite significant reductions in LDL-C levels, ezetimibe combination therapy with 80 mg of simvastatin was associated with an insignificant increase in cIMT, in comparison to simvastatin monotherapy. In terms of reduction of cardiovascular events, the Study of Heart and Renal Protection (SHARP) demonstrated a 17% reduction with ezetimibe plus simvastatin in the rate of major atherosclerotic events in comparison to placebo [97].

It should be noted that this study was carried out in a select group of patients who had advanced chronic kidney disease. The large Improved Reduction of Outcomes: Vytorin Efficacy International Trial (IMPROVE-IT) recruited 18,000 patients to examine the combination of ezetimibe and simvastatin in patients after acute coronary syndrome. The results are due to be released in 2014 and are hoped to give important information on the effect and safety profile of LDL-C lowering with combination therapy. Concerns were raised about the safety of ezetimibe after the Simvastatin and Ezetimibe in Aortic Stenosis (SEAS) trial found a significantly higher onset of cancer in its treatment arm. This finding, however, was refuted in analysis of the SHARP cohort and also of the data available from IMPROVE-IT [98].

In conclusion, ezetimibe is effective at lowering plasma levels of LDL-C in monotherapy, or in combination with statins. It has been shown to result in lower risk of cardiovascular events, albeit in a select group of patients, and further trial data are awaited with regard to its effect on cardiovascular end points. Current guidelines endorse ezetimibe in addition to statin therapy when LDL-C targets are not met with the maximal tolerated statin dose and when patients are intolerant of statins or have contraindications to them [24].

As mentioned previously, the target for ezetimibe is the cholesterol transporter NPC1L1. Genetic variants in the gene coding for this protein have been identified, with resulting interindividual variety in response to ezetimibe. The possibility of genetic variance in NPC1L1 was first raised when the genomic data of eight individuals not responsive to ezetimibe in terms of LDL-C reductions were examined [99]. One individual possessed two novel polymorphisms in the NPC1L1 gene, V55L and I1233N, both of which were absent in the control group. The authors proposed that compound heterozygosity in this subject was the reason for his lack of response.

In another study, 101 subjects with dyslipidemia were examined with regard to their NPC1L1 genotype and treated with ezetimibe for a total of 12 weeks [100]. Subjects lacking the haplotype 1735C-25342A-27677T were found to have a significantly greater reduction in LDL-C versus those who had at least one copy of the haplotype (35.9% versus 23.6%; $p = 0.0054$). The conclusion reached was that genetic variants in NPC1L1 are responsible for interindividual variability in response to LDL-C lowering by ezetimibe.

Bile Acid Sequestrants

As detailed earlier in the chapter, bile acids are produced in the liver from the cytochrome P450-mediated oxidation of cholesterol. They are then secreted into the intestinal lumen to be either excreted or reabsorbed into the enterohepatic circulation. Bile acid sequestrants (BASs) are one of the oldest lipid-lowering medications available. They act as positively charged nonabsorbable resins that can bind to the negatively charged bile salts, preventing reabsorption into the enterohepatic circulation. Reduced reabsorption of bile acids results in upregulation of hepatic CYP7A1, causing increased oxidation of cholesterol into bile salts, and a depletion of intrahepatic cholesterol. Reduced intracellular cholesterol results in SREBP-driven increased expression of HMG-CoAR and LDLR, with a net effect of reduction in plasma LDL-C concentrations.

Three BASs are available: cholestyramine, colestipol, and colesevelam-HCL. Colesevelam differs slightly from the other first-generation BASs in that it has been synthetically engineered to contain longer hydrophobic side chains, resulting in its increased binding of bile salts. In addition to lowering LDL-C, colesevelam has been shown to reduce HbA1c in patients with type 2 diabetes mellitus [101]. BASs are unfortunately associated with a common frequency of side effects even at low dose, which limits their use in clinical practice. These include gastrointestinal upset such as flatulence, constipation, dyspepsia, and nausea. Another adverse effect of BAS therapy is the reduced absorption of several drugs and fat-soluble vitamins (A, D, E, and K), which has led to the advice that any BAS should be taken four hours before other drugs or one hour after.

The Lipid Research Clinics Coronary Primary Prevention Trial showed a reduction in LDL-C of 20% with cholestyramine therapy versus placebo, with a resultant significant 19% reduction in fatal and nonfatal MIs [102]. This finding has been echoed in further clinical trials for all BASs, with a reduction in LDL-C of 18–25% at maximum dose. The addition of BASs to statin therapy results in an additional LDL-C-lowering effect of 10–15%. The combination of ezetimibe, a statin, and colesevelam was shown to result in significantly increased LDL-C reduction when compared to combination therapy with statin and ezetimibe alone, in a cohort of patients with familial hypercholesterolemia and baseline LDL-C levels >2 mmol/L [103].

Bile acid sequestrants are currently recommended as second-line agents in addition to statin therapy, where targets are not met with maximum tolerated dose of statins or when the patient cannot tolerate them [24].

Novel Medications

Despite statins' universally accepted LDL-C-lowering effect, it is thought that up to 30–50% of patients with moderate to high risk of CVD do not achieve target goals for non-HDL-C [104]. Work is ongoing to discover novel medications that help to further lower LDL-C in patients with very high CVD risk (e.g., familial hypercholesterolemia) or that help patients who are statin-intolerant.

Microsomal Triglyceride Transfer Protein Inhibitors

Microsomal triglyceride transfer protein (MTP) is responsible for the hepatic assembly of VLDL particles through the transfer of triglycerides to apolipoprotein B. Mutations in the MTP gene are known to lead to a deficiency in apolipoproteins B-48 and B-100, known as abetalipoproteinemia, in which sufferers are hypocholesterolemic. It is thought that pharmacological inhibition of MTP results in hepatic production of VLDL, the precursor to LDL, causing a lowering of plasma LDL-C levels.

Lomitapide (BMS-201038) is the only MTP inhibitor to have been investigated in clinical trials. In a small trial of six patients with homozygous familial hypercholesterolemia, lomitapide therapy resulted in an LDL-C reduction of 50.9% [105]. However, one-third of the cohort experienced derangement in liver function tests. This is thought to be due to a side effect of MTP inhibition that causes increased hepatic fat stores and results in a state analogous to nonalcoholic fatty liver disease.

To examine the safety of MTP inhibition further, investigators carried out another study with lomitapide in 29 patients with FH [106]. A similar reduction in LDL-C to that in the first study was found, with 93% of patients reporting gastrointestinal upset. Derangement of liver transaminases greater or equal to three times the upper limit of normal were seen in ten patients, with four demonstrating derangement 5 or more times greater than the upper limit of normal. All derangements were managed with dose reduction or temporary discontinuation, with no permanent discontinuation necessary. The results of this trial led the U.S. Food and Drug Administration (FDA) to approve lomitapide as a therapy for patients with homozygous familial hypercholesterolemia. No surrogate or cardiovascular end-point data for lomitapide is yet available.

Antisense Oligonucleotide Therapies

Mipomersen is an antisense oligonucleotide therapy that specifically binds to the apolipoprotein B-100 mRNA, blocking translation of the gene product. The reduction in production of apo B-100 results in reduced hepatic production of the atherogenic lipoproteins VLDL, IDL, LDL, and lipoprotein(a). Mipomersen has been shown to reduce LDL-C in addition to standard therapy in patient cohorts with homozygous/heterozygous FH, in those with preexisting CAD, and in those intolerant of statin therapy and at high risk of CVD [107,108]. Mipomersen therapy was associated with an additional reduction in LDL-C of 25–37% from baseline. In addition, mipomersen therapy resulted in reduction in levels of apo-B, Lp(A), non-HDL-C, and triglycerides. Some concerns have arisen regarding the effect of mipomersen on liver architecture, with persistent rises in transaminases showing evidence of hepatic steatosis on MRI. Mipomersen is approved by the FDA for therapy in patients with homozygous and severe heterozygous familial hypercholesterolemia.

PCSK9

The effect of mutations in proprotein convertase subtilisin kexin type 9 (PCSK9) on lipid homeostasis were first described in 2003 [31]. Over the following years, the exact mechanism of PCSK9 was elucidated; several more mutations, and their effect on LDL-C levels, have been described. PCSK9 is a serine protease that is secreted by the liver. It acts to regulate plasma LDL-C levels through post-translational downregulation of the LDL-receptor (LDLR), by increased lysosomal degradation. On secretion, the prodomain is autocatalytically cleaved and continues to remain associated with the catalytic domain of the protein; it is thought the reduction of LDLR by PCSK9 is independent of any enzymatic activity.

The role of PCSK9 in cholesterol homeostasis was determined through the discovery of two mutations in the *PCSK9* gene, which led to a third locus associated with autosomal dominant hypercholesterolemia in addition to LDLR and APOB. Shortly after the publication of these findings, it was found that overexpression of PSCK9 in mice, using an adenovirus constitutively expressing murine PCSK9, resulted in a two-fold increase in plasma total cholesterol, a five-fold increase in non-HDL cholesterol, and a near complete absence of LDLR. The reduction in LDLR appeared to be independent of any effect on LDLR mRNA levels, confirming that the effect of PCSK9 on LDLR levels was at a post-translational level [109].

Mutations in PCSK9, and the consequent increase in plasma LDL-C levels and so increased CVD risk, were recognized to be due to the gain-of-function mutations. The potential role of PCSK9 as a therapeutic target arose following the publication by Cohen et al. in 2006 of the discovery of loss-of-function mutations in PCSK9 and an associated reduction in cardiovascular risk through low levels of LDL-C [35]. Cohen et al. reported that approximately 2% of African-Americans were heterozygous for one of two loss-of-function nonsense mutations (Y142X or C679X) in PCSK9, with a resultant 40% reduction in mean LDL cholesterol. This reduction proffered an 80–90% reduction in the incidence of coronary heart disease. Similar results were found in Caucasian subjects through a novel mutation, R46L, resulting in a 15% reduction in LDL-C and a 50% reduction in risk of coronary heart disease.

To date, two methods of PCSK9 inhibition have been investigated. The first is the use of an antisense oligonucleotide (ASO) targeting PCSK9 mRNA. Such a method has been shown to reduce levels of total cholesterol in both mice and nonhuman primates by up to 50% [110], achieved through a lowering of plasma levels of PCSK9 mRNA and protein with increased hepatic expression of LDL-R protein. The second method has been to target the binding of PCSK9 and LDLR through use of humanized anti-PCSK9 monoclonal antibodies. Several such drugs are in ongoing clinical trials, and early results appear promising. In comparison to placebo, injection of the monoclonal antibody REGN727 in patients with familial hypercholesterolemia resulted in marked reductions in LDL-C with no significant adverse effects [111].

In another study, the combination of REGN727 with 80 mg of atorvastatin was associated with a 73.2% reduction in LDL-C, in comparison to 17.3% in those receiving atorvastatin 80 mg plus placebo [112]. A similar reduction (66.2%) was seen in those receiving a lower dose of atorvastatin (10 mg) in addition to REGN727. Subjects in the study treatment group also demonstrated significant reductions in Apo B, non-high-density lipoprotein-C, lipoprotein(a), and triglycerides, with no significant adverse findings, although further, adequately powered studies are required to fully assess the safety profile of such drugs.

The studies just described show promise in the therapeutic lowering of PCSK9 levels and subsequent reduction in LDL-C levels greater than that currently achieved with statin therapy alone. In years to come, this approach will potentially play a vital role in cholesterol-lowering therapy in patients intolerant of statins and in those for whom statin therapy does not achieve target levels of LDL-C, with the aim of reducing cardiovascular risk beyond that currently possible.

31.4.4 HDL-C

The role of elevated LDL-C and low levels of plasma HDL-C in increasing cardiovascular risk were described in detail earlier. The reduction in LDL-C levels through statin therapy has been shown to significantly reduce the incidence of and mortality associated with coronary heart disease [10]. However, many patients still show increased residual risk along with increased incidence of cardiovascular events despite adequate statin therapy, particularly with the rising prevalence of obesity, type 2 diabetes mellitus, and the metabolic syndrome.

Several studies have demonstrated that low HDL-C levels are an independent risk factor for cardiovascular events [13,14]. Elevating HDL-C levels to reduce cardiovascular risk, in addition to reductions gained by lowering LDL-C, has been an important target for pharmacological therapy as an adjunct to statins. To date, this potential avenue for lowering CVD risk has not been successful, leading to questions concerning the role of HDL-C as a causal factor in CVD risk [56].

31.4.4.1 CETP

Similar to the development of PCSK9 inhibitors, the Mendelian disorder of CETP deficiency was the stimulus for the development of cholesteryl ester transfer protein (CETP) inhibitors. CETP plays a vital role in the atheroprotective process of reverse cholesterol transportation, which was described in detail earlier. In summary, CETP involves the HDL-mediated transport of cholesterol from the peripheral tissues to the liver for recycling or excretion as bile acids. It is secreted by hepatic and adipose tissue and is circulated in the plasma, bound to HDL-C molecules. It aids the transfer of cholesterol esters, in exchange for triglyceride molecules, from HDL to VLDL and LDL. Patients with CETP deficiency have markedly elevated HDL-C levels, and it was thought that pharmacological inhibition of CETP could induce a state analogous to CETP deficiency, with the aim of increasing HDL-C and potentially reducing CVD risk. Observational data from two large genome analyses showed an association of SNPs around the CETP locus with HDL-C levels and CVD risk, with inhibition of CETP resulting in higher HDL-C levels and a concordant CVD risk reduction [113,114].

To date, several CETP inhibitors have been investigated with varying results. The first, torcetrapib, was an irreversible CETP inhibitor that was found to increase HDL-C levels by up to 106% at maximum dosage [115]. In an effort to ascertain the clinical effect of torcetrapib, the trial known as Investigation of Lipid Level Management to Understand its Impact in Atherosclerotic Events (ILLUMINATE) randomized 15,067 subjects with a background of CVD or type 2 diabetes to torcetrapib plus atorvastatin or placebo plus atorvastatin [116]. The trial was stopped only 1.5 years into the planned 4.5-year follow-up as there was found to be a significantly increased rate of cardiovascular events in the torcetrapib group versus placebo (464 versus 373; HR 1.25; 95%CI 1.09–1.44). This was despite a seemingly beneficial change in lipid profile, with an increase in HDL-C of 72.1% and a decrease in LDL-C of 24.9% from baseline at 12 months. It was additionally found that systolic blood pressure in the torcetrapib group was significantly raised by 5.4 mmHg versus placebo, and that there were significant decreases in serum potassium and increases in serum bicarbonate, sodium, and aldosterone. It was thought that the excess mortality and changes in blood pressure found were possibly due to off-target effects of torcetrapib on the renin–angiotensin–aldosterone system.

Dalcetrapib is a weaker CETP inhibitor that was found to increase HDL-C by around 30% with very little effect on LDL-C [117]. Initial phase II safety trials were promising, with dalcetrapib therapy being well tolerated without significant changes in blood pressure or any change in atherosclerotic plaque progression/vascular inflammation as visualized by PET-CT imaging [118]. The dal-OUTCOMES trial was a large multicenter placebo-randomized control trial involving 15,871 patients with a recent acute coronary syndrome [119]. These patients were randomized to dalcetrapib or placebo in addition to standard evidence-based statin therapy. Dalcetrapib was associated with a significant increase in HDL-C levels compared to placebo; however, the trial was stopped at interim analysis on the grounds of futility given that treatment with dalcetrapib had no significant effect on cardiovascular outcomes. Interestingly, the researchers found no association between baseline HDL-C levels and risk of cardiovascular events in either the treatment or the placebo arm of the trial cohort. The trial did not find any concerns with regard to adverse effects associated with dalcetrapib, except for a small (0.6 mmHg) increase in systolic blood pressure in comparison to placebo.

The third CETP inhibitor to be investigated, anacetrapib, is a powerful CETP inhibitor that raises HDL-C by 138% and lowers LDL-C by 40%, compared to placebo, with no apparent safety concerns [120]. Its role as an adjunct to optimal lipid-lowering therapy on cardiovascular outcomes is currently being investigated in the Randomized Evaluation of the Effects of Anacetrapib through Lipid-modification (REVEAL) study, the results of which are expected in 2017. Evacetrapib, the fourth CETP inhibitor, is similarly being investigated in a large phase III outcome trial in the Assessment of Clinical Effects of Cholesteryl Ester Transfer Protein Inhibition with Evacetrapib in Patients at a High-Risk for Vascular Outcomes (ACCELERATE) trial. Phase II studies found evacetrapib to have an effect on the lipid profile, with a rise in HDL-C of 79–89% and a decrease in LDL-C of 11–14% in conjunction with statin therapy [121].

To date, the cardiovascular outcome data on CETP inhibitors have been disappointing, with two large phase II trials failing to reach completion because of adverse effects (torcetrapib) and futility (dalcetrapib). It is hoped that the two trials currently under way will show the benefit of this novel class of drugs on cardiovascular outcomes through modification of the plasma lipid profile, in particular its action on HDL-C.

31.4.4.2 Nicotinic Acid (Niacin)

Nicotinic acid, better known as Niacin, was first noted, in the 1950s, to cause decreased levels of total cholesterol and LDL-C along with increased HDL-C. Later, it was also shown to cause decreased levels of triglycerides and lipoprotein(a). Niacin's role as a therapeutic intervention in the management of lipid abnormalities, in particular raising HDL-C levels, has been extensively investigated with varying results.

Niacin alters plasma lipid parameters through various mechanisms. It exerts an anti-lipolytic action through activation of the nicotinic acid receptor HCA_2 (also known as G protein-coupled receptor (GPR109A), resulting in inhibition of cyclic adenosine monophosate (cAMP) and a decreased release of free fatty acids from adipose tissue. This causes decreased hepatic synthesis of triglycerides, along with VLDL particles, and consequently decreased levels of LDL-C. Additionally, the reduction in plasma supply of free fatty acids to the hepatic tissue has been shown to result in decreased hepatic expression of peroxisome proliferator-activated receptor γ (PPARγ), coactivator-1β (PGC-1β), and apolipoprotein C-3 (APOC3). This has the consequence of reduced hepatic production and increased clearance of VLDL particles.

Niacin has also been shown to decrease hepatic triglyceride synthesis directly, through inhibition of diacylglycerol acyltransferase-2. Its effect on the plasma HDL-C profile is less clear but is thought to have several aspects. It has been shown to cause decreased hepatic clearance of ApoA1, the major component of HDL-C, resulting in increased reentry of HDL-C into the circulation from hepatic cells. It has also been shown to increase plasma HDL-C through decreased CETP gene expression, resulting in decreased exchange of cholesterol esters (HDL-C) and triglycerides (LDL-C and VLD-L). Niacin has also been purported to have effects on the atherosclerotic process, independent of lipid profile modification. It has been shown to inhibit expression of vascular cell adhesion molecule 1 (VCAM1), resulting in stabilization of atherosclerotic plaques alongside an anti-thrombotic effect. In addition, niacin-mediated activation of macrophages expressing the HCA_2 receptor results in increased transcription and activity of PPARγ, and the cholesterol transporters ABCA1 and ABCG1. This process increases the efflux of cholesterol from atherosclerotic plaques to HDL-C through reverse cholesterol transport.

As detailed in the preceding paragraph, the receptor GPR109A is responsible for the lipid-lowering mechanism of niacin. GPR109A is coded for by the HM74A gene and a gene adjacent to it, HM74, has been found to code for a similar receptor, GPR109B. Genomic analysis has demonstrated variance in the haplotypes for these two genes. However, to date there is no data suggesting any interindividual variability with regard to response to niacin [122].

The role of niacin in a clinical setting with the purpose of reducing cardiovascular end points by its modification of the plasma lipid profile has been intensively studied. The hope is that it can help to reduce the residual risk that remains despite intensive lowering of LDL-C by statin therapy. Niacin has an effect on the whole spectrum of dyslipidemia, with a rise in HDL-C of 15–35% seen, along with a reduction in LDL-C and triglycerides by 15–18% and 20–40%, respectively. One of the first studies to show a potential benefit of niacin therapy was the Coronary Drug Project (CDP), which found that, in a population of 8341 males after myocardial infarction, niacin therapy resulted in no reduction in overall mortality versus placebo. However, it did display a statistically significant 14% relative risk reduction in nonfatal MI versus placebo.

A 15-year follow-up study of the niacin treatment arm showed an 11% reduction in overall mortality [123]. Several studies have examined the effect of niacin on surrogate end points of atherosclerosis, in particular carotid intima-media thickness (cIMT)—a measurement of atherosclerotic plaque thickness using ultrasound. Arterial Biology for the Investigation of Treatment Effects of Reducing Cholesterol (ARBITER) 3, the third in a series of trials examining the effect of niacin in addition to simvastatin therapy on cIMT [124]—demonstrated a significant reduction in cIMT in subjects receiving niacin and simvastatin versus placebo and simvastatin. Following these trials, which suggested a potential positive benefit on cardiovascular outcomes and surrogate markers from niacin therapy, two large clinical trials were designed with the aim of proving a benefit of niacin in combination with statin therapy.

AIM-HIGH was a double-blind randomized control trial (RCT) that examined the effect of simvastatin (± ezetimibe to achieve LDL-C <2.07 mmol/l) plus niacin, versus simvastatin (± ezetimibe) plus placebo, on the primary composite end point of death from coronary heart disease, nonfatal myocardial infarction, ischemic stroke, hospitalization for an acute coronary syndrome, or symptom-driven coronary or cerebral revascularization [125]. The trial was stopped early because of a lack of proven efficacy of niacin versus placebo after 36 months of follow-up, despite significant rises in HDL-C in the niacin group versus placebo. A much larger trial, HPS2-THRIVE, looked at 25,673 patients receiving niacin plus the antiflushing agent laropiprant in addition to statin therapy. It failed to show a benefit of niacin therapy on the primary outcome of a combination of coronary death, nonfatal myocardial infarction, stroke, or coronary vascularization. In addition, an increase in adverse events was seen in the treatment arm, with a significant increase in diabetic complications and new-onset diabetes.

Unfortunately, niacin therapy is associated with a high incidence of the side effect of flushing due to the activation of the nicotinic acid receptor HM74A and the subsequent release of prostaglandins PGI_2, PGD_2, and PGE_2. Interestingly, in a study of mice lacking the gene (PUMA-G) coding for GPR109A, it was found that the mice lacked any flushing response to niacin [126]. This suggests that any genetic predisposition to a lack of flushing response to niacin will also, unfortunately, negate any lipid-lowering effect, given that the two share a common receptor.

Because of the negative results of these trials, current guidelines suggest that the use of niacin should be considered only in subjects with triglyceride levels >2.3 mmol/L (200 mg/dL).

31.4.4.3 Triglycerides

The role of elevated triglyceride levels in cardiovascular risk was discussed in more detail elsewhere in the chapter. In summary, recent data suggest that there is a causal link between triglyceride-containing lipoproteins, triglyceride-mediated pathways, and cardiovascular disease. In addition, elevated levels of triglycerides (>10 mmol/l or 880 mg/dl) bring a hugely increased risk of acute pancreatitis and necessitate preventative action. The causes of elevated triglyceride levels are multiple and are summarized in Table 31.7. In cases of secondary hypertriglyceridemia, management should include, where possible, addressing the underlying problem. Several pharmaceutical methods of triglyceride lowering have been identified and their efficacy and effect on cardiovascular risk is discussed next.

TABLE 31.7 Primary and Secondary Causes of Hypertriglyceridemia

Primary	Secondary
Familial hypertriglyceridemia	Alcohol excess
Familial combined hyperlipidemia	Obesity
Familial dysbetalipoproteinemia	Physical inactivity
Familial hypoalphalipoproteinemia	Type 2 diabetes
Familial chylomicronemia	Renal disease
	Pregnancy
	Hypothyroidism
	Autoimmune disorders
	Drugs: thiazide diuretics; β-blockers; estrogens; corticosteroids; isoretinoin; ciclosporin; bile acid-binding resins; antiretroviral protease inhibitors; antipsychotics

Fibrates

Fibrates act to reduce triglyceride levels through the activation of the nuclear transcription factor peroxisome proliferator-activated receptor-α (PPARα). Once activated, PPARα binds to another nuclear receptor, rentinoid X. The resultant heterodimer binds to specific peroxisome proliferator response elements, causing alterations in the expression of genes controlling lipid metabolism. Activation of lipoprotein lipase and apo A-V, along with reduced production of apo C-III, results in increased lipolysis and clearance of triglyceride-rich lipoproteins. Also, the production of Apo-B and VLDL is diminished and the clearance of LDL is increased. Fibrates also have the effect of increasing HDL through increased production of apo A-I/II.

Fibrates have been shown to be effective in lowering triglycerides by up to 50%, with an additional effect on raising HDL-C levels. The latter appears to be greatest in those with low baseline levels. Despite the benefits of fibrate therapy for lipid profiles, the data pointing toward their benefit for cardiovascular outcomes are limited. The Fenofibrate Intervention and Event Lowering in Diabetes (FIELD) study, a large study involving almost 10,000 patients with type 2 diabetes, failed to show any benefit of fibrate versus placebo on the primary end point of cardiovascular event incidence. However, it did show a significant relative reduction (24%) in nonfatal myocardial infarction in its fibrate arm [127].

Similarly, the Action to Control Cardiovascular Risk in Diabetes (ACCORD) trial reported no benefit in the combination of fibrate and simvastatin, versus simvastatin alone, on rates of fatal cardiovascular events, nonfatal myocardial infarction, or stroke [128]. A meta-analysis published in 2010 of 18 trials with more than 45,000 patients and 2870 major cardiovascular events, 4552 coronary events, and 3880 deaths, reported a 10% relative risk reduction for major cardiovascular events driven primarily by a 13% relative risk reduction for coronary events, but found no significant benefit on cardiovascular mortality [129]. This benefit was more evident in patients with high baseline triglyceride levels. Current guidelines advocate the use of fibrates to lower triglycerides in patients with severe hypertriglyceremia (>2.3 mmol/L or 200 mg/dL) [24].

Several studies have identified common polymorphisms associated with a variation in triglyceride-lowering in response to fibrate therapy. These include variants at CYP7A1, the APOA1/C3/A4/A5 cluster, and the PPARα locus. In a candidate gene study of loci identified through a large GWAS, in which 95 loci were identified in association with variance in lipid levels, the investigators identified a significant association between increased levels of triglycerides and HDL in response to fibrate therapy and the rs964184 SNP near the APOA1 locus [130].

Omega 3 Fatty Acids

The omega 3 fatty acids (also known as n-3 polyunsaturated fatty acids)—eicosapentenoic acid (EPA), and docosahexenoic acid (DHA)—are naturally occurring fats in fish oils. Administration of fish omega 3 fatty acids as a dietary supplement has been shown to lower triglyceride levels by around 30%, through a mechanism not entirely understood but thought to involve decreased hepatic secretion of VLDL. They have also been purported to inhibit development of atherosclerosis, reduce blood pressure, and have an antiarrhythmic effect. However, there are conflicting results on their beneficial effect on these parameters.

Epidemiological data from the 1970s pointed toward the potentially beneficial effect of omega 3 fatty acids on the CVD risk in Greenland Eskimos. Two large studies have shown a positive benefit, in the role of secondary prevention, in both post-myocardial infarction patients and in patients with heart failure, on CVD mortality and morbidity [131,132]. However, a recently published study demonstrated no benefit associated with omega 3 fatty acids in the primary prevention of death from CVD or in CVD hospital admissions, in a cohort with multiple cardiovascular risk factors, but no history of previous myocardial infarction [133]. Several meta-analyses of trials examining omega 3 fatty acids have reported conflicting results on the effect on CVD risk and mortality [134]. Their use is currently advocated in patients with elevated triglycerides as an adjunct to diet if levels exceed 5.6 mmol/L (496 mg/dl) [24].

31.5 CONCLUSION AND FUTURE DIRECTIONS

This chapter highlighted the important role that lipids play in the body's metabolism and in determining CVD risk. The individual aspects of the plasma lipid profile were examined, highlighting elevated LDL-C levels as the most significant factor in increasing that risk. Measurement of plasma LDL-C levels, along with novel markers such as apo B and Lp(a) remain the mainstay of CVD risk estimation. Observational data have shown low levels of HDL-C to be an independent risk factor; however, pharmacological elevation of HDL-C has, to date, not shown any positive impact on risk reduction. Recent data point toward the role of triglyceride-mediated pathways in increased risk of CVD. This remains an important avenue of investigation.

The identification of monogenic dyslipidemias (e.g., mutations in the LDL receptor, MTP, and PCSK9) has opened up new avenues for pharmacological targeting of lipid pathways. Along with monogenic disorders, multiple common genetic variants have been identified as playing a role in altering plasma lipid levels. However, because the vast majority of these variants have been shown to have relatively small effect sizes, it is thought that the cumulative effect of several variants is more important in determining an individual's plasma lipid levels than individual variants alone. Work is ongoing to identify variants with significant effect sizes in the hope that this will improve cardiovascular risk assessment and potentially highlight new genetic targets for pharmacological therapy.

The extensive work on the pharmacogenetic response to lipid-modifying therapy, in particular statin therapy, has highlighted novel genes and pathways (*SLCO1B1, APOE LDL-R*, *PCSK9*, *KIF6*, *CLMN*) that may enable more targeted management of cardiovascular risk. Current clinical management of dyslipidemia and elevated CVD risk involves administering lipid-lowering therapy to those above a certain threshold of cardiovascular risk estimated from a prognostic model. Monitoring of LDL concentrations is commonly utilized to guide treatment.

There are challenges in implementing pharmacogenomic discoveries in routine clinical practice. Overcoming them requires wider availability of clinically licensed testing, more compelling evidence of efficacy, cost effectiveness analysis, and smoother integration of pharmacogenomic information into clinical decision making. As most statins are now off-patent, there may not be a great incentive to reduce their use. Given that approximately four individuals must be screened to identify one at a higher risk of myopathy, it may well be less expensive do without genotyping and simply start individuals on statin drugs/doses that are less likely to have muscle toxicities.

The example of *SLCO1B1* indicates that pharmacogenomics is a powerful way to stratify patients for risk of adverse effects. It shows that: (1) the genetically mediated risk is not readily identified by other means; (2) the variants are common and the effects are large; and (3) treatment modifications in the form of increased monitoring or alternative therapy are available. Vanderbilt University is an example of an institution where SLCO1B1 genotyping has been implemented into clinical practice [135]. Patients with risk factors for cardiovascular disease who may need statin therapy in the future are genotyped for SLCO1B1 521T>C preemptively and the results are placed in their electronic health record. An electronic order for simvastatin triggers an electronic alert to warn about the increased risk for myopathy in patients with the CC or CT genotype.

Chapter Outline

32.1 Overview **747**
32.2 Epidemiology and Public Health Impact **747**
  32.2.1 Risk Factors for Hypertension 748
  32.2.2 Hypertension Causation 748
  32.2.3 Heritability of Blood Pressure and Hypertension 748
32.3 Genetic Basis of Hypertension **749**
  32.3.1 Sodium and Vascular Volume 749
  32.3.2 Autonomic Nervous System 753
  32.3.3 Vascular Mechanisms 753
32.4 Need for Stratified Approaches to Treatment with Antihypertensives **754**
  32.4.1 Nongenetic Approaches 755
  32.4.2 Genetic Approaches 758
32.5 Pharmacogenomics of Blood Pressure Response to Antihypertensive Drugs **758**
  32.5.1 Thiazide Diuretics 758
  32.5.2 β-Blockers 761
  32.5.3 Calcium Channel Blockers 762
  32.5.4 ACE Inhibitors and ARBs 763
32.6 Pharmacogenomics of Antihypertensive Treatment—Related Outcomes **764**
  32.6.1 Clinical Trials 764
  32.6.2 Genes with Strong Evidence of Association with Treatment-Related Outcomes 764
  32.6.3 Additional Genes with Evidence of Association with Treatment-Related Outcomes 769

32.1 OVERVIEW

Blood pressure (BP) is determined by cardiac output and peripheral vascular resistance—cardiac output depends on stroke volume and heart rate, while peripheral resistance depends on functional and anatomic changes in the small arteries (lumen diameter 100–400 μm) and arterioles. BP is expressed as two numbers—systolic BP (SBP) is the highest pressure in each cardiac cycle and is related to cardiac output, while diastolic BP (DBP) is the lowest pressure in the cardiac cycle and reflects peripheral vascular resistance. BP is a quantitative trait and is normally distributed in the general population. Variation in extracellular fluid volume, the contractile state of the heart, and vascular tone determine variation in BP level.

32.2 EPIDEMIOLOGY AND PUBLIC HEALTH IMPACT

In adults, there is a continuous, incremental risk of cardiovascular disease, stroke, and renal disease, with increasing BP starting as low as 115/75 mmHg [1]. Hypertension as a disease process was borne out in epidemiologic studies demonstrating that people with elevated BP have a greater risk of developing strokes and heart attacks than matched people with normal BP. Hypertension is defined based on a cut-off at the upper end of BP distribution, “at which the benefits of action (i.e., therapeutic intervention) exceed those of inaction” [2]. Based on this definition, there are more than 1 billion people with high BP worldwide, and the World Health Organization (WHO) suggests that this will

rise to 1.5 billion by 2020 [3]. Hypertension is estimated to contribute 3.5 times more to the total global disease burden of cardiovascular disease than smoking and 1.6 times more than hypercholesterolemia. Worldwide, 20% of deaths in men, 24% of deaths in women, 62% of strokes, and 49% of heart disease are attributable to BP [4].

32.2.1 Risk Factors for Hypertension

The risk factors for hypertension can be classified into modifiable (weight, diet, smoking, alcohol intake, diabetes, physical activity, psychosocial stressors) and unmodifiable factors (age, sex, ethnicity, family history). Males generally have higher BP than females. SBP increases linearly at age 30–84 years along with mean arterial pressure, but DBP increases linearly up to age 50–60 years, after which it begins to decline, with a steep increase in pulse pressure [5,6]. The late decline of DBP after the age of 60 years and the continuous rise in SBP reflect increased large-artery stiffness in older age. Positive associations have also been documented between body mass index (BMI) and BP in both cross-sectional and prospective studies [7]. The odds of progression to hypertension increase by 20–30% for every 5% gain in body weight. There is a consistent dose–response relation between salt intake and BP within the range of 3–12 g salt per day. A reduction of only 3 g per day predicts a decrease in BP of 3.6–5.6/1.9–3.2 mmHg in hypertensive subjects and 1.8–3.5/0.8–1.8 mmHg in normotensive subjects [8,9]. At all ages, hypertension is more common in African-Americans than in whites; in all ethnic and racial groups, it is more common in the economically disadvantaged. Interestingly, hypertension is more prevalent in the African-American population in the United States than in African Caribbean and native black African populations [10,11]. In some societies, BP shows only a small age-related increase and may be related in part to an agrarian lifestyle and in part to the high-potassium and low-sodium diet of the hunter-gatherer, the low level of formal education, a more rural lifestyle, a lower consumption of food, and cultural isolation [12–15].

From an evolutionary perspective, high BP may be the undesirable pleiotropic effect of a genotype that may have optimized fitness in an ancient environment. When humans arrived >40,000 years ago, they lived in this primarily salt-poor environment consuming <690 mg of salt per day. This required ancestral humans to develop a kidney-based regulatory mechanism for the conservation of extracellular fluid and electrolytes; natural selection over generations molded their adaptation to the low salt content in their environment. However, in modern society access to salt is almost unlimited, with a sodium consumption of about 4 g or more per day (equivalent to 10 g of salt) [16]. Thus, high BP is a disease of modern civilization with its abundance of dietary salt, processed foods, and longer lifespans [17]. Different populations show different predispositions to the trait, and this may reflect different evolutionary selection pressures given that different populations do not necessarily share the same ancestral histories. For example, hypertension occurs earlier and with more severity in people of African ancestry compared to those of European ancestry [18]. The rates of hypertension and sodium sensitivity are generally higher in individuals carrying the ancestral alleles of sodium-conserving genes, which show strong latitudinal clines with the ancestral sodium-conserving alleles more prevalent in African populations and less so in northern regions [19–22]. It is also hypothesized that the renin–angiotensin–aldosterone system (RAAS) was initially adapted for sodium conservation and may be maladaptive in modern societies with ready access to dietary sodium [22].

32.2.2 Hypertension Causation

The majority (95%) of individuals with hypertension have essential or primary hypertension, in which no single underlying cause is identified for the high BP, which is thought to result from a genetic predisposition underlying the cumulative effects of various lifestyle factors over many years. The remaining 5% of patients have secondary hypertension, which is due to an underlying disease or is a side effect of medication. The most common underlying condition is chronic kidney disease, but others include monogenic syndromes and structural abnormalities in the cardiovascular system.

32.2.3 Heritability of Blood Pressure and Hypertension

Family studies have consistently demonstrated a genetic component influencing BP and hypertension. The Montreal adoption study [23] demonstrated correlation coefficients of 0.38 and 0.16 between biological and adoptive siblings, respectively, while the Victorian Family Heart Study [24] estimated correlation coefficients of 0.44 for nontwin siblings, 0.78 for monozygous twins, 0.50 for dizygous twins, and 0.12 for spouse–spouse pairs. Hunt et al. [25] showed familial aggregation of hypertension from an analysis of life table data for 94,292 persons, and found the relative risks of developing hypertension to be 4.1 in men and 5 in women aged 20–39 who had at least two first-degree relatives affected by hypertension. Two additional measures that are commonly used to assess the genetic component of a trait are heritability (h^2)—the fraction of variation in disease susceptibility due to genetic factors, and sibling recurrent risk (λs)—the degree of elevated risk of disease for a sibling of an affected individual compared with a member of the general population. The heritability of clinical SBP and DBP is around 15–40% and 15–30%, respectively; for ambulatory night-time SBP and DBP, the heritabilities are 32–70% and 32–50% [26–32]. The sibling recurrent risk

(λ_s) of hypertension is ~1.2–1.5 [33]. Taking this along with heritability and correlation estimates, hypertension and BP can be considered traits with relatively modest genetic effects.

32.3 GENETIC BASIS OF HYPERTENSION

The genetic basis of hypertension is best understood by reviewing the causative genes for the rare monogenic forms of hypertension and the common single-nucleotide polymorphisms (SNPs) that have been identified from large-scale genome-wide association studies (GWASs) (Table 32.1, Figure 32.1).

32.3.1 Sodium and Vascular Volume

Vascular volume is a primary determinant of arterial pressure over the long term; sodium is the principal determinant of extracellular fluid volume. The effect of sodium on BP is related to NaCl—nonchloride sodium salts have little or no effect on BP [34,35]. Mendelian forms of syndromic hypotension and hypertension [36] have all been linked to mutations in genes whose encoded proteins regulate the balance of salt and water in the kidney (Table 32.1).

Glucocorticoid-remediable aldosteronism or familial hyperaldosteronism type 1 (FH-I, OMIM #103900) is an autosomal dominant syndrome in which hypertension is caused by increased aldosterone secretion driven by

Note: Key genes at each locus are shown with their known or potential BP-regulating pathway and established antihypertensive treatment. GWAS studies: AGEN [7], BP-Extremes [10], CHARGE [8], GBPG [9], Gene-centric [6], HYPERGENES [11], and ICBP [5].

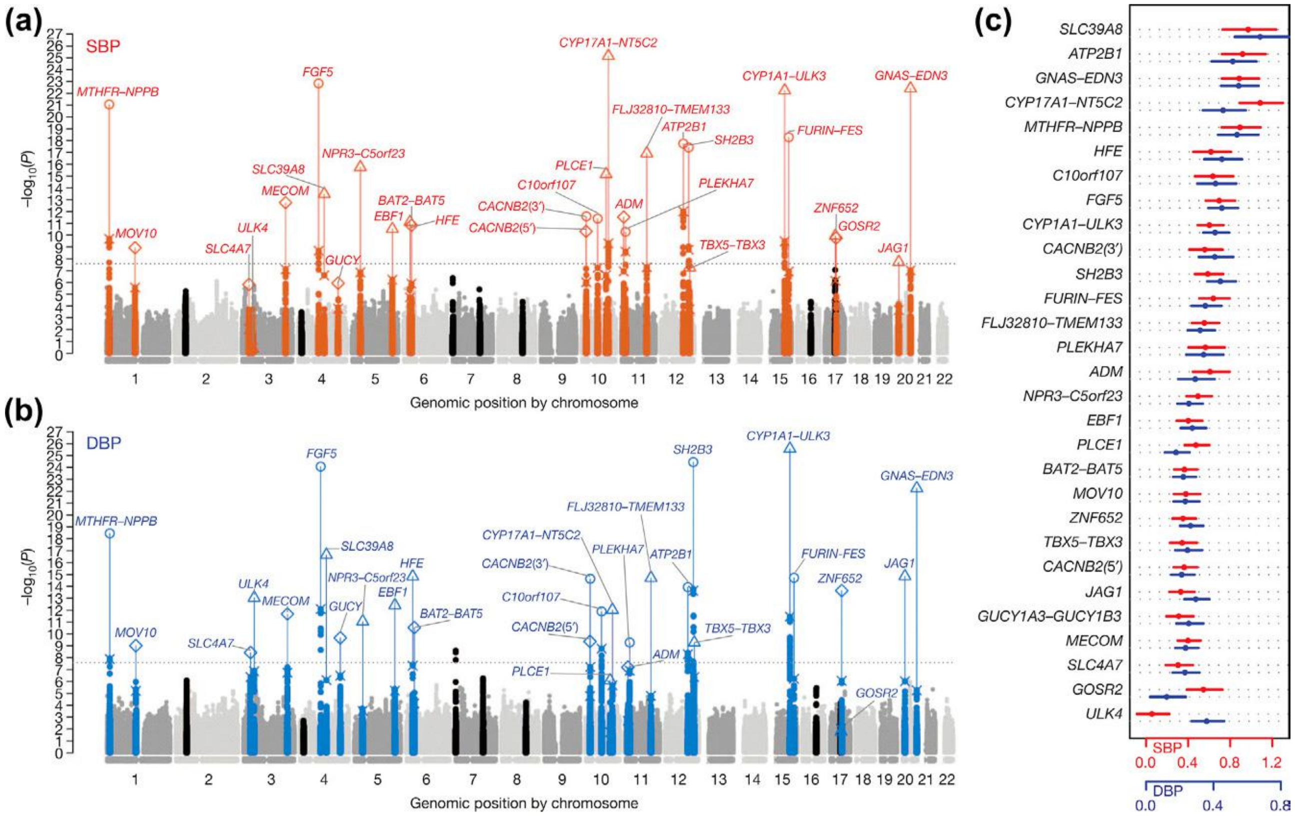

FIGURE 32.1 Genome-wide $-\log_{10}$ p-value plots and effects for significant loci. The plots are shown for systolic (SBP: panel a) and diastolic (DBP: panel b). SNPs in loci reaching genome-wide significance are labeled in red for SBP and blue for DBP (±2.5 Mb of lowest p-value); lowest p-values in the initial genome-wide analysis as well as the results of analysis, including validation data, are labeled separately. The lowest p-values in the initial GWAS are denoted by "X." The range of sample sizes in the final meta-analysis, including the validation data, are denoted by a circle (96–140 k), triangle (>140–180 k), and diamond (>180–220 k). SNPs near unconfirmed loci are in black. The horizontal dotted line is $p = 2.5 \times 10^{-8}$. Panel c shows the effect size estimates and 95% confidence bars per BP-increasing allele of the 29 significant variants for SBP (red) and DBP (blue). Effect sizes are expressed in mmHg/allele. the adrenocorticotropic hormone (ACTH). It results from a chimeric gene containing the 5′ regulatory sequences of 11β-hydroxylase (*CYP11B1*) (which confers ACTH responsiveness) fused with the distal coding sequences of aldosterone synthase (*CYP11B2*), leading to the use of ACTH rather than angiotensin II or potassium as the main controller of aldosterone secretion [37]. In contrast, familial hyperaldosteronism type 2 (FH-II, OMIM #605635) is an autosomal dominant syndrome due to hyperplasia or adenoma of the aldosterone-producing adrenal cortex. The genetic abnormality causing FH-II has been localized to chromosome 7p22 [38], though the causative gene has not yet been identified. Apparent mineralocorticoid excess (OMIM #218030) is another low-renin hypertension syndrome accompanied by hypokalemia and metabolic alkalosis. The main defect in apparent mineralocorticoid excess is absence or reduced activity of 11β-hydroxysteroid dehydrogenase (*HSD11B2*), resulting in hypertension in which cortisol acts as a potent mineralocorticoid [39]. Finally, defects in enzymes of cortisol biosynthesis result in autosomal recessive disorders collectively called congenital adrenal hyperplasia (CAH) [40]—11β-hydroxylase (OMIM #202010; *CYP11B1*), 3β-hydroxysteroid dehydrogenase (OMIM #613890; *HSD3B2*), 17α-hydroxylase (OMIM #609300; *CYP17A1*), and cholesterol desmolase (OMIM #118485; *CYP11A1*).

Monogenic low-renin hypertension syndromes can also be caused by mutations in renal ion transporters. Pseudohypoaldosteronism type II (Gordon's syndrome; familial hyperkalemia; OMIM #145260) is an autosomal dominant form of hypertension associated with hyperkalemia, nonanion gap metabolic acidosis, and increased salt reabsorption by the kidney. It is caused by mutations in the WNK kinases [41]. Gordon's syndrome thus results from either gain-of-function mutations in *WNK1* or loss-of-function mutations in *WNK4*. Liddle's syndrome (OMIM #177200) is an autosomal dominant condition with a clinical picture of hypertension and aldosterone excess, but with very low aldosterone and renin levels, caused by mutations in the genes coding the beta or gamma subunits of ENaC (*SCNN1B*, *SCNN1G*) resulting in deletions of proline-rich regions [42,43]. These regions facilitate binding of Nedd4-2 (*NEDD4L*), a regulatory repressor that promotes channel degradation. The inability of beta and gamma subunits to bind Nedd4-2 results in constitutive expression of sodium channels and prolongs the half-life of ENaCs at the renal distal tubule apical cell surface, leading to increased rates of sodium reabsorption, volume expansion, and hypertension.

Conversely, mutations that reduce salt retention, such as those associated with Bartter's (*SLC12A1, KCNJ1, CLCNKB, BSND, CaSR, ClCK-A*) syndrome and Gitelman's (*SLC12A3*) syndrome, tend to lower BP and protect against hypertension [36,44]. In addition to the kidney, the heart secretes a family of vasodilatory and natriuretic hormones in response to increased wall stress—atrial natriuretic peptide (*NPPA*) and B-type natriuretic peptide (*NPPB*). Knockout of one copy of *NPPA* in mice increases BP, while overexpression of *NPPA* lowers BP [45,46]. There is now convincing evidence that common variations in the *NPPA-NPPB* locus influence levels of natriuretic peptides and BP in opposite directions [47–50]. Furthermore, a SNP near the natriuretic peptide clearance receptor (*NPR3*) also showed genome-wide significant association in European, African, and Japanese BP GWASs [47,50,51]. A GWAS for hypertension using an extreme case-control design identified a SNP in the 5′ region of the uromodulin gene (*UMOD*), which is almost exclusively expressed in the thick ascending limb of the loop of Henle in the kidney. This SNP identifies a potentially novel pathway of BP regulation through an effect on sodium homeostasis [52]. Moreover, independent studies have identified SNPs that are highly correlated with the hypertension SNP near *UMOD* to be associated with chronic kidney disease [53].

32.3.2 Autonomic Nervous System

The autonomic nervous system maintains cardiovascular homeostasis via pressure, volume, and chemoreceptor signals through three endogenous catecholamines (norepinephrine, epinephrine, and dopamine) synthesized in the adrenal medulla (epinephrine) and cytosol of adrenergic neurons. Adrenergic reflexes modulate BP over the short-term, and adrenergic function, in concert with hormonal and volume-related factors, contributes to the long-term regulation of arterial pressure. Norepinephrine has more affinity for α receptors, whereas epinephrine binds more avidly to β receptors. α1 Receptors (*ADRA1A, ADRA1B, ADRA1D*) are located on postsynaptic cells in smooth muscle and elicit vasoconstriction. α2 Receptors are localized on presynaptic membranes of postganglionic nerve terminals and act as negative feedback controllers, inhibiting further norepinephrine release. Activation of sinus node and myocardial β1 receptors (*ADRB1*) stimulates, respectively, the rate and strength of cardiac contraction and consequently increases cardiac output. β1 Receptor activation also stimulates renin release from the kidney. Activation of β2 receptors (*ADRB2*) by epinephrine relaxes vascular smooth muscle and results in vasodilation.

Pheochromocytomas (PCCs) and paragangliomas (PGLs) are rare neuroendocrine tumors of the adrenal glands and the sympathetic and parasympathetic paraganglia. The annual incidence of PCC is around 2–4 per million. PCCs and sympathetic PGLs are very similar histologically as well as functionally and cause hypertension, which may be either paroxysmal or sustained. About 30% of PCCs and PGLs are currently believed to be caused by germline mutations. Autosomal dominant inherited pheochromocytomas are due to a variety of *RET* proto-oncogene mutations. Other pheochromocytoma susceptibility genes include *RET* (multiple endocrine neoplasia syndrome type 2 (MEN-2)), the tumor suppressor gene *VHL* observed in families with von Hippel–Lindau syndrome, and the gene that encodes succinate dehydrogenase subunit B and D (*SDHB, SDHD*) and causes familial PGL [54]. Incidence and prevalence of malignant PGL are higher in carriers of the SDHB mutation than in carriers of the SDHD mutation, but lower in carriers of the SDHB mutation [55].

32.3.3 Vascular Mechanisms

Vascular diameter and compliance of resistance arteries are important determinants of arterial pressure. Vascular changes in hypertension may result from either abnormal extracellular stimuli or an altered intracellular signaling cascade, leading to enhanced vasoconstriction, blunted vasodilation, and vascular wall hypertrophy/remodeling. All of these contribute to elevated peripheral vascular resistance. Among the humoral factors that regulate arteries in hypertension are: (1) vasoconstrictor agents such as angiotensin II, endothelin-1, catecholamines, and vasopressin; (2) vasodilator agents such as nitric oxide, endothelium-derived hyperpolarizing factor, and natriuretic peptides; (3) growth factors such as insulin-like growth factor-1, platelet-derived growth factor (PDGF), epidermal growth factor (EGF), and basic fibroblast growth factor; and (4) cytokines such as transforming growth factor-β, tumor necrosis factor, and interleukins [56].

Vascular endothelial function also modulates vascular tone. The vascular endothelium synthesizes and releases a spectrum of vasoactive substances, such as nitric oxide, a potent vasodilator. Nitric oxide exerts vasodilating and antiproliferative effects on smooth-muscle cells and inhibits thrombocyte aggregation and leukocyte adhesion. The synthesis of nitric oxide is controlled by the enzyme endothelial nitric oxide synthase (*NOS3*), and is induced by calcium-mobilizing agents and fluid shear stress. Other vascular relaxation factors include endothelins and prostacyclin. Endothelin-1 (*EDN1*) activates specific ETA receptors (*EDNRA*) on vascular smooth-muscle cells to cause vasoconstriction and cell proliferation. In contrast, endothelial ETB receptors (*EDNRB*) mediate vasodilation via release of nitric oxide and prostacyclin (*PGI2*).

Ion transport by vascular smooth-muscle cells may contribute to hypertension-associated abnormalities of vascular tone and vascular growth, both of which are modulated by intracellular pH. An increased Na^+/H^+ exchanger (*SLC9A1*) can stimulate vascular tone and cell growth by increasing sodium reabsorption in renal proximal tubule cells [57]. Other ion transporters considered are Na^+ bicarbonate transporter (*SLC4A10*) and the Na^+-Ca^+ exchanger NCX (*SLC8A1*). One hypothesis for the mechanism by which excess salt intake elevates BP is through the observed rise in cardiotonic steroids such as ouabain in response to salt intake [58]. It is believed that ouabain inhibits the plasma membrane Na^+/K^+ ATPase, leading to an increase in cytosolic Na^+ concentration that raises the cytosolic Ca^{2+} concentration through the involvement of the Na^+/Ca^{2+} exchanger NCX (*SLC8A1*) and thereby increases contraction in vascular or heart muscle [59].

32.4 NEED FOR STRATIFIED APPROACHES TO TREATMENT WITH ANTIHYPERTENSIVES

Hypertension substantially increases risks for stroke, coronary heart disease (including heart attack), renal failure, and heart failure, and it is the most common chronic disease for which medications are prescribed [60]. Clinical trials comparing different antihypertensive treatments with placebo have shown that effective antihypertensive treatment can reduce mortality from stroke by 35–40%, myocardial infarction by 20–25%, and heart failure by >50% [61].

The guidelines on antihypertensive therapy around the world—such as from the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC) in the United States [62], the Fifth Joint Task Force of the European Society of Cardiology and Other Societies on Cardiovascular Disease Prevention in Clinical Practice [63], the Chinese Hypertension Guideline Committee [64], and the Japanese Society of Hypertension [65]—all considered four drug classes as appropriate first-line therapy for hypertension: thiazide diuretics and thiazide-like diuretics; calcium channel blockers (CCBs); angiotensin-converting enzyme (ACE) inhibitors; and angiotensin receptor blockers (ARBs). β-Blockers are no longer considered an appropriate first-line therapy [63]. Despite multiple first-line therapies for hypertension, less than 50% of hypertensive patients worldwide have their BP controlled, with the control rate ~10% in the Middle East, 13% in Northern Europe, 20% in Southern Europe, 24% in Asia, 28% in North America, and 31% in Latin America. This is according to a global study in 2010 [66]. The control rates in the most recent study were higher, but still all below 50% [67].

Additionally, considerable interindividual variability has been documented in BP responses to agents from all classes of antihypertensive drugs [68,69], and response rates to monotherapy with any given antihypertensive drug are only about 50% [70]. Current selection of initial antihypertensive therapy is essentially by trial and error. The difficulty in determining the most appropriate medication for a specific patient likely contributes to the fact that less than half of hypertensive patients worldwide currently have their BP controlled.

Stratifying hypertensive patients based on the predictors of BP response to antihypertensive drugs can potentially guide antihypertensive therapy to improve the control rate and better prevent long-term adverse cardiovascular events. The most appropriate end points for antihypertensive treatment are prevention of long-term cardiovascular outcomes such as death, nonfatal myocardial infarction, nonfatal stroke, heart failure, and renal failure. BP response to antihypertensive treatment is a good surrogate marker for predicting reduction in these long-term clinical outcomes. Large clinical trials in which a difference in BP treatment arms was observed usually also showed a significant difference in cardiovascular outcomes. For example, differences in total cardiovascular events were observed in the Anglo-Scandinavian Cardiac Outcomes Trial–Blood Pressure Lowering Arm (ASCOT-BPLA) by treatment strategy [71]. Differences in heart failure events between treatment strategies were observed in the Antihypertensive and Lipid-Lowering to Prevent Heart Attack Trial (ALLHAT) [72]. On the other hand, in large trials where there was no difference in on-treatment BP between treatment strategies, usually there was no difference in long-term outcomes—for example, the INternational VErapamil SR Trandolapril Study (INVEST) [73] and the Nordic Diltiazem Study (NORDIL) [74].

The predictors of BP response to antihypertensive drugs include nongenetic (demographic and clinic) and genetic factors. The majority of the reports on predictors

TABLE 32.2 Studies with Blood Pressure Response Phenotype and GWAS Data

Full Name	Acronym	Mean Pretreatment BP (mmHg)	Mean Age	Antihypertensives (Monotherapy)	Race/Ethnicity (Sample Size)
Genetic Epidemiology of Responses to Antihypertensives [76]	GERA	147/96	49	Hydrochlorothiazide (25 mg)	380 European Americans, 225 African-Americans
Genetic Epidemiology of Responses to Antihypertensives 2 [86]	GERA 2	133/85	49	Candesartan	236 Caucasians, 203 African-Americans
Genetics of Drug Responsiveness in Essential Hypertension Study [77]	GENRES	151/100	51	Amlodipine (5 mg), bisoprolol (5 mg), hydrochlorothiazide (25 mg), losartan (50 mg)	206 Finnish men
Pharmacogenomics Evaluation of Antihypertensive Responses [75]	PEAR	152/98	49	Atenolol (100 mg), hydrochlorothiazide (25 mg)	461 Caucasians, 207 African-Americans
Pharmacogenomics Evaluation of Antihypertensive Responses 2[a]	PEAR 2	146/93	50	Metoprolol (100 mg), chlorthalidone (25 mg)	∼180 Caucasians, ∼120 African-Americans ∼120 Caucasians, ∼80 African-Americans
Nordic Diltiazem [74]	NORDIL	171/102	61	Thiazide diuretics[b]	420 Caucasians
Milan Italian study [98]	Milan study	148/98	46	Hydrochlorothiazide (HCTZ)	215 Caucasians

[a] PEAR2 is ongoing; sample sizes were estimated based on patients enrolled by August 2013. [b] NORDIL had a washout period before treatment and therefore is considered to have valid baseline BP data; it had patients on monotherapy of other antihypertensives, such as diltiazem (CCB) and β-blockers, but the number of patients with the genotype was not published.

of BP response were generated from four clinical trials: the Pharmacogenomics Evaluation of Antihypertensive Responses (PEAR) study [75], the Genetic Epidemiology of Responses to Antihypertensives (GERA and GERA2) [76], and the Genetics of Drug Responsiveness in Essential Hypertension Study (GENRES) [77]. Table 32.2 lists the studies with appropriately measured BP response phenotype after antihypertensive treatment and DNA available for pharmacogenomic association analysis.

32.4.1 Nongenetic Approaches

The nongenetic predictors of BP response include pretreatment BP, age, race, and plasma renin activity, with pretreatment BP and plasma renin activity being the most consistent. The effect of pretreatment BP is nonspecific to antihypertensive drug class, while age, race, and plasma renin activity are specific to antihypertensive drug class. Other factors have been shown to be associated with BP response to certain antihypertensives in some studies but not in others.

32.4.1.1 *Pretreatment Blood Pressure*

The GERA study first reported in 2002 that higher baseline BP was associated with better response to four weeks of treatment with hydrochlorothiazide (HCTZ, a thiazide diuretic) [76]. An Italian study showed that baseline SBP, age, and gender were associated with SBP response after treatment with the ACE inhibitor fosinopril [78]. The PEAR study showed that pretreatment BP is a significant predictor of SBP and DBP response to atenolol (β-blocker) and HCTZ both as monotherapy and as add-on therapy. The higher the pretreatment BP, the greater the reduction achieved by antihypertensive treatments [79]. GENRES reported that placebo BP level was the best predictor for BP responses to four antihypertensive drug monotherapies: amlodipine (CCB), bisoprolol (β-blocker), HCTZ, and losartan (ARB) [80]. Since the association of pretreatment BP with BP response was observed in all five antihypertensive drug classes, it appears to be nonspecific to drug class.

32.4.1.2 *Plasma Renin Activity*

The RAAS plays an important role in BP regulation, and hypertensive patients are characterized by interindividual variation in its activity [81]. In the early 1970s, Laragh and colleagues first proposed measurement of plasma renin activity as a method of characterizing relative participation of a patient's vasoconstriction and volume components [82,83]. They suggested that low activity corresponds to better BP response to diuretics and CCBs, while high activity favors a response to ACE inhibitors and β-blockers [84]. This theory has been confirmed by several studies.

In the Veterans Affairs Cooperative Study on Single-Drug Therapy of Hypertension trial, a total of 1105 ambulatory men were randomized to 1 of 6 antihypertensive drugs: HCTZ, atenolol, captopril (an ACE inhibitor), clonidine (an α2 receptor blocker), diltiazem (CCB), or prazosin (an α1 receptor blocker). The BP control rate was evaluated by comparing the percentage of patients achieving a goal of <140/90 mmHg. It was found that HCTZ was best in low- and medium-renin profiles and that captopril was best in medium- and high-renin profiles. Clonidine and diltiazem had consistent response rates regardless of renin profile [85]. This study concluded that in men with stage 1 and stage 2 hypertension, although BP responses to different antihypertensives were consistent with baseline renin profile, age and race were better predictors of BP response.

The GERA study showed that lower baseline plasma renin activity was associated with significantly greater BP response to HCTZ [76]. Later, investigators reported that higher baseline plasma renin activity predicted greater response to candesartan (ARB) [86]. Their findings supported the notion that characteristics associated with poor response to diuretic therapy are associated with better ARB response [76,86]. The GENRES study found that, in Finnish hypertensive men, plasma renin activity was positively correlated with BP responses to losartan (ARB) and bisoprolol (β-blocker), and negatively correlated with BP response to HCTZ and amlodipine (CCB) [87].

Analysis of the PEAR study showed that plasma renin activity was an independent predictor of SBP and DBP responses to atenolol and HCTZ, not only in monotherapy but also in add-on therapy. The predictive effects of plasma renin activity were directionally opposite for atenolol and HCTZ responses, with higher renin predicting greater BP responses to atenolol as monotherapy or as an add-on and lesser responses to HCTZ as monotherapy or as an add-on (Figure 32.2).

A recent retrospective analysis of the GERA study assessed the BP control rates of three different treatment strategies among patients with stage 1 essential hypertension: (1) Thiazide diuretic (HCTZ) for all; (2) thiazide diuretic for all black subjects and white subjects age ≥50 years, and a RAAS blocker (candesartan) for white subjects aged <50 years; (3) thiazide diuretic (HCTZ) for plasma renin activity <0.6 ng/ml/h (suppressed renin activity) and a renin–angiotensin system blocker (candesartan) for plasma renin activity ≥0.6 ng/ml/h (nonsuppressed renin activity). It was found that the renin-based strategy was associated with the highest control rate of 69.4% versus 61.3% for the age/race strategy ($p<0.0001$) and 53.8% for the thiazide for all strategies ($p<0.0001$). This study also found that not all of the racial difference in response to candesartan versus HCTZ can be explained by differences in plasma renin activity status [88].

32.4.1.3 *Age and Race*

Age and race, as predictors of BP response to antihypertensives, are correlated to plasma renin activity. Older age and black race are used as markers for low activity, whereas younger age and white race are markers for higher activity. The British Hypertension Society recommends the use of a treatment algorithm based on age and race [89]. Hypertension can be broadly classified as "high renin" or "low renin" and is therefore best treated initially with one of two categories of antihypertensive drugs: those that inhibit the renin–angiotensin system—ACE inhibitors and agiotensin receptor blockers (A drugs) and β-blockers (B drugs); and those that do not inhibit it—calcium channel blockers (C drugs) and diuretics (D drugs). People who are younger than 55 and white tend to have higher renin concentrations than those aged 55 or older or who are black (of African descent). A or B drugs are therefore generally more effective as initial BP-lowering treatments in younger white patients than are C or D drugs [89].

GENRES reported that in moderately hypertensive Finnish men, age was positively associated with BP responses to amlodipine and HCTZ [77]. In the GERA study, black race was associated with significantly greater SBP and DBP responses to HCTZ, and older age was a predictor of better DBP, but not SBP response, to HCTZ [76].

The PEAR study has confirmed the racial differences in BP response to HCTZ versus atenolol. In this study, where uncomplicated hypertensive patients were randomized to either HCTZ or atenolol monotherapy, African-Americans showed a greater BP-lowering effect than whites with HCTZ (−13.0/−7.4 mmHg versus −8.0/−4.2 mmHg, $p<0.001$), but a smaller BP-lowering effect than whites with atenolol monotherapy (−1.1/−2.9 mmHg versus −9.9/−9.2 mmHg, $p<0.0001$) [90].

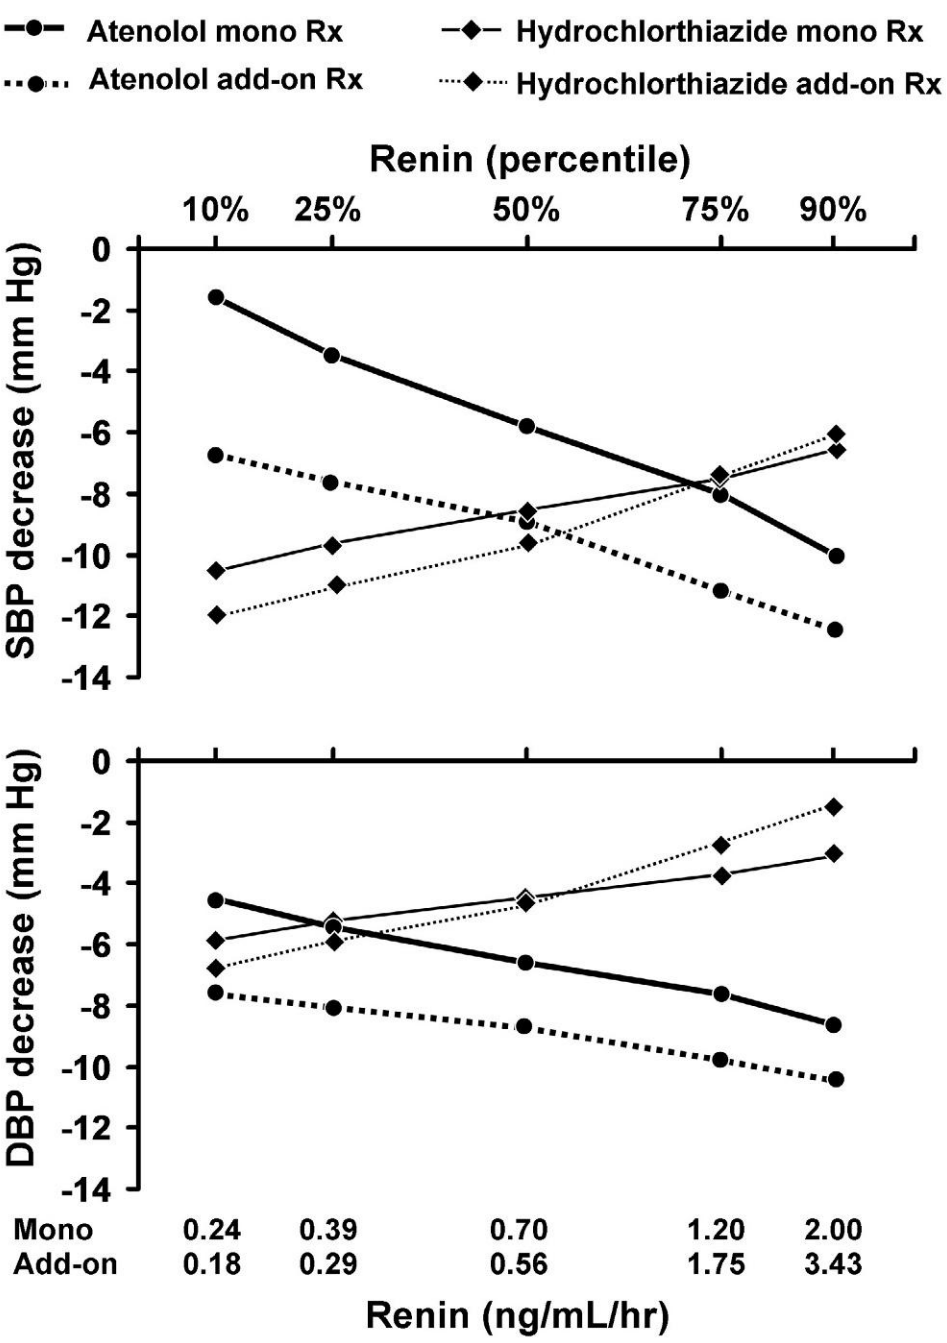

FIGURE 32.2 **Predicted blood pressure responses as a function of plasma renin activity.** The plotted points are at the observed 10th, 25th, 50th, 75th, and 90th percentiles of plasma renin activity distributions prior to mono- and add-on therapy. Participants were randomized to receive atenolol monotherapy followed by hydrochlorothiazide add-on therapy ($N = 180$) or hydrochlorothiazide monotherapy followed by atenolol add-on therapy ($N = 183$). The predicted blood pressure responses at each renin percentile are from a single linear regression model in which all other predictors (race, sex, age, log hypertension duration, current smoker, ethanol intake, height, waist circumference, and baseline blood pressure) were held constant at their respective mean values. DBP—diastolic blood pressure; SBP—systolic blood pressure. *Source: From Turner et al.* [79] *with permission.*

32.4.1.4 Other Factors

In a study of more than 3000 untreated Chinese hypertensive individuals randomized to eight weeks of antihypertensive monotherapy, women were shown to have better SBP reduction from atenolol than men, with a mean difference of 3.9 mmHg. It was also shown that women had better reduction in DBP after HCTZ treatment compared to men, with a mean difference of 1.8 mmHg. However, there were no gender differences in BP response to nifedipine-SR (a CCB) and captopril [91]. The PEAR study also showed that females responded better to atenolol in SBP and DBP as monotherapy (−4.21/−0.79 mmHg) and as an add-on (−3.73/−2.39 mmHg), while no evidence of gender differences was found in response to HCTZ [79]. However, the GERA study showed that females responded better to HCTZ for both SBP and DBP [76].

Other factors that did not show consistent association with BP response to antihypertensives include duration of hypertension [79], current smoker (atenolol add-on therapy) [79], and alcohol intake (SBP response to HCTZ add-on therapy) [79]. GENRES also reported that serum total calcium concentration and daily urinary excretion of sodium were both negatively correlated with BP response to amlodipine, but not in response to the other three drugs [87].

In summary, the most consistent nongenetic predictors of BP response to antihypertensives are pretreatment BP and plasma renin activity, while demographical factors such as age and race can be used to capture information for plasma renin activity.

32.4.2 Genetic Approaches

Several easily determined clinical characteristics have been shown to predict BP responses to commonly prescribed antihypertensive drugs, but the majority of interindividual BP response variation remains unexplained. The GERA study reported that the combined effects of all identified predictors accounted for 38% of interindividual variation in SBP response and 20% in DBP response to HCTZ [76]. The predictors of BP response to candesartan accounted for 39% and 33% of interindividual variation in SBP and DBP responses, respectively [86]. The PEAR study reported that the percentage of variation in BP response explained by baseline BP, age, race, and plasma renin activity was 16% for DBP and 21% for SBP response after HCTZ monotherapy, and 27% and 29%, respectively, after atenolol monotherapy [79].

Pharmacogenomics, which utilizes genetic information to determine drug response, is one tool that might be useful in further individualizing antihypertensive drug selection. We discuss the pharmacogenomics of BP response in Section 32.5 and long-term cardiovascular outcomes after antihypertensive therapy in Section 32.6. Our focus is on genetic variants that meet one of the following criteria: (1) replication in an independent sample or a different race/ethnicity group; (2) association with multiple related phenotypes, such as prior association with BP or hypertension; and (3) functional basis. We do not discuss a single association reported in the literature or ones for which there were problems that we believe bring the data into question (such as deviation from Hard-Weinberg equilibrium or inappropriate study design).

32.5 PHARMACOGENOMICS OF BLOOD PRESSURE RESPONSE TO ANTIHYPERTENSIVE DRUGS

Most pharmacogenomics studies of antihypertensives have used the candidate gene approach, which focuses on genetic variations that can influence antihypertensive drug pharmacokinetic or pharmacodynamic mechanisms. The first GWAS of an antihypertensive drug was published in 2008 by Turner and colleagues and was based on an analysis of BP response to HCTZ in the GERA study [92]. Since then two more hypertension pharmacogenomic GWAS have been published, one on BP response to HCTZ and the other on BP response to the ARB candesartan. As of June 2013, there was no GWAS published on BP response to β-blockers, CCBs, and ACE inhibitors.

The genes with the most compelling evidence of antihypertensive pharmacogenomic association with BP response have been those with a prior BP or hypertension association or those with functional evidence of involvement with BP regulation and replication across different populations, either in independent studies or in different race/ethnicity groups. The top genes from the candidate genes studies are *NEDD4L*, which is associated with BP response to thiazide diuretics, and *ADRB1*, which is associated with BP response to β-blockers. The most compelling genes from GWAS analyses are SNPs in the chromosome 12 region associated with HCTZ response in African-American patients, and those in the *PRKCA* and *GNAS-EDN3* regions associated with HCTZ response in European patients.

32.5.1 Thiazide Diuretics

Multiple hypertension treatment guidelines from different regions of the world recommend thiazide or thiazide-like diuretics as a first-line treatment for patients with essential hypertension [62–65]. In most countries, thiazide diuretics are the cheapest antihypertensives available and the mainstay of antihypertensive pharmacotherapy. HCTZ is the second most commonly prescribed antihypertensive in the United States, with approximately 135 million prescriptions dispensed in 2008 either in monotherapy or in combination therapy [93]. Despite the widespread use of this drug class, the mechanism by which thiazide diuretics lower BP remains poorly understood. They achieve their diuretic effect by decreasing sodium reabsorption via inhibition of the Na^+/Cl^- cotransporter in the renal distal convoluted tubule [94].

Thiazide use acutely results in an increase in fluid loss to urine and a decrease in extracellular fluid and plasma volume, which results in diminished venous return, increased renin release, reduced cardiac output, and decreased BP [94]. However, this does not explain the chronic BP-lowering effect of thiazides, because the plasma and extracellular fluid volumes almost fully recover 4–6 weeks after thiazide initiation, although BP reduction is maintained. Possible mechanisms for chronic BP lowering include direct vasodilation mediated by endothelial or vascular smooth muscle and indirect compensation for acute decreases in cardiac output [94]. There have been many candidate genes studies on the pharmacogenetic association of BP response and thiazide diuretics, most of which used HCTZ.

32.5.1.1 ADD1

Alpha adducin, *ADD1*, is a ubiquitously expressed protein that is part of the cytoskeleton and may modulate ion transport. In a family linkage study in 1997, the nonsynonymous SNP Gly460Trp in the *ADD1* gene that encodes α-adducin was found to be associated with sensitivity to changes in sodium balance. Patients who were carriers of the 460Try allele had a lower baseline plasma renin activity and a greater BP-lowering response to two months of HCTZ treatment compared to Gly/Gly homozygotes (mean arterial BP decrease of 15.9 versus 7.4 mmHg, $p = 0.001$) [95]. A later study, utilizing erythrocytes as a mirror to transport in the cell membrane, reported that the Gly460Trp polymorphism may affect renal Na handling through an alteration in ion transport across the cell membrane [96]. The association between this polymorphism and BP response to thiazide diuretics has been confirmed by some subsequent studies [97,98] but not others [99–102].

32.5.1.2 GNB3

The T allele of the C825T polymorphism of the gene encoding the G-protein β3 subunit, *GNB3*, has been associated with low plasma renin and elevated DBP [103]. This suggests that the T allele might also be associated with a volume-expanded, sodium-sensitive, and therefore diuretic-responsive form of hypertension. Turner and colleagues tested whether this polymorphism was associated with BP response to HCTZ in the GERA study of 197 blacks and 190 non-Hispanic whites. They found that the T allele was associated with better response to HCTZ with a gene-dose effect, even after adjusting for other significant predictors [104]. This association was later confirmed by an independent study in the Netherlands [105] but not replicated by others [101].

32.5.1.3 NEDD4L

To date, the candidate gene with the most compelling evidence for thiazide pharmacogenomic association is *NEDD4L*, the neural precursor cell expressed developmentally down-regulated 4-like gene (also known as *NEDD4-2*), encodes a ubiquitin ligase that plays a critical role in epithelial sodium transport by regulating the cell surface expression of the epithelial sodium channel (ENaC). By targeting ENaC for degradation, *NEDD4L* is a significant determinant of sodium reabsorption in the distal nephron. Several studies have shown that polymorphisms in *NEDD4L*—specifically rs4149601 G>A, which is known to result in a cryptic splice site—are associated with hypertension in multiple populations [106,107]. In a prior human study, G carriers of this SNP were also shown to have higher salt sensitivity and lower plasma renin concentration compared to the AA genotype [108].

Based on these data, one would expect individuals who carry the G allele of rs4149601 to respond better to thiazide diuretics. This hypothesis was confirmed in the NORDIL study, where patients treated with a combination of thiazide diuretics and β-blockers, or either drug alone, were compared to patients treated with the CCB diltiazem. In this study, rs4149601 G allele carriers were shown to have greater BP response than patients with the AA genotype (SBP: −19.5 versus −15.0 mmHg; DBP: −15.4 versus −14.1 mmHg) when treated with a thiazide diuretic/β-blocker. No differences in response to diltiazem by genotype were shown [109].

The PEAR study evaluated the association of the G allele of rs4149601 with BP response to HCTZ and atenolol separately, finding a significant association in HCTZ-treated patients (Figure 32.3), where there was

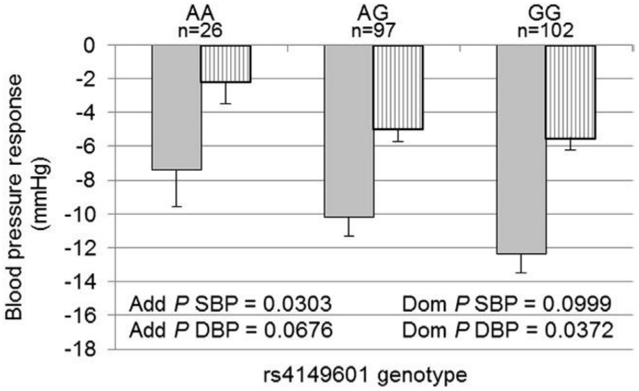

FIGURE 32.3 **Blood pressure response by NEDD4L rs4149601 genotype in white patients treated with HCTZ in PEAR.** Solid gray bars indicate ΔSBP; gray and white lined bars indicate ΔDBP. Values are shown as means ± standard error. Add—additive, Dom—dominant. *Source: From McDonough et al.* [110] *with permission.*

better BP reduction when the G allele was increased (SBP: −12.4 mmHg, −10.2 mmHg, and −7.4 mmHg; DBP: −5.5 mmHg, −5.0 mmHg, and −2.2 mmHg for GG, GA, and AA). However, there was no evidence of such association in the atenolol-treated patients [110]. The G allele was also shown to be associated with cardiovascular outcome in the NORDIL and INVEST studies (see the next section).

32.5.1.4 GWAS Signals

Three GWASs of hypertensive pharmacogenomics had been published as of June 2013. Two of them reported pharmacogenomic associations between BP response and HCTZ treatment, one in African-Americans and the other in European Americans.

The first GWAS analysis of hypertension pharmacogenomics was published in 2008 and used the GERA study as a basis. A haplotype was found to be associated with DBP response to HCTZ in African-Americans [92], located on chromosome 12q15 (consisting of SNPs rs317689, rs315135, and rs7297610 near *LYZ*, *YEATS4*, and *FRS2*, of which rs7297610 is the strongest). This association was later replicated in an independent sample of PEAR African-American hypertensive patients treated with HCTZ as monotherapy or as an add-on [111]. It was not observed in patients treated with atenolol (Figure 32.4).

The PEAR study also explored expression of the genes *YEATS4* and *FRS2* pre- and post-HCTZ treatment, finding that the CC genotype (associated with better BP response to HCTZ) had higher baseline expression of the *FRS2* gene compared to the CT genotype, but also finding that there was no difference in the expression level of the *YEATS4* gene [111].

The most recent antihypertensive pharmacogenomic GWAS involved five independent studies, two as discovery cohorts (PEAR and GERA) and three (GENRES, NORDIL, and Milan) as replication cohorts [100]. An intronic polymorphism, rs16960228, in protein kinase C alpha (*PRKCA*) on chromosome 17q24.3 was replicated for the same direction of association with DBP response in the NORDIL and GENRES studies, and the combined four-study meta-analysis p-value achieved genome-wide significance ($p = 3.3 \times 10^{-8}$). SBP/DBP responses were consistently greater in rs16960228 A allele carriers than in GG homozygotes (>4/4 mmHg) across study samples (Figure 32.5).

This association was further validated in three ways. First, in PEAR rs16960228 was also associated with DBP response to the β-blocker, compared with the opposite-direction-of-association compared response to HCTZ (which was expected given the different pharmacologies of these drug classes). Second, SNPs in *PRKCA* were significantly associated with DBP response in PEAR African-Americans. Third, gene expression analysis using RNA demonstrated that the carriers of the rs16960228 variant A allele had significantly greater relative *PRKCA* expression level than GG homozygotes [100].

The blood pressure responses are adjusted for pretreatment blood pressure levels, age, and sex; p-values are for contrast of adjusted means between genotype groups. *Source: From Turner et al.* [100] *with permission.*

The rs2273359 polymorphism in the *GNAS-EDN3* region shows a consistently significant association of SBP response to HCTZ in PEAR, GERA, and NORDIL (data for this SNP were not available in GENRES and the Milan study). Among the participants in the three studies, CG heterozygotes demonstrated consistently greater BP response to HCTZ than CC homozygotes (no GG homozygotes were observed) (see Figure 32.6). The combined p-value from the three-study meta-analysis approached genome-wide significance ($p = 5.5 \times 10^{-8}$) [100]. This region was previously associated with BP and hypertension in GWAS analyses.

32.5.2 β-Blockers

The most compelling pharmacogenomics association for BP response to β-blockers is that of *ADRB1*, which was shown to be associated not only with BP response, but also with long-term cardiovascular outcomes.

32.5.2.1 ADRB1

ADRB1 encodes the β1-adrenergic receptor, which is the primary protein target of all marketed β-blockers. It contains two nonsynonymous polymorphisms, one at codon 389, Arg389Gly, and one at codon 49, Ser49Gly. There is substantial evidence for functional consequences for both polymorphisms, but particularly for Arg389Gly. In membrane adenylyl cyclase assays from recombinantly expressing cells, the Arg389 form of *ADRB1* had greater basal and against-stimulated activity compared with the Gly389 form; therefore, it also had greater downstream signaling in response to agonist [112]. The Ser49Gly polymorphism lies in the region that may play a role in membrane insertion, expression, trafficking, and agonist-promoted down-regulation [113].

Two independent studies found enhanced agonist-promoted down regulation with the Gly49 form of the receptor [114,115]. Based on functional data for these two SNPs, one would hypothesize that the more responsive Ser49 and Arg389 forms have the greatest β-blockade efficacy. Consistent with this hypothesis, several studies have shown that patients with the Arg389Arg genotype or those with the Ser49Arg389 haplotype have the greatest BP response to β-blockers (metoprolol) [116–118].

Despite some studies that failed to show such an association [119,120], this gene is of particular interest because Gly389 has also been associated with decreased SBP and DBP in a large genetic study evaluating 30 regions that code for known antihypertensive drug targets [121]. More important, this polymorphism has also been associated with cardiovascular outcomes after antihypertensive treatment in a large clinical trial (see the next section).

32.5.2.2 GRK4

G protein-coupled receptor kinases are a family of serine/threonine kinases that phosphorylate activated G protein-coupled receptors (GPCRs), leading to receptor desensitization, deactivation, and endocytosis. *GRK4* plays a role in BP homeostasis through phosphorylation of GPCRs that are important to BP regulation, including dopamine receptors and potentially β1-adrenergic receptors—the key protein target of β-blockers. The African American Study of Kidney Disease and Hypertension (AASK) trial evaluated

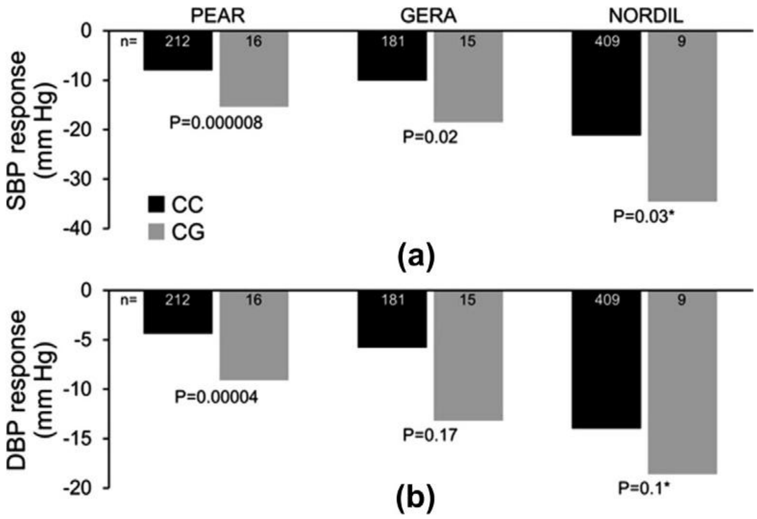

FIGURE 32.6 Blood pressure response to hydrochlorothiazide by chromosome 20 rs2273359 genotype of participants from three independent studies. (a) systolic blood pressure response; (b) diastolic blood pressure response. The blood pressure responses are adjusted for pretreatment blood pressure levels, age, and sex; *p*-values are for contrast of adjusted means between genotype groups. *Source: From Turner et al.* [100] *with permission.*

the association of three nonsynonymous polymorphisms in *GRK4* Arg65Leu (rs2960306), Ala142Val (rs1024323), and Ala486Val (rs1801058). It also evaluated the time taken to reach a mean arterial pressure of 107 mmHg after metoprolol treatment. A significant sex-specific association for Ala142Val was found among African-American men with early hypertensive nephrosclerosis: men with the 142Ala polymorphism were less responsive to metoprolol if they also had a 65Leu variant; this association was not seen in women [122].

Vandell and colleagues also studied the association of these three *GRK4* SNPs with BP response to atenolol in the PEAR study. They found that the variant alleles of all three SNPs showed, or trended toward, a lesser BP lowering. They further evaluated the haplotype of the two more common variants and found that increasing copies of the variant 65Leu-142Val haplotype were associated with significantly reduced atenolol-induced DBP lowering (−9.1 ± 6.8 versus −6.8 ± 7.1 versus −5.3 ± 6.4 mm Hg in participants with, respectively, 0, 1, and 2 copies; p = 0.0088). There was no evidence of such association with HCTZ-induced BP response [123]. The variant alleles of all three *GRK4* SNPs were also associated with increased risk for adverse cardiovascular outcomes [123].

32.5.3 Calcium Channel Blockers

Most candidate genes in the CCB pharmacogenomic literature are those that encode proteins relevant to calcium regulation, such as the L-type calcium channel subunits α1C (*CACNA1C*) and β (*CACNB2*) and the β1 subunit of the calcium-activated potassium channel, also known as the BK channel (*KCNMB1*). The majority of the pharmacogenetic studies with CCBs were based on analysis of verapamil SR (a nondihydropyridine CCB) in the INVEST genetic substudy (INVEST-GENES). While there was no evidence of association of *CACNA1C* and *CACNB2* SNPs and BP responses to verapamil-SR, there were significant differences in long-term cardiovascular outcome by genotype for them [124,125].

32.5.3.1 *KCNMB1*

KCNMB1 encodes the β1 subunit of the large-conductance calcium and voltage-dependent potassium (BK) channel in vascular smooth muscle. *KCNMB1* knockout mice have decreased calcium sensitivity, elevated BP, and cardiac hypertrophy [126,127]. *KCNMB1* has two common nonsynonymous polymorphisms: Glu65Lys (rs11739136) and Val110Leu (rs2301149). The Lys65 variant of the Glu65Lys SNP was associated with decreased risk of diastolic hypertension in a Spanish population and was found to result in a BK channel with enhanced calcium sensitivity. This finding supports more efficient negative feedback on the L-type calcium channels resulting in vascular smooth-muscle relaxation [128]. Additionally, Lyn65 carriers appeared to have significantly lower 5-year risk of cardiovascular events compared with the Gly65 homozygotes [129].

In a study of healthy twins, Val110Leu was one of four polymorphisms associated with heart rate variability and baroreflex activity [130]. INVEST assessed the association of these two nonsynonymous SNPs with BP response in hypertensive patients with coronary artery disease after verapamil-SR monotherapy. The study reported that the SBP response did not differ by *KCNMB1* genotype. However, Lys65 variant carriers achieved BP control earlier than

Glu65Glu individuals (1.47 versus 2.83 months, $p=0.01$) and were less likely to require multiple drugs at the time of BP control (adjusted (OR; 95% CI = 0.43 (0.19–0.95)) [131]. This finding was consistent with a prior report indicating that Lys65 is protective.

32.5.4 ACE Inhibitors and ARBs

ACE inhibitors and ARBs are both inhibitors of RAAS. ACE inhibitors act to prevent the conversion of angiotensin I to angiotensin II and prevent the degradation of bradykinin, while ARBs block angiotensin II receptors.

The candidate genes for pharmacogenomic associations in BP response to these two drug classes have been in those in the RAAS: angiotensin-converting enzyme (*ACE*), angiotensinogen (*AGT*), angiotensin receptor 1 (*AGTR1*), and renin (*REN*). However, the prior associations of *ACE*, *AGT*, and *AGTR1* either have been conflicting or have shown no association. In the case of *REN*, only one study reported an association result.

32.5.4.1 ACE

The *ACE* gene encodes the angiotensin-converting enzyme involved in catalyzing the conversion of angiotensin I into a physiologically active peptide, angiotensin II. Angiotensin II is a potent vasopressor and aldosterone-stimulating peptide that controls BP and fluid-electrolyte balance. This enzyme plays a key role in the RAAS. Strong evidence exists for an association between the ACE insertion and deletion (I/D) polymorphism of intron 16 and plasma ACE activity, with increased levels among those with the D allele 132. Therefore, a majority of pharmacogenetic candidate gene studies of ACE inhibitors and ARBs evaluated the *ACE* I/D polymorphism. However, some showed no association [78,133–140] while others reported conflicting results, with either the I allele or the D allele having better response to ACE inhibitors [141–145].

32.5.4.2 AGT

AGT encodes angiotensinogen, preangiotensinogen, or the angiotensinogen precursor, which is expressed in the liver and is cleaved by the enzyme renin in response to lowered BP. The resulting product, angiotensin I, is then cleaved by ACE to generate the physiologically active enzyme angiotensin II. The protein is involved in maintaining BP and in the pathogenesis of essential hypertension and preeclampsia. Mutations in this gene are associated with susceptibility to essential hypertension, and can cause renal tubular dysgenesis, a severe disorder of renal tubular development.

AGT is another gene often evaluated in pharmacogenetic studies of ACE inhibitors and ARBs, especially the SNP rs699, which leads to the substitution of a threonine (Thr) for a methionine (Met) at codon 235. This SNP has been shown to be functional, with higher plasma AGT levels observed in individuals with the Thr/Thr genotype compared to those with the Met/Met genotype [146]. In studies that found a significant association, it was found that Thr/Thr individuals had better BP response to ACE inhibition than Met/Thr and Met/Met individuals [147,148]. In other studies, no association was found [135,138–140].

32.5.4.3 AGTR1

Angiotensin II is a potent vasopressor hormone and a primary regulator of aldosterone secretion. It is an important effector, controlling BP and volume in the cardiovascular system. *AGTR1* encodes the type 1 receptor that is thought to mediate the major cardiovascular effects of angiotensin II. This gene may play a role in the generation of reperfusion arrhythmias following restoration of blood flow to ischemic or infarcted myocardium. The main polymorphism studied was A1166C, and most studies showed lack of association with BP response to RAAS blockade [78,138–140,149,150].

32.5.4.4 GWAS Findings

The only GWAS on BP response to ARBs to date was published in 2012 on candesartan in the GERA study. Almost 200 European Americans and African-Americans with primary hypertension from the two extremes of BP response after candesartan monotherapy were included in the analysis [151]. SNPs associated with candesartan in European Americans were validated by opposite direction of associations with HCTZ response in a separate European American population and same direction of association in African-Americans. A SNP (rs11020821) on chromosome 11q21 near *FUT4* was associated with BP response to candesartan; another SNP in this region (rs3758785 in *GPR83*) had an opposite direction of association with HCTZ response and the same direction of association with candesartan response in African-Americans. Another interesting locus was rs11649240 on chromosome 16, in amiloride-sensitive sodium channel subunit *SCNN1G*, which is involved in mediating renal sodium reabsorption and maintaining BP when the RAAS is inhibited by candesartan [151].

In summary, most BP response pharmacogenomic associations were published on thiazide diuretics, specifically HCTZ. The candidate genes with the most compelling evidence for pharmacogenomic association are *NEDD4L*, which is associated with BP response to thiazide diuretics, and *ADRB1*, which is associated with BP response to β-blockers. The most compelling genes from GWAS analyses were chromosome 12-region SNPs associated with HCTZ response in African-Americans, and the *PRKCA* and *GNAS-EDN3* regions associated with HCTZ response in hypertensive patients of European descent.

32.6 PHARMACOGENOMICS OF ANTIHYPERTENSIVE TREATMENT—RELATED OUTCOMES

Along with genetic markers that can affect BP response to antihypertensive drugs, there are also genetic markers that can influence long-term cardiovascular outcomes after antihypertensive treatment. Many of these are candidate genes, and some also have a documented role in BP response or an association with hypertension risk. Others are novel findings that are limited to treatment-related outcomes.

32.6.1 Clinical Trials

The majority of the data on the pharmacogenomics of antihypertensive treatment-related outcomes arise from four large hypertension-outcome clinical trials: INVEST [73], NORDIL [74], ALLHAT [72], and LIFE [152] (Table 32.3). These clinical trials have between two and four randomized drug classes, and have high-quality clinical data. The other studies on antihypertensive treatment-related outcomes are population-based, often having observational data from medical records and/or prescription drug records.

The genes with the strongest evidence of a positive association affecting treatment-related cardiovascular outcomes are those with replication in multiple cohorts, association with other related phenotypes, and/or functional evidence that supports the association. These top genes are *ADRB1*, *NEDD4L*, *CACNB2*, *CACNA1C*, and *FGB*, identified in candidate gene approaches, and then *SIGLEC12*, *A1BG*, and *F5*, identified through a genome-spanning approach. Additionally, there are genes with strong evidence for no association, including *ADD1* and *ACE*.

32.6.2 Genes with Strong Evidence of Association with Treatment-Related Outcomes

32.6.2.1 ADRB1

ADRB1 has prior association with BP and hypertension [121], strong evidence for a functional effect, and association with BP response to β-blocker treatment. It was also evaluated for association with long-term cardiovascular outcomes after antihypertensive therapy. The two nonsynonymous SNPs with functional evidence, Ser49Gly and Arg389Gly, were studied in relation to cardiovascular outcomes in individuals treated with β-blockers in a genetic substudy of the INVEST trial [153]. In INVEST, the Ser49-Arg389 haplotype was associated with risk of the primary outcome (all-cause death, nonfatal myocardial infarction, and nonfatal stroke) in individuals in the CCB strategy treatment group (HR (95% CI) = 8.58 (2.06–35.8) (Figure 32.7), but not in the β-blocker strategy treatment group (HR (95% CI) = 2.31 (0.82–6.55) (Figure 32.7) [153]. This suggests that treatment with the β-blocker strategy had a protective role in individuals with the Ser49-Arg389 haplotype.

The interaction of genetic variants in *ADRB1* and β-blocker treatment was also investigated in a population-based case-control study of pharmacologically treated hypertensive patients [154]. Cases were identified with incident myocardial infarction or ischemic stroke and were matched to controls; genetic variation throughout *ADRB1* was examined for association with risk of adverse cardiovascular outcomes and interaction between outcomes and hypertensive treatment. Two SNPs (rs17875422 and rs2429511), located in the promoter region of *ADRB1*, showed a significant

TABLE 32.3 Clinical Trials in Treatment-Related Antihypertensive Outcome Pharmacogenomic Studies

Full Name	Acronym	Genetic Samples	Randomized Drug Classes	Average Follow-Up Time (Years)
International Verapamil-SR Trandolapril Study	INVEST [73]	5979	BB, CCB	2.7
Nordic Diltiazem Study	NORDIL [74]	4196	BB, CCB	4.5
Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial	ALLHAT [72]	39,114	CCB, ACEI, TD, A1B	4.9[a]
Losartan Intervention for Endpoint Reduction in Hypertension Study	LIFE [152]	3503	BB, ARB	4.8

[a] *4.9 years was the average follow-up in the CCB, ACEI, and TD arms; the A1B arm was stopped early with an average follow-up of 3.3 years.*

BB—β-blocker; CCB—calcium channel blocker; ACEI—ACE inhibitor; TD—thiazide diuretic; A1B—α-1-blocker; ARB—angiotensin receptor blocker.

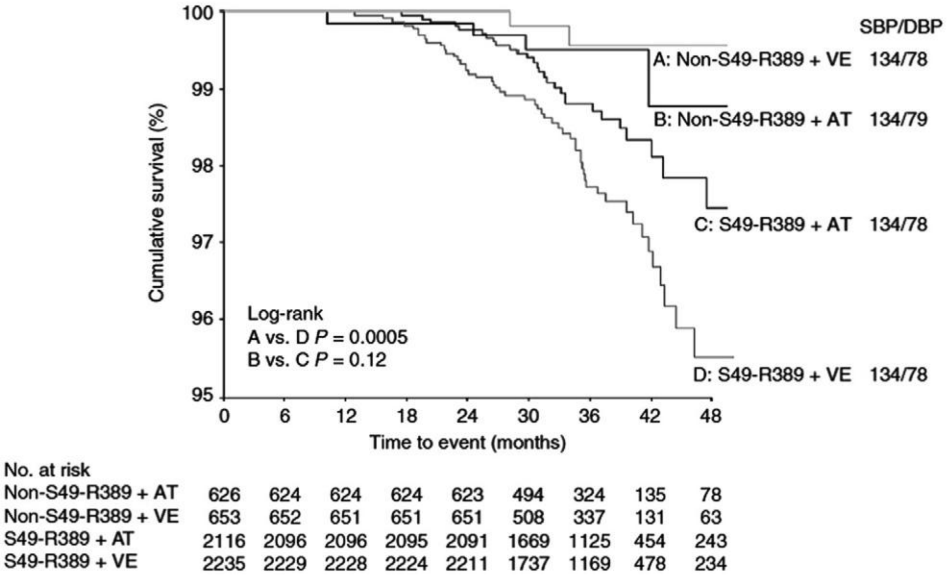

FIGURE 32.7 All-cause mortality and mean on-treatment blood pressure by ADRB1 Ser49-Arg389 haplotype and atenolol/verapamil-SR therapy. HR—hazard ratio; CI—confidence interval; S49-R389, Ser49-Arg389 haplotype; AT—atenolol; VE—verapamil-SR; SBP—systolic blood pressure; DBP—diastolic blood pressure. *Source: From Pacanowski et al.* [153] *with permission.*

interaction between adverse cardiovascular outcomes and β-blocker use [154]. For both SNPs, variants carriers had an increased risk of adverse cardiovascular outcomes when treated with a β-blocker; individuals who were homozygous for the common allele had a decreased risk of adverse cardiovascular outcomes when treated with a β-blocker [154]. Collectively, these two studies, and the functional evidence for the Ser49Gly and Arg389Gly variants, support the role of *ADRB1* in β-blocker treatment-related outcomes.

32.6.2.2 NEDD4L

Another gene that shows evidence of playing a role in both BP response and cardiovascular outcomes is *NEDD4L*. Prior studies in humans have shown that the GG genotype at *NEDD4L* rs4149601 is associated with higher salt sensitivities, lower plasma renin levels, and higher DBP [106–108]. These data suggest individuals with the G allele at rs4149601 may respond better to thiazide diuretics, and have better outcomes.

In NORDIL, this suggestion was confirmed. Those who carried the G allele at rs4149601 and were treated with the β-blocker/diuretic strategy had better cardiovascular outcomes compared to those with the AA genotype (OR (95% CI) = 0.52 (0.36–0.74), $p < 0.0001$) (Figure 32.8) [109]. However, for those individuals treated with diltiazem, there were no significant differences in cardiovascular outcome resulting from the rs4149601 genotype ($p = 0.77$) (Figure 32.8) [109].

In INVEST, rs4149601 was also examined in relation to adverse cardiovascular outcomes and diuretic use (HCTZ). Among individuals treated with HCTZ, there was no evidence of a difference in adverse cardiovascular outcomes by genotype in whites ($p = 0.477$) (Figure 32.8) [110]. However, in whites not treated with HCTZ, there was a significant increase in adverse cardiovascular events in those with the AG genotype as compared to the AA genotype (OR (95% CI) = 10.65; 1.18–96.25); $p = 0.022$ (Figure 32.8), and this trend remained when the AG and GG genotypes were combined (OR (95% CI) = 8.94 (0.99–80.54) $p = 0.051$ (Figure 32.8) [110]. However, there was no replication in Hispanics or African-Americans in INVEST [110]. These two pharmacogenomic studies, the prior associations of *NEDD4L* with hypertension, and the functional implications of rs4149601 all contribute to *NEDD4L*'s importance in thiazide diuretic treatment-related outcomes, with the data suggesting that individuals who carry the G allele may have more favorable outcomes with thiazide diuretic treatment.

32.6.2.3 CACNB2

CACNB2, the β_2 subunit of the voltage-gated L-type calcium channel, is responsible for targeting cell-surface expression of the α_1 pore-forming subunit, the binding site for all currently available CCBs. *CACNB2* has also been associated in GWASs with BP and hypertension [47,155]. It is the only gene to date with two independent signals observed: one in the 3′ end of the gene and one in the 5′ end [47,155].

CACNB2 was also studied in relation to cardiovascular outcomes in INVEST. A SNP that lies in the promoter region of *CACNB2*, rs2357928, was found to have a significant treatment interaction in whites (interaction $p = 0.002$)

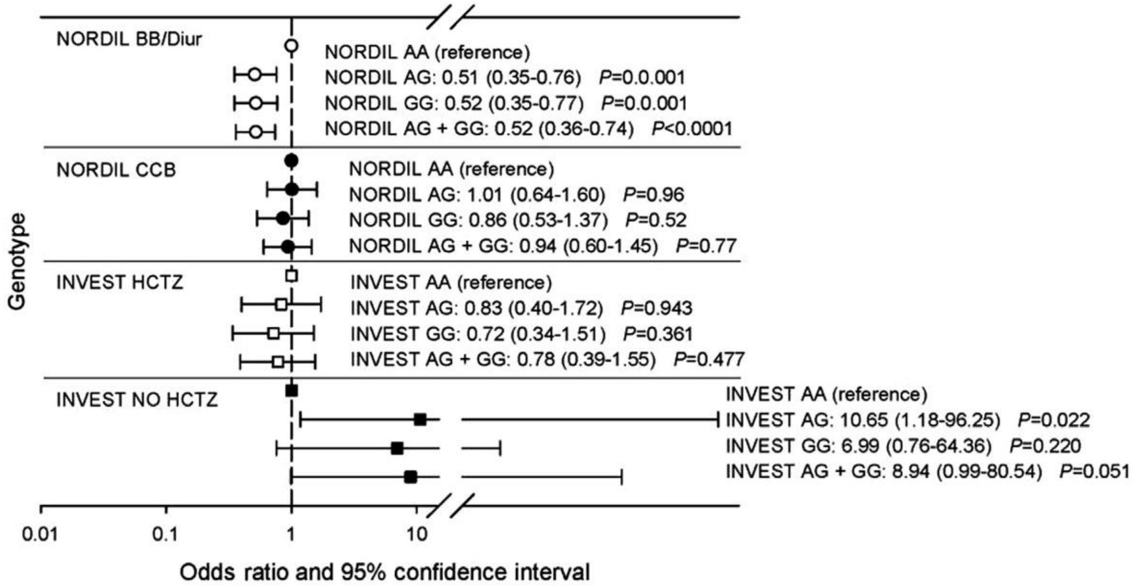

FIGURE 32.8 **Comparison of genotypes.** Impact of *NEDD4L* rs4149601 genotypes AG and GG compared to AA (reference): in patients treated with β-blockers/diuretics (BB/Diur) or diltiazem (CCB) on the risk of receiving a primary end point in NORDIL; and in patients treated with hydrochlorothiazide (HCTZ) or without hydrochlorothiazide (NO HCTZ) on the risk of receiving the primary outcome in INVEST. *Source: Data from Svensson-Farbom et al.* [109] *and McDonough et al.* [110].

(Figure 32.9) [125]. This interaction remained significant after false discovery rate (FDR) adjustment (FDR-adjusted interaction p = 0.024). In whites, those with the GG genotype were found to be at higher risk for the primary outcome when treated with a CCB strategy compared to a β-blocker strategy (HR (95% CI) = 2.35 (1.19–4.66), p = 0.0143 (Figure 32.9) [125].

In contrast, in whites who were A carriers, there was no evidence of a difference in outcomes by treatment strategy (Figure 32.9). This association did not appear to be mediated through differences in BP response. Additionally, there was a trend observed in the same direction for treatment interaction in Hispanics at rs2357928 (interaction p = 0.069) [125]. It was also found that the G-allele at rs2357928 significantly increases promoter activity, as indicated by a luciferase assay [125]. Together these data suggest that, in addition to a likely role in BP and hypertension, variants in *CACNB2* may also influence treatment-related outcomes in patients with hypertension.

32.6.2.4 *CACNA1C*

CACNA1C encodes the α1c subunit of the L-type calcium channel. This subunit is the major pore-forming subunit of the L-type calcium channel and is the binding site for all currently available CCBs. Variants in *CACNA1C* were associated with SBP, DBP, and hypertension in the CHARGE (Cohorts for Heart and Aging Research in Genomic Epidemiology) Consortium when examining antihypertensive drug targets [121]. Additionally, in a whole-exome sequencing and bioinformatics analysis for autosomal dominant long QT syndrome, a novel variant in *CACNA1C* (Pro857Arg) was identified, and was shown to cause a gain-of-function mutation leading to increased expression of the channel [156]. This gene was evaluated for pharmacogenomic effect in INVEST. A synonymous SNP at codon 1835, rs1051375, was found to have a significant interaction with treatment strategy in the combined cohort containing whites, Hispanics, and African-Americans (interaction p = 0.0001) [124]. Individuals with the AA genotype had lower rates of the primary outcome (all-cause death, nonfatal myocardial infarction, and nonfatal stroke) in the CCB strategy (Figure 32.10) [124], whereas individuals with the GG genotype had lower rates of the primary outcome in the β-blocker strategy (Figure 32.10) [124]. This treatment interaction remained when looking at whites alone (interaction p = 0.002) [124]. These pharmacogenomic results and the associations of SNPs in *CACNA1C* with BP and other cardiovascular traits support *CACNA1C*'s role in treatment-related cardiovascular outcomes.

32.6.2.5 *Fibrinogen-beta*

The fibrinogen-beta (*FGB*) gene encodes the fibrinogen-β chain, one of the three polypeptide chains that make up the coagulation factor fibrinogen. Higher plasma fibrinogen levels have been associated with coronary heart disease, stroke, and mortality [157]. Additionally, the A allele at the *FGB*-455 G>A variant has been associated with higher levels of fibrinogen [158]. It is also known that ACE inhibitors

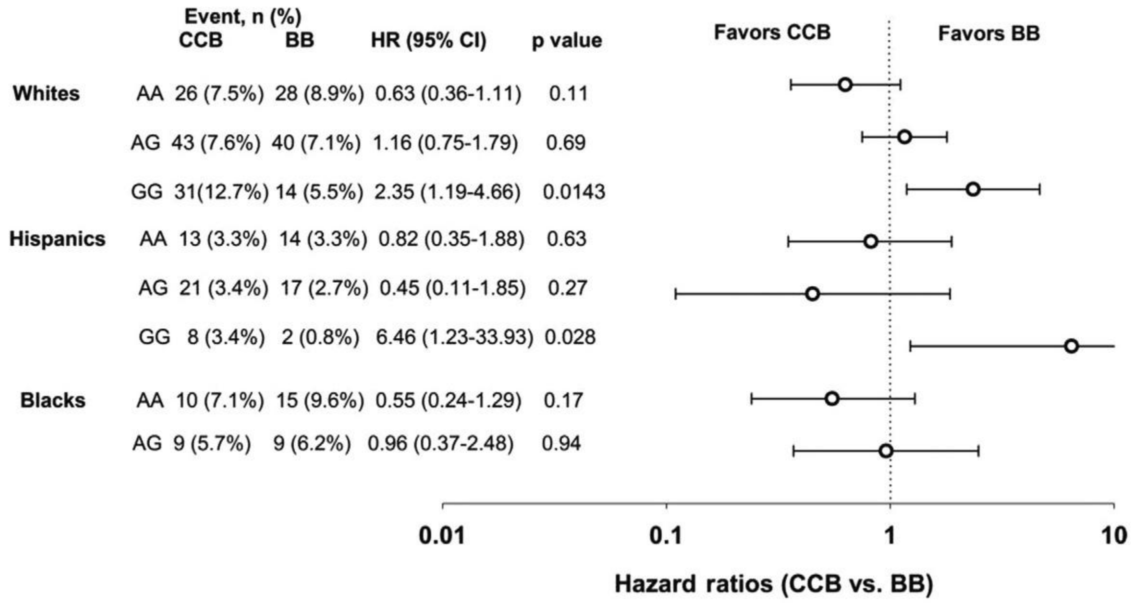

FIGURE 32.9 **Pharmacogenetic association of *CACNB2* rs2357928 and treatment strategies in the three race/ethnicity groups in INVEST.** Hazard ratios are shown in log scale. lower plasma fibrinogen concentrations [159]. The pharmacogenomic relationship between the *FGB*-455 G>A variant and ACE inhibitors was investigated with cardiovascular outcomes (stroke, heart failure, all-cause mortality, and end-stage renal disease) in the GenHAT (Genetics of Hypertension Associated Treatment) study, the genetic substudy of ALLHAT [160]. It was found that GG homozygotes had a higher risk of stroke and mortality when treated with lisinopril compared to amlodipine (stroke: HR = 1.38, $p < 0.001$; mortality: HR = 1.12, $p = 0.02$), and that A allele carriers had a slightly lower risk (interaction $p = 0.03$ and 0.04 for stroke and mortality, respectively) [160]. It was also found that GG homozygotes had a higher risk of mortality and end-stage renal disease when treated with lisinopril compared to chlorthalidone (mortality: $HR = 1.05$, $p = 0.23$; end-stage renal disease: $HR = 1.27$, $p = 0.08$), and that A allele carriers had a lower risk (interaction $p = 0.03$ for both mortality and end-stage renal disease) [160]. These results, coupled with the functional evidence of association between fibrinogen levels and ACE inhibitors, and fibrinogen levels and the *FGB*-455 G>A variant, suggest that *FGB* may be involved in ACE inhibitor treatment-related outcomes.

32.6.2.6 Genetic Risk Scores: SIGLEC12, A1BG, and the Selectin Region

One of the issues in hypertension pharmacogenomics is how to put the results together into something that is clinically meaningful, as there are many single-gene associations, each contributing a smaller effect. One method that can be used to combine the results of many associations is the building of a risk score, where each risk allele or genotype is assigned a point value and the sum of the point values across all associated SNPs becomes the test variable. This approach was used in an analysis of nonsynonymous SNPs on the Illumina HumanCVD chip in INVEST [161]. First, single SNPs were identified that were associated with a treatment interaction when looking at adverse cardiovascular outcomes [161]. Two SNPs were found that were associated with treatment-related cardiovascular outcomes in INVEST whites and Hispanics: *SIGLEC12* rs16982743 (Gln29Stop) and *A1BG* rs893184 (His52Arg) (combined interaction $p = 0.0038$ and 0.0036, respectively) [161]. Additionally a region on chromosome 1 was identified that showed associations with treatment interaction in both INVEST whites and Hispanics. This region encompassed *F5*, *SELP*, and *SELE*; through additional analyses, rs4525 (His865Arg) in *F5* was selected as the best signal to represent the region.

A genetic risk score constructed from rs16982743, rs893184, and rs4525 was significantly associated with treatment-related adverse cardiovascular outcomes in whites and Hispanics from INVEST and in NORDIL (meta-analysis interaction $p = 2.39 \times 10^{-5}$) (Figure 32.11) [161]. In individuals with a genetic risk score of 0 or 1, CCB treatment was associated with lower risk of adverse cardiovascular outcomes compared to β-blocker treatment (OR (95% CI) = 0.60 (0.42–0.86) (Figure 32.11). In those with a genetic risk score of 2–3, CCB treatment was associated with higher risk of adverse cardiovascular outcomes compared to β-blocker treatment, OR (95% CI) = 1.31 (1.08–1.59) (Figure 32.11) [161].

These gene regions all are related to immune cell trafficking and/or are in the immunoglobulin superfamily. *SIGLEC12* encodes the sialic acid–binding Ig-like lectin 12, a single-pass, type I transmembrane protein belonging to

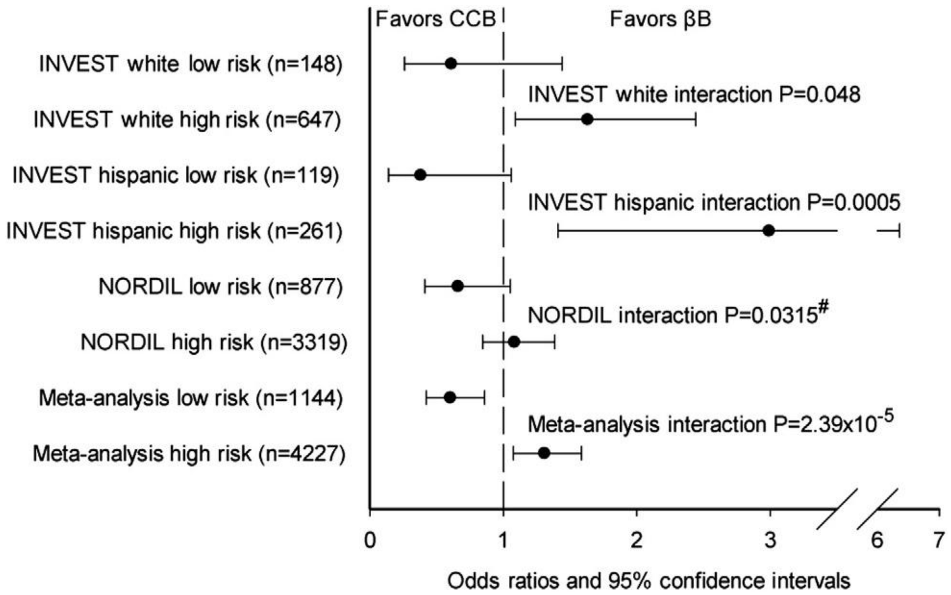

FIGURE 32.11 **Risk-score pharmacogenomic association with the primary outcome in INVEST.** Risk score calculated from *SIGLEC12* rs16982743, *A1BG* rs893184, and *F5* rs4525. One point was given for each genotype that conferred higher risk in the CCB arm/group versus the βB arm/group: rs16982743 GG (Gln/Gln), rs893184 GG (Arg/Arg), and rs4525 AA (His/His). Low Risk defined as a risk score = 0 or 1; High Risk defined as a risk score = 2 or 3. #: One-sided *P*-value based on one-sided hypothesis in replication cohort. CCB: Calcium channel blocker treatment strategy. βB: β-blocker treatment strategy. *Source: Used with permission from McDonough et al.* [161].

the immunoglobulin superfamily. It is expressed on the epithelial cell surface and on some macrophages. It has been suggested that *SIGLEC12* could be involved in the negative regulation of macrophage signaling by functioning as an inhibitory receptor [162]. Additionally, other members of the *SIGLEC* family have been shown to be expressed abundantly on macrophages recruited during the pathogenesis of atherosclerosis [163]. The alpha 1B-glycoprotein precursor (*A1BG*) encodes a plasma glycoprotein with unknown function. The A1BG protein is a member of the immunoglobulin superfamily, and has been shown to form a complex with CRISP-3 (cysteine-rich secretory protein 3), which is present in neutrophilic granulocytes and is thought to play a role in innate immunity [164].

The last region identified from the treatment interaction analyses contains signals in three genes: *F5*, coagulation factor V; *SELP*, selectin P; and *SELE*, selectin E. *F5* encodes an essential cofactor in the blood coagulation cascade, participating as half of the complex that activates prothrombin to thrombin during the blood-clotting process [165]. *SELP* and *SELE* are members of the selectin family of cell adhesion molecules, and both mediate leukocyte rolling, a process essential for the initiation of atherosclerosis [166]. P-selectin is in stored platelets and endothelial cells and, upon activation, redistributes to the plasma membrane; E-selectin, on the other hand, is only expressed on endothelial cells [166]. Many prior genetic associations have been seen with *F5*, *SELP*, *SELE*, and CVD [167–169].

These results suggest cardiovascular outcomes may differ based on the *SIGLEC12*, *A1BG*, and *F5* genotypes and antihypertensive treatment strategy. Such specific genetic associations and the use of a genetic risk score provide insight into a potential approach to selecting personalized antihypertensive treatment.

32.6.2.7 *ADD1*

There are genes that initially showed evidence of a positive pharmacogenomic association, but for which subsequent studies have been unable to replicate results. This is the case with *ADD1*, the α-adducin gene. *ADD1* is a ubiquitously expressed protein that is part of the cytoskeleton and may modulate ion transport. One SNP in *ADD1*, Gly460Trp (rs4961), which was previously associated with hypertension and salt sensitivity [95], has been studied many times for a pharmacogenomic effect. A population-based case-control study found that, in Trp460 variant carriers, diuretic use was associated with a significant decrease in the risk of myocardial infarction or stroke compared to all other antihypertensive therapies (OR (95% CI) = 0.49 (0.32–0.77)) [170]. However, this was also studied in GenHAT [171], INVEST [172], PHARMO [173], and LIFE [139], and was not replicated. Taken together, these results suggest that there is no pharmacogenomic effect between *ADD1* Gly460Trp, cardiovascular outcomes, and diuretic use.

32.6.2.8 *ACE*

ACE is another gene with strong evidence for no pharmacogenomic effect. The *ACE* I/D variant, a 287-bp insertion/deletion in intron 16, has been extensively studied: individuals with the D allele have higher plasma ACE activity [132]. The interaction between the *ACE* I/D genotype, antihypertensive treatment, and risk of adverse cardiovascular outcomes was studied in GenHAT [174]. There was no difference by *ACE* I/D genotype, antihypertensive treatment (diuretic, CCB, ACE inhibitor, or α-blocker), and cardiovascular outcomes ($p \geq 0.26$) [174].

Two other studies saw similar results, observing no evidence of a pharmacogenomic effect for adverse cardiovascular outcomes by *ACE* I/D genotype [139,175]. In the LIFE study, there were no differences between *ACE* I/D genotype, cardiovascular events, and treatment with an ACE inhibitor or β-blocker [139]. In a hypertension case-control cohort from the population-based Rotterdam study, there were also no differences observed between *ACE* I/D genotype, risk of myocardial infarction or stroke, and ACE inhibitor or β-blocker use [175]. However, in a population-based registry of pharmacy records linked to hospital discharge records (PHARMO), significant treatment interaction was observed between *ACE* rs4341 (which is in linkage disequilibrium with *ACE* I/D), ACE inhibitor treatment, and the risk of myocardial infarction [176]. Individuals who were ACE inhibitor users with the rs4341 G allele (which is inherited with the *ACE* D allele) had a greater reduction in risk for myocardial infarction compared to those with the CC genotype (synergy index for interaction (SI) = 0.58, 95% CI, 0.35–0.95) [176]. While there were significant results in one study, the other three studies did not see an association between antihypertensive treatment outcomes and *ACE* I/D genotype, which suggests that there is no pharmacogenomic effect.

32.6.3 Additional Genes with Evidence of Association with Treatment-Related Outcomes

Other genes evincing association with treatment-related outcomes do not have replication but are reasonable candidate genes, many antihypertensive drug targets, or hypertension genes. In many cases, these have been evaluated in only one study, but their biological plausibility makes them worth mention. These include *KCNMB1*, *NR1H3*, *MMP9*, *MMP12*, *NOS3*, *NPPA*, *RYR3*, *AGT*, and *AGTR1*. Many of these were combined through the use of a gene panel in GenHAT [177].

32.6.3.1 *KCNMB1*

The interaction between *KCNMB1* nonsynonymous SNPs, Glu65Lys and Val110Leu, and treatment strategy for long-term cardiovascular outcome (all-cause death, nonfatal myocardial infarction, and nonfatal stroke) was studied in INVEST [131]. The results showed that at the Val110Leu variant, Leu110 variant carriers had a 32% reduced risk of the primary outcome compared to noncarriers when both treatment groups were combined [131]. While the treatment interaction term was not significant with the Val110Leu variant, the association was limited to those individuals randomized to the CCB strategy (HR (95% CI) = 0.55 (0.31–0.97)), and was not observed in those randomized to the β-blocker strategy (HR (95% CI) = 0.84 (0.51–1.41)) [131].

32.6.3.2 Liver X Receptor Alpha

NR1H3 encodes for liver X receptor-α (LXRA), a nuclear receptor that has been associated with body mass index and cholesterol levels. Evidence has also shown that ligands of liver X receptors decrease RAAS activation [178]. Taken together, this suggests that variants in *NR1H3* may contribute to adverse cardiovascular outcomes. Seven tag SNPs in *NR1H3* were evaluated for association with adverse cardiovascular events in INVEST [179]. A significant treatment interaction was observed with rs2279238, where T carriers had increased risk of adverse cardiovascular outcomes in the CCB strategy compared to the β-blocker strategy (OR (95% CI) = 2.86 (1.50–5.46), Interaction p = 0.0015) [179].

32.6.3.3 MMP9 and MMP12

MMP9 and *MMP12* are two matrix metalloproteinases. MMP-9, gelatinase-B, functions in the degradation of type IV and V collagens; elevated levels of MMP-9 have been observed in individuals with hypertension. MMP-12 is also known as the macrophage metalloelastase and is up regulated in atherosclerotic lesions. Two SNPs in *MMP9* (Arg279Gln, rs17576; Arg668Gln, rs2274756) and two SNPs in *MMP12* (Asn122Ser, rs652438; −82A>G, rs2276109) were investigated in the GenHAT study to determine whether hypertensive participants randomized to a diuretic (chlorthalidone), a CCB (amlodipine), or an ACE inhibitor (lisinopril) had different cardiovascular outcome rates.

Pharmacogenomic associations were seen for Arg279Gln, Arg668Gln, and Asn122Ser with numerous cardiovascular outcomes. In general, at *MMP9* Arg279Gln, modest pharmacogenomic effects were seen for the composite cardiovascular disease outcome and for combined coronary heart disease, with individuals with the GG genotype having lower risk when randomized to the diuretic versus the CCB or the ACE inhibitor. This is in comparison to individuals who were A carriers [180]. At *MMP9* Arg668Gln, lower HRs were observed for individuals with the AA genotype for most diuretic treatment outcomes when compared to CCB treatment. At the *MMP12* Asn122Ser SNP, higher HRs were seen in individuals with at least one G allele who were on the ACE inhibitor compared to the CCB for both coronary heart disease and the composite cardiovascular disease outcome. However, there were no pharmacogenomic effects observed with the −82A>G variant [180].

32.6.3.4 NOS3

NOS3, nitric oxide synthase 3, is the endothelial nitric oxide synthase that catalyzes nitric oxide production. Nitric oxide is a signaling molecule involved in vasodilation and vascular smooth-muscle relaxation. Decreases in nitric oxide lead to hypertension and atherosclerosis [181], whereas overproduction leads to cell damage. Variants in *NOS3* have been associated with various cardiovascular diseases, including myocardial infarction [182] and coronary artery disease [183]. Additionally, CCB's mechanism of inhibiting calcium influx into smooth-muscle cells leads to vasorelaxation and may act through activation of *NOS3* [184].

The theory that variants in *NOS3* may be associated with different cardiovascular outcomes in individuals on a CCB treatment strategy was tested in the GenHAT study [185]. Three SNPs in *NOS3*—rs3918226, rs1800779, and rs1799983—were tested for a pharmacogenetic effect on cardiovascular outcomes. Significant findings were observed with stroke and all-cause mortality [185]. At rs3918226 (*NOS3*-690 C>T), T allele carriers had a lower risk for stroke when treated with a CCB compared to an ACE inhibitor (HR (95% CI) = 0.49 (0.31–0.80), interaction p = 0.04) [185]. Also, at rs1799983 (*NOS3* Glu298Asp), Asp carriers (T carriers) had a lower risk of all-cause mortality when treated with a CCB compared to an ACE inhibitor (HR (95% CI) = 0.85 (0.75–0.97), interaction p = 0.04) [185].

32.6.3.5 NPPA

The atrial natriuretic precursor A gene, *NPPA*, encodes the precursor for atrial natriuretic polypeptide, which acts as a diuretic by controlling extracellular fluid volume and electrolyte homeostasis [186]. Prior associations have been seen between SNPs in *NPPA* and adverse cardiovascular outcomes such as stroke [187] and coronary artery disease [188]. Two of these SNPs, *NPPA* G664A and *NPPA* T2238C, were studied in GenHAT to determine if individuals treated with a diuretic would have different outcomes based on their genotype when compared to individuals treated with a CCB or an ACE inhibitor [189]. A pharmacogenetic effect was observed at *NPPA* T2238C—C allele carriers had lower rates of coronary heart disease and stroke when treated with a diuretic compared to a CCB; individuals with the TT genotype had lower rates when treated with a CCB compared to a diuretic (interaction p = 0.03 and 0.01, respectively, for coronary heart disease and stroke) [189].

32.6.3.6 RYR3

Genes involved in the maintenance of calcium homeostasis have also been considered as candidate genes for hypertension pharmacogenomics. One is the ryanodine receptor 3 gene (*RYR3*), an intracellular calcium channel expressed in human arterial endothelial cells which mediates the mobilization of stored calcium to initiate muscle contraction in cardiac and skeletal muscle [190]. SNPs in *RYR3* have been associated with carotid intima-media thickness [191]. Additionally, evidence associates both *RYR3* and CCBs with heart failure [192,193]. Using a case-only design, GenHAT tested three SNPs in *RYR3* for a pharmacogenomic effect between antihypertensive treatment and adverse cardiovascular outcomes [194]. There was evidence of a pharmacogenomic effect with two of the SNPs, rs877087 and rs2077268, and heart failure. At rs877087, TT homozygotes fared worse when treated with a CCB compared to a diuretic (TT cases = 26% for CCB and 19% for diuretic); also, CC homozygotes fared better when treated with a CCB compared to a diuretic (CC cases = 32% for CCB and 29% for diuretic, interaction $p = 0.005$) [194]. At rs2077268, similar trends were seen: minor allele homozygotes, TT, did worse on a CCB compared to a diuretic (TT cases = 5% for CCB and 2% for diuretic), and major allele homozygotes, CC, did better on a CCB compared to a diuretic (CC cases = 69% for CCB and 72% for diuretic, interaction $p = 0.01$) [194].

32.6.3.7 AGT

The pharmacogenomic effect of the *AGT* Met235Thr variant was investigated in the Rotterdam study and in PHARMO [176,195]. In the Rotterdam population-based case-control cohort, ACE inhibitor users with one copy of the Thr allele (Thr/Thr or Met/Thr genotype) had an increased risk of myocardial infarction compared to ACE inhibitor users with the Met/Met genotype (SI (95% CI) = 4.00 (1.32–12.11)) [195]. However, the PHARMO study found no association between the Met235Thr genotype, ACE inhibitor use, and myocardial infarction risk [176].

32.6.3.8 AGTR1

SNPs in *AGTR1* were investigated in both the Rotterdam study and PHARMO for any association with antihypertensive treatment and adverse cardiovascular outcomes [175,176]. The *AGTR1* 573 C/T polymorphism (rs5182) was investigated in a population based case-control cohort from the Rotterdam study. It was found that individuals currently using ACE inhibitors with the CT or CC genotype at rs5182 had a reduced risk of myocardial infarction as compared to those currently using ACE inhibitors with the TT genotype [175]. There was no significant interaction observed with the risk of stroke [175].

The PHARMO study looked at the pharmacogenomic effect of the *AGTR1* 1166 A/C polymorphism in relation to antihypertensive treatment and myocardial infarction risk. In ACE inhibitor users who were prescribed low daily doses, the risk of myocardial infarction was reduced in A carriers compared to those with the CC genotype (SI (95% CI) = 3.67 (1.18–11.4)) [176].

32.6.3.9 Gene Panels

Another method of combining multiple associations is the gene panel, which stratifies patients into different treatment groups. This approach was used in GenHAT to identify subgroups of individuals at high and low risk of coronary heart disease based on antihypertensive treatment [196]. The initial panel contained 78 SNPs in hypertension pharmacogenomic candidate genes; a specific panel was identified to stratify individuals into each of the four treatment groups: diuretic, CCB, ACE inhibitor, and α-blocker [196]. The panels in the specific treatment groups were then used to see if including the SNP data improved the prediction of coronary heart disease.

Overall, the panels identified between the four treatment groups had little overlap, but they did improve the prediction of coronary heart disease in each treatment group at a statistically significant level [196]. For the diuretic, the SNPs included were *NOS3* rs3918226, *SELE* rs5361, *ICAM1* rs1799969, *AGT* rs5051, and *GNAS* rs7121. For the CCB, the following SNPs were identified: *MMP1* rs1799750, *F5* rs6025, *NPPA* rs5065, *PDE4D* rs6450512, and *MMP9* rs2274756. The SNPs on the panel for the ACE inhibitor were *AGT* rs5051, *PON1* rs705379, *MMP12* rs652428, *F12* rs1801020, *GP1BA* rs6065, and *PDE4D* rs27653. The SNPs included for the α-blocker panel were *F2* rs1799963, *PAI1* rs1799768, *MMP7* rs11568818, *AGT* rs5051, *ACE* rs4343, and *MMP2* rs243865 [196]. Each of the four panels was also tested for a pharmacogenomic effect; evidence was seen in three of them (diuretic, CCB, and α-blocker) [196].

Overall, the top signals so far identified as having an association with treatment interaction are in strong biologically plausible genes; they have evidence of replication and/or associations with related phenotypes. Additionally, many of the SNPs have been shown to be functional. These top genes include *ADRB1*, *NEDD4L*, *CACNB2*, *CACNA1C*, and *FGB* (identified in candidate gene approaches) and *SIGLEC12*, *A1BG*, and *F5* (identified by genome spanning). While all of these results are convincing, additional replication is necessary and studies need to be conducted to determine how these results can be used in the clinical setting to stratify patients to a specific antihypertensive treatment regimen or strategy based on genetic information.

32.7 FUTURE PERSPECTIVES

Although presently there are many genes with compelling data for both BP response and treatment-related outcomes, more work needs to be done. Many of the genes highlighted in this chapter need additional replication and functional studies, especially those identified through GWASs, to further elucidate their role in hypertension pharmacogenomics and their mechanisms of action. Additionally, studies must be carried out to determine how these data can be incorporated into patient care.

The first step in integrating results in the clinical setting will be determining which SNPs/genes have enough evidence to be clinically actionable. Once there is enough evidence, methods of combining results will have to be investigated. Two approaches have so far been used to combine multiple single SNP/gene findings to make them more useful in a clinical setting. The first, genetic risk scores, has been used in BP response [197] and treatment-related outcomes [161]. Genetic risk scores are more commonly seen in disease genetics [198,199], but their use in pharmacogenomics is valuable for future clinical translation. This is especially true for hypertension pharmacogenomics, as multiple genetic signals are likely involved. Risk scores are typically constructed from prior association signals and tested in an independent population [198,199]. In both cases of the use of genetic risk scores in hypertension pharmacogenomics, the scores were constructed in the discovery population but were confirmed through permutation testing [197] or through replication in an independent population [161]. The second method of combining multiple SNPs/genes employs a gene panel to stratified subjects into a treatment category. This method was used in GenHAT to identify risk groups for coronary heart disease [177]. Both methods rely on combining multiple signals into one clinically useful variable.

In the future, it is likely that whole-genome SNP or sequence data will be available in a patient's medical record [200]. When this occurs, the implementation of genetic data in patient care will not depend on a genetic test result and there will be no need to conduct multiple tests to determine what drug the patient responds to. At present, a single SNP chip would be most useful as a means of stratifying patients to the best antihypertensive treatment option. This way only a single test would be ordered. However, difficulties remain, as we have many new discoveries every year, and the level of evidence differs according to antihypertensive drug class.

There are still many unanswered questions in hypertension pharmacogenomics, and many regions of the genome have yet to be interrogated. There are many ongoing GWASs for both BP response and treatment-related outcomes. For BP response, these include PEAR [75], GENRES [77], GERA [76,86], and NORDIL [74], as well as UNISA and INPH (Italian Network for the Pharmacogenomics of Hypertension). For treatment-related outcomes, there are INVEST [73], NORDIL [74], ASCOT [71], and SPS3 [201]. There is also ALLHAT's GenHAT substudy [72], which, although not doing a GWAS at this time, may be useful for replication. The completion and publication of these studies will further define the potential for clinical implementation in hypertension pharmacogenomics.

The International Consortium for Antihypertensives Pharmacogenomics Studies, or ICAPs (www.pharmgkb.org/page/icaps) was formed in mid-2012 with the goal of facilitating collaboration among research groups and performing meta-analyses for both BP response and treatment-related outcomes. The international collaboration that ICAPs fosters will advance the field of hypertension pharmacogenomics; moreover, the results of the meta-analyses should provide a list of SNPs and genes that have strong evidence for clinical implementation.

All in all, the next decade should see many exciting results in the field of hypertension pharmacogenomics.

33.1 OVERVIEW

33.1.1 The Resting ECG

Muscles contract as a result of electrical changes known as "depolarizations." Such changes can be detected by electrodes attached on the surface of the body [1]. In order to measure depolarizations in heart muscle during a resting ECG, the patient must be fully relaxed, with no other skeletal muscles contracting. Standard readings are in the form of a 12-lead electrocardiogram (ECG), the 12-lead tracing being derived from six chest and four limb electrodes. Before going further, it is important to briefly summarize the anatomy of the heart. Blood enters the right atrium from the rest of the body via two large veins: the inferior vena cava from below and the superior vena cava from above. The left atrium receives blood from the lungs via the pulmonary veins. The atria are the two upper chambers of the heart, and their contraction forces blood into the lower two

chambers, the ventricles. The blood is then pumped out of the heart by the ventricles to supply the lungs (from the right ventricle via the pulmonary artery) and the rest of the body (from the left ventricle via the aorta). Depolarization begins in the sinoatrial (SA) node and spreads as a wave through the atrial muscles. There is then delay as depolarization spreads through the atrioventricular (AV) node, but thereafter conduction is rapid as it travels down specialized conduction tissue [1]. This begins as a single pathway, the "bundle of His," and then divides into right and left branches. Within the mass of ventricular muscle, conduction spreads rapidly through "Purkinje fibers" which are specialized tissues. The speeds of conduction through the various tissues are as follows: atrial muscle 1 meter per second (m/s); AV node 0.2 m/s; His bundle, bundle branches, and Purkinje tissue 4.0 m/s; and ventricular muscle 0.5 m/s [1]. On the ECG tracing, the P wave represents depolarization of the atria, (see Figure 33.1). The PR interval represents conduction through the AV node and His bundle and measures the time it takes for the depolarization wave to spread from the atria to the interventricular septum. The QRS complex is the combination of three deflections "Q", "R" and "S" (see Figure 33.1) seen in rapid succession and represents depolarization of the ventricles. The T wave represents ventricular muscle repolarization [1]. U waves can occasionally be seen as extra humps on the end of a T wave and are thought to represent repolarization of the papillary muscles of the heart. However, they can also be indicative of hypokalaemia.

Normally each heartbeat consists of a P wave followed by a QRS complex. The QRS complex should then have only one associated T wave. The time taken for each of these sections of the ECG can be measured. Normal paper speed is 25 millimeters per second (mm/s), one large square represents 200 milliseconds (ms), and one small square represents 40 ms. The normal limits are as follows: PR interval, 120–200 ms; QRS complex, <120 ms; T-wave duration is difficult to measure [1]. Therefore, the QT interval, discussed in the next section, is usually taken as the best indication of the time taken for repolarization of the ventricles.

33.1.2 The QT Interval

On a 12-lead ECG, the QT interval is measured from the beginning of the QRS complex to the end of the T wave as it returns to baseline [2]. It can be affected by both ventricular conduction velocities and the velocity of repolarization. Manual measurements of the QT interval should be taken from leads II and V5 or V6, with the longest value being used. A mean value should be derived from at least 3–4 cardiac cycles. The end of the T wave can be determined reliably by the slope method [2], defined by the intersection point between the tangent drawn at the maximum downslope of the T wave and the isoelectric line. If the T wave is notched, the tangent should be applied to the maximum slope as described by Postema et al. [2]. (See Figure 33.1.) Long-QT syndrome (LQTS) is characterized by a prolonged QT interval in the surface ECG, and can be associated with a propensity to develop syncope and sudden cardiac death (SCD). In most documented cases, death was caused by the malignant polymorphic ventricular arrhythmia called torsades de pointes (TdP). Cardiomyocytes differ from other tissues (neurons and skeletal muscle) in that they possess a long action potential, approximately 300 ms [3]. For normal sinus rhythm to be maintained, an ordered pattern of conduction and repolarization is essential. The normal QT in healthy people without other cardiac conductance–altering factors is usually ~400 msec when measuring this interval in lead II of the ECG. Taking the measurement in this lead is suggested because it is considered to have the longest interval [3]. The absolute value of the measured QT interval should be corrected for heart rate because the QT interval varies with changes in heart rate. For example, in tachycardia the action potential will be shorter, and the absolute measure of QT will also be shorter as a consequence of this [3] (see Section 33.1.4).

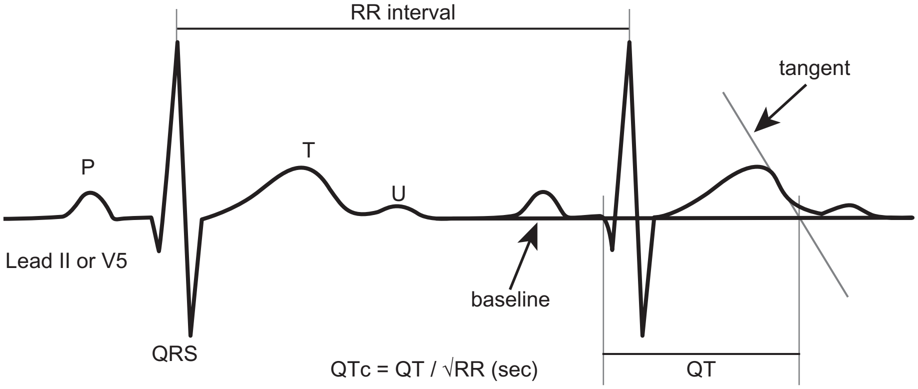

FIGURE 33.1 **QT interval.** A tangent is drawn to the steepest slope of the last limb of the T wave in lead II or V5. The end of the T wave is the intersection of the tangent with the baseline. QT is heart rate corrected with Bazett's formula using the preceding RR interval. *Source: Reprinted from Postema et al.* [2] *with permission.*

33.1.3 Torsades de Pointes

In 1966, Dessertenne reported his index case of an elderly woman with complete AV block and syncopal attacks due to a polymorphic ventricular tachycardia (VT) [4]. He termed this condition *torsades de pointes* (TdP). The definition of TdP is as follows: a polymorphic ventricular tachycardia characterized by a "twisting of the points" around the isoelectric line on the electrocardiogram (ECG) preceded by a long QT interval [3]. The polymorphic nature of TdP may not always be evident, particularly when the arrhythmia is recorded on only one or two leads. A pause-dependent tachycardia associated with severe QT prolongation may therefore appear to be "monomorphic" when in fact it represents TdP [5]. Such diagnostic difficulties reinforce the need for documentation of the index arrhythmia event and for review by expert physicians. It is also important to note that TdP can be seen in both congenital and acquired long QT syndrome.

TdP is often self-limiting, producing transient syncope, but it can also degenerate into ventricular fibrillation and cause cardiac arrest or sudden death. We still do not know why in some patients TdP stops after a few seconds whereas in others it continues with serious or devastating consequences. Although QT prolongation is clearly associated with an increased risk of TdP, there is no reliable criterion to identify the length of QT prolongation that is associated with a clinically significant increased risk of TdP [3]. This makes it difficult for clinicians to decide what QT interval represents significant risk of TdP and requires intervention. In acquired LQTS, torsades de pointes is characteristically preceded by a "short-long-short" ventricular sequence ("pause-dependent" phenomenon) [5]. Common associated features are pause-dependent changes in T-wave morphology and late coupled ventricular ectopy, which is often slower than coarse ventricular fibrillation [5]. See Figure 33.2a for an example of a short-long-short ECG sequence and Figure 33.2b for an example of QRS complexes twisting around an isoelectric line in Torsades de Pointes. Figure 33.2c from Kannankeril et al. [6] shows the 12-lead ECG of an elderly patient with advanced heart disease who had begun taking dofetilide. An abnormal QT interval is followed by a pause, then four beats of polymorphic ventricular tachycardia. After another pause there is sustained TdP.

In some types of congenital LQTS it is postulated that TdP is more likely to be triggered by adrenergic stimulation, and in such cases, is classified as adrenergic-dependent. However, these classifications are not mutually exclusive; adrenergic-dependent TdP is more likely to occur in the presence of pauses or slow heart rates [7].

33.1.4 Corrected QT Interval

It is generally accepted that in the context of drug-induced QT prolongation, an increase in the corrected QT (QTc) interval of >40 ms is alarming, and increases in mean QTc of 6 ms are important. In clinical practice, diagnosis of potentially serious QT interval changes requires this trait to be measured with precision [8,9]. The risk of proarrhythmia varies from drug to drug and may be a patient-specific response. It is unpredictable and influenced by several predisposing factors discussed in Section 33.3. However, QT interval assessment does remain a prerequisite for drug development, approval, and clinical testing [9].

The very real problem of erroneous QTc increases (overcorrection) at heart rates of more than 60 beats/min, or QTc decreases (undercorrection) at heart rates of fewer than 60 beats/min must always be taken into consideration by clinicians and researchers as well as the pharmaceutical industry and regulatory bodies [9]. The role of drug safety assessment and the "thorough QT" test is discussed later in this chapter. Based on analysis of digitized data for QT and RR interval measurements in healthy individuals, and using Bazett's formula, the ranges of QTc in Table 33.1 have been suggested for diagnosis of long-QT syndrome [10]. These values are generally accepted in research and clinical practice.

The various methods of correcting QT interval are summarized as follows:

- Bazett: $QTcB = QT/RR^{1/2}$ [9]
- Fridericia: $QTcFi = QT/RR^{1/3}$ [9]
- Framingham-Sagie: $QTcFa = QT + 154\,(1\text{–}60/\text{heartrate})$ [11]
- Hodges: $QTcH = QT + 1.75\ (\text{heart rate}\text{–}60)$ [12]

Chiladakis et al. showed that the different QTc formulas provide significantly different ΔQTc values at lower as well as higher heart rates, whereby the QTcB exhibits the highest ΔQTc variability across the various heart rate stages investigated (60 beats/min, 80 beats/min, and 100 beats/min). Conversely, Hodge's formula showed the least heart rate–dependent ΔQTc values followed by Fridericia, and Framingham [9]. Despite these findings, Bazett's formula remains the most commonly used method of QTc correction; however, its limitations should be remembered, and in borderline cases it may be useful to perform QTc correction by one of the methods with a ΔQTc that is less heart rate–dependent.

33.1.5 Cardiac Myocyte Ion Currents and Action Potentials

The QT interval of the ECG is predominantly determined by duration of the action potential (AP) of ventricular cells. Indeed, most cases of QT interval prolongation are caused by factors that prolong the duration of the AP, mainly by delaying repolarization phase 3 [3]. The normal synchronous contraction of the atria and of the ventricles in sequence require rapid activation of groups of cardiac cells [13].

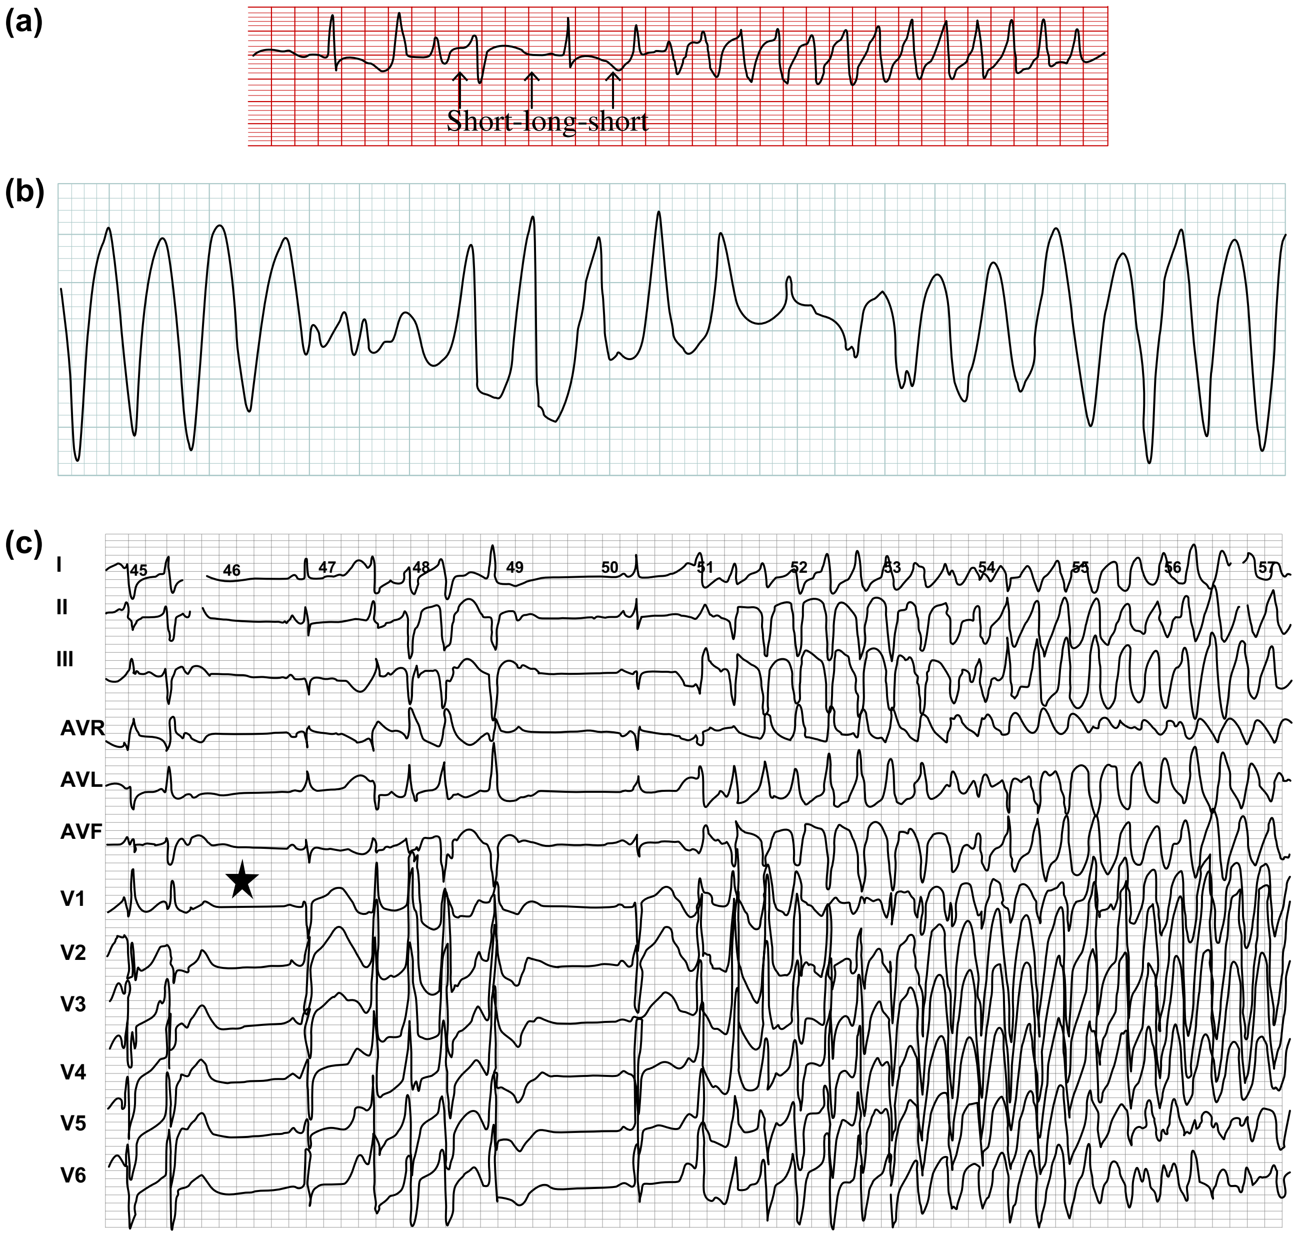

FIGURE 33.2 **Short-long-short sequence preceding TdP; TdP, and drug-induced LQTS.** (a) TdP is usually preceded by a short-long-short ECG sequence. Here one or more premature ventricular complexes are followed by a compensatory pause. The subsequent sinus beat may have an especially long QT and deformities of T or U waves. This sinus beat is followed by another premature ventricular complex that precipitates TdP. (b) The QRS complexes are twisting around an isoelectric line in a sinusoidal fashion. (c) A common feature is a pause (often after an ectopic beat) with deranged repolarization in the following cycle. Shown is a 12-lead ECG recorded from a 79-year-old patient with advanced heart disease who had recently begun taking dofetilide. The abnormal QT interval is followed by a pause (star) and then four beats of polymorphic ventricular tachycardia (TdP). Sustained TdP occurs after another pause. *Source: (a) and (b) from Kallergis et al.* [121]; *(c) from Kannankeril et al.* [6] *with permission*.

An activation mechanism must enable rapid changes in heart rate and also respond to changes in autonomic tone. The propagating cardiac action potential fulfils these roles. More than 20 currents subdivided as depolarizing and repolarizing are involved in the AP generation of ventricular cells [3].

There are five phases in a normal action potential (Figure 33.3). Phase 4, the resting potential, is stable at ~−90 mV in normal working myocardial cells [13]; it is followed by phase 0 (upstroke depolarization), caused by the very rapid activation of voltage-gated sodium channels

TABLE 33.1 Suggested Bazett-Corrected QTc Values for Diagnosing QT Prolongation

Rating	1–15 yrs (ms)	Adult Male (ms)	Adult Female (ms)
Normal	<440	<430	<450
Borderline	440–460	430–450	450–470
Prolonged	>460	>450	>470

ms = milliseconds.

FIGURE 33.3 **Myocardial action potential.** Phase 0 rapid depolarization is mediated by sodium entry into cells. Phase 1 and 3 repolarization results from potassium efflux from cells. Balanced slow calcium entry and potassium exit cause the plateau in phase 2. Potassium re-enters and sodium exits cells during phase 4 recovery. *Source: From Kallergis et al.* [121].

Nav1.5. Next is phase 1, a phase of rapid repolarization due to the transient outward K^+ current. Phase 2, the plateau phase is maintained by inward Ca^{2+} current flowing through slowly inactivating Cav1.2 voltage-gated channels. This is the longest phase. Phase 3 is a phase of rapid depolarization which restores the membrane potential back to its resting value [13]. It occurs through the action of outward currents including: I_{Ks} (slow delayed rectifier potassium current) and I_{Kr} (rapid delayed rectifier potassium current). The main pore-forming subunit (alpha subunit) of I_{Ks} is called KvLQT1 or *KCNQ1* (new nomenclature: Kv7.1); of I_{Kr}, HERG or *KCNH2* (new nomenclature: Kv11.1) [3]. The currents generated by all other ion transporters (ATPases, exchangers, and ion channels) also contribute to shape the AP, as shown in Figure 33.3.

The action potentials of pacemaker cells in the sinoatrial (SA) and atrioventricular (AV) nodes are significantly different from those in the myocardium. In the pacemaker cells, the membrane potential at the onset of phase 4 is more depolarized (−50 to −65 mV). It undergoes slow diastolic depolarization and gradually merges into phase 0 [13]. Indeed, rate of depolarization in phase 0 is much slower than that in the myocardial cells. This ultimately results in slow propagation of the cardiac impulse in the nodal regions [13].

Characteristics of the action potential are also different across the myocardial wall from endocardium, mid-myocardium, to epicardium [13], with epicardial cells having a prominent phase 1 and the shortest action potential. Mid-myocardial cells have the longest action potential duration. Overall, prolonged repolarization in cardiac ventricular myocytes may be due to an increase in depolarizing inward currents or to a decrease in repolarizing outward currents.

A decrease in repolarizing outward currents mostly involves potassium channels, in particular the delayed rectifier potassium current, I_K in cases of drug-induced LQTS [3]. The rapid delayed rectifier potassium current (I_{Kr}) is the primary molecular target for most blocking drugs known to cause TdP. It links congenital and acquired LQTS. Interestingly, it was only through finding genetic mutations in congenital LQTS that the role of specific ion channels in human physiology could be ascertained [3].

Some animal models have investigated drug-induced TdP occurring after pretreatment with the α-blocker methoxamine or after complete atrioventricular nodal ablation [14]. A likely mechanism in both situations is the inhibition of I_{Ks} and enhancement of the pharmacologic effect of the I_{Kr} blockade. Striking action potential lability on drug exposure, in the dog model of atrioventricular nodal ablation, separates arrhythmia-prone from arrhythmia-resistant animals. This suggests that measurement of the QT interval alone may not be sufficient in assessing risk, as other indices of repolarization are also important [14].

33.2 GENETIC SYNDROMES

Congenital and drug-induced long-QT syndromes were beginning to be described in the 1950s; as early as the 1960s, the link between congenital and drug-induced long-QT syndrome was being considered.

33.2.1 Congenital Long-QT Syndrome

Congenital LQTS has a prevalence of 1 in 2000 to 1 in 3000 [15] and may account for up to 13% of sudden infant death [16]. The rare congenital forms of long-QT syndrome (cLQTS) are mainly divided into the autosomal recessive variety associated with deafness (first described by Jervell and Lange-Nielsen in 1957) and the more prevalent autosomal dominant Romano-Ward syndrome (described by Romano et al. in 1963 and Ward in 1964). There are now 13 genes implicated in congenital long-QT syndrome (see Table 33.2) and novel genes continue to be identified.

LQT1, LQT2, and LQT3 phenotypes account for the majority of cLQTS cases. LQT1 accounts for 40–55% [17,18]. The LQT1 gene is *KCNQ1*, isolated on chromosome 11p15.5. *KCNQ1* encodes potassium channel subunits, which are highly expressed in the heart. Four KvLQT1 alpha subunits interact with other proteins (e.g., the minK beta subunit) to create the IK_s ion channel [17]. This channel is responsible for the delayed potassium rectifier current of the cardiac action potential, as mentioned previously. Mutations in the *KCNQ1* gene can be inherited in an autosomal dominant or recessive manner, and it is implicated in Romano-Ward and Jervell and Lange-Nielsen syndromes. The LQT1 phenotype is characterized by events induced by exercise.

LQT2 accounts for 30–35% of cases of congenital LQTS [17,18]. It is caused by a variety of mutations in the *human ether-à-go-go gene (HERG)* (also known commonly as *KCNH2*) See Section 33.3.1. This is also a potassium channel gene, located on chromosome 7. The *KCNH2* gene encodes the rapid component of the potassium rectifying current (IK_r). The mutations may involve the pore or the nonpore region of the HERG channel. Pore mutations carry a high risk for cardiac events and may affect young patients [19], whereas nonpore mutations often lead to TdP in the presence of hypokalemia. The most common trigger in LQT2 tends to be emotional stress [18]. LQT3 accounts for 5–10% of cardiac event cases [17,18]. It is caused by mutations in the sodium channel gene (*SCN5A*), located on chromosome 3p21–24, and is characterized by events occurring at rest or during sleep.

Each of the three major genotypes has a distinctively different T-wave repolarization pattern on ECG, with LQT1 exhibiting a broad-based T-wave pattern, LQT2 exhibiting a notched or bifid T wave, and LQT3 having a typical late-onset peaked or biphasic T wave [10]. Studies investigating triggers for cLQTS have also found that, of patients experiencing cardiac events while swimming, 99% had LQT1; of patients experiencing events triggered by loud noises (e.g., alarm clocks), 80% had LQT2 [18].

Criteria for the diagnosis of congenital long-QT syndrome were first introduced in 1985 by Schwartz [20] and consisted of three major and four minor criteria. The criteria were updated in 1993 (see Table 33.3) [21] to take into account the role of sex-related differences, the wide spectrum of clinical abnormalities observed in LQTS, and the contribution of molecular biology. This set of more specific diagnostic criteria provides a quantitative score to discriminate between patients likely or unlikely to be affected by cLQTS [22].

Now, with at least 13 disease-causing LQTS genes identified, we can become more reliant on genotyping to assist us with diagnosis in cLQTS. However, patients who are positive for a cLQTS disease–causing genotype may be completely asymptomatic, with a normal QTc on 12-lead ECG. This can make diagnosis a challenge and can be explained by the concept of low penetrance. Penetrance represents the probability that a genotype positive individual will manifest clinical signs of the condition. In 1999 Priori et al. investigated penetrance in cLQTS families and found that out of 5 families investigated,

TABLE 33.2 Congenital Long-QT Syndrome Genes

Disease Subtype	OMIM Reference Number (www.omim.org)	Syndrome	Gene	Locus	Frequency in LQTS	Gene Protein Product	Functional Effect
LQT1	#192500	RWS, JLNS	*KCNQ1*	11p15.5	40–55%	I_{Ks} channel, α-subunit	Loss-of-function

KCNQ1—potassium voltage-gated channel, KQT-like subfamily, member 1; RWS—Romano-Ward syndrome; JLNS—Jervell and Lange-Nielsen syndrome; *KCNH2*—potassium voltage-gated channel, subfamily H, member 2; *SCN5A*—sodium voltage-gated channel, type V, α subunit; *ANK2*—ankyrin 2; *KCNE1*—potassium voltage-gated channel, I_{SK}-related subfamily, member1; *KCNE2*—potassium voltage-gated channel, I_{SK}-related subfamily, member 2; *KCNJ2*—potassium channel, inwardly rectifying, subfamily J, member 2; AS—Andersen syndrome; *CACNA1C*—calcium voltage-dependent channel, L-type, α-1C subunit; TS—Timothy syndrome; *CAV3*—caveolin 3; *SCN4B*—sodium voltage-gated channel, type IV, β subunit; *AKAP9*—A-kinase anchor protein 9; *SNTA1*—syntrophin α1; *KCNJ5*—potassium channel, inwardly rectifying, subfamily J, member 5.

penetrance varied from 14%–33%. When family history of sudden death at a young age was included (with those dying young assumed to be genotype positive), penetrance varied from 25%–60% [23].

Other factors to be considered in the explanation of incomplete penetrance in cLQTS is the presence of multiple mutations. Mullally et al. [24] assessed the risk of life-threatening cardiac events in patients with multiple cLQTS mutations. Mutations (numbering ≥ 2) could involve either; the same allele of one cLQTS-associated gene, both alleles of the same cLQTS-associated gene, or different cLQTS genes. Patients with autosomal recessive Jervell and Lange-Nielsen syndrome were excluded. Patients with multiple mutations were found to have a longer QTc at enrollment, and had a greater risk for life-threatening cardiac events than those with a single cLQTS mutation [24].

The yield of genetic testing has been found to be highest (72%) among those tested having the highest clinical probability [10]. However, a negative genetic test in a subject with clinical cLQTS (i.e., genotype negative/phenotype positive LQTS) provides no basis for excluding the diagnosis. A positive genetic test may be beneficial in influencing treatment decisions and may provide the means for precise “carrier” status classification of potentially at-risk relatives.

TABLE 33.3 Diagnostic Criteria LQTS—1993 Schwartz

The International Long-QT Syndrome Registry was set up in 1979, and extensive clinical and genetic studies have been conducted since it began. Indeed, publications from the Registry have provided insight into risk mechanisms; genotype-phenotype associations; risk stratification by age, gender, and phenotype; and the importance of syncope as a cardiac event that frequently precedes aborted cardiac arrest or sudden cardiac death.

In 1991, Moss et al. [25] demonstrated the link between QTc and the risk of cardiac events. Zareba et al. subsequently examined the influence of genotype on the clinical course of the long-QT syndrome and found the risk of cardiac events to be higher among patients with a LQT1 mutation and those with a LQT2 mutation than those with a LQT3 mutation. However, the risk of lethal cardiac events was found to be highest in those with a LQT3 mutation [26].

Other studies that have investigated genotype-phenotype correlations and risk stratification in cLQTS include another study by Priori et al. [27]. This group developed a tool for gene-specific risk stratification with possible implications for disease management. They found the risk of cardiac events among those with a LQT1 mutation to be strongly dependent on QTc duration: males with a LQT1 mutation, and a QTc ≥500 ms, were at high risk for a first cardiac event in childhood, whereas for females with a mutation in the same gene and QTc in the same range, the risk of a first event remained unchanged over time [27]. Patients of either sex who had a mutation at the LQT1 locus and a QTc of <500 ms, had less than 30% risk of a first cardiac event before the age of 40 years. Female patients with a mutation at the LQT2 locus had a more severe prognosis irrespective of QTc duration. In patients with a LQT3 mutation prognosis was mainly influenced by sex, with male patients having a higher probability of becoming symptomatic by age 40 than female patients [27].

33.2.1.1 *Clinical Assessment and Management*

When a prolonged QTc is identified after a syncopal event in the absence of an acquired cause of prolonged QTc (see Section 33.3), the diagnosis of cLQTS should be considered, and family members can also be assessed. If there is a known pathogenic mutation in a patient originally diagnosed with cLQTS, then all first-degree relatives should be referred to a clinical geneticist and offered genetic testing for the familial mutation. Appropriate clinical follow-up of relatives should be arranged as required. Genetic testing of close family relatives is referred to as "cascade screening."

Sudden unexplained death in a young individual should be thoroughly investigated to determine the cause. If a structurally normal heart is identified at autopsy in a young person, conditions such as LQTS must be considered. Postmortem genetic testing is sometimes referred to as "molecular autopsy." LQTS represents a leading cause of autopsy-negative sudden death in the young [28].

Rarely, asymptomatic individuals with LQTS are identified when an ECG is obtained for other reasons (e.g., presurgery assessment) [10]. Gathering detailed information regarding family history in a suspected individual is essential because careful questioning may reveal a long-term pattern of similar episodes (syncope, sudden death), not only in first-degree relatives (mother, father, siblings, children) but also in more remote relatives in the family. Data on co-morbidities (such as congenital deafness) in evaluated individuals or family members should also be obtained [10]. It is important to distinguish, through careful history, acquired factors that result in QT prolongation from the inherited form of the condition [10]. Causes of abnormal prolongation of the QT interval include myocardial ischemia, cardiomyopathies, hypokalaemia, hypocalcemia, hypomagnesemia, autonomic influences, drug effects, and hypothermia (as discussed later in this chapter).

Beta-blockers are considered the first-line prophylactic therapy in LQT1 and LQT2. These drugs should be administered to all intermediate- or high-risk affected individuals and considered on an individual basis in low-risk cases [10]. Lifestyle and preventive measures such as the avoidance of potentially QT-prolonging drugs, adrenergic-type stimuli, and avoidance of alarm clocks should always be considered.

Some physician-investigators suggest beta-blocker therapy in all LQTS patients, even those at low risk (unless there is a contraindication), because of their mechanism of action and in view of the adrenergic-mediated triggers in this disorder, especially in those with LQT1 and LQT2. Implantable cardioverter-defibrillator (ICD) insertion can be highly effective in high-risk LQTS patients [10]. Surgical left-cervicothoracic sympathetic denervation, the surgical procedure introduced for treatment of LQTS before beta-blockers became available, can be considered in patients with recurrent syncope despite beta-blocker therapy and in patients who experience arrhythmia storms with an ICD [10]. Gene-specific LQTS therapies—sodium channel blockers, potassium channel activators, alpha-adrenergic receptor blockers, protein-kinase inhibitors, and atropine—have great potential and should also be considered.

33.3 DRUG-INDUCED VARIATION IN QTc

Acquired long-QT syndrome has many different etiologies, including drugs, and several clinical conditions contribute, such as severe heart failure, cardiomyopathies, and left-ventricular hypertrophy [3]. For example, left-ventricular hypertrophy generates significant electrical remodeling, and its most characteristic feature is an extension of the duration of ventricular action potentials. This remodeling also increases the dispersion of repolarization and hence favors polymorphic ventricular tachycardia and sudden death [3]. See Table 33.4 for some of the risk factors for drug-induced LQTS. It has been demonstrated that each 10 ms increase in QTc interval contributes ~5% exponential increase in risk of cardiac events in patients with long-QT syndrome (LQTS) [29]. To further complicate matters, both cardiac and noncardiac drugs have been reported to prolong QT interval and induce arrhythmia in patients who have a QTc interval length within the reference range [8,30].

In 1964, Selzer and Wray [31] first described what would subsequently be termed *drug-induced LQTS* (diLQTS) and observed that quinidine could provoke QT prolongation and arrhythmias in otherwise healthy patients. The list of drugs causing QT prolongation includes those with no apparent cardiac action and those from different therapeutic families [32].

The Phenotype Standardization Project, sponsored by the International Serious Adverse Events Consortium (iSAEC) established a definition of the phenotype for drug-induced torsades de pointes (diTdP) to support research into pharmacogenomic markers of risk [33]. The proposed requirements for case classification are as follows:

- "The diLQTS event must have occurred during treatment with a known QT-prolonging drug, and/or a drug suspected of QT prolongation".
- "On withdrawal of the drug there is partial resolution of clinically significant QT prolongation (in the opinion of an arrhythmia specialist)".
- "Arrhythmia documentation must be reviewed by an appropriately experienced physician/electrophysiologist".

Three clinical subphenotypes for suspected diTdP were also defined to describe all possible presentations. Behr et al. [33] summarise them as follows:

- "Classical diTdP"– the pause-dependent onset of polymorphic VT (at least five beats) with associated QT prolongation documented with or without resuscitation and/or subsequent VF and cardiac arrest.
- "Probable diTdP" – polymorphic VT and/or VF documented but the typical onset of TdP has not been seen. QT prolongation must have been documented.
- "Possible diTdP" – ventricular arrhythmia has not been documented but a history of unexplained syncope has been elicited with severe QT prolongation on the ECG (QTc > 550 ms).

The absolute numbers of individuals exposed to risk of diTdP are significant, as up to 3% of all prescriptions worldwide include potentially proarrhythmic medications [5].

33.3.1 The Human Ether-à-go-go Gene Channel

The original name of the human ether-à-go-go channel (HERG) came from William Kaplan in the 1960s. Kaplan found that flies with mutations in this gene, when anesthetized with ether, showed movements in their legs similar to a popular dance called "à -go-go" [3]. The HERG is encoded in chromosome 7 and was first isolated in 1994 by Warmke and Ganetzky by screening a human hippocampal cDNA library with a mouse homolog of "ether- à -go-go" [3]. It is a member of the family of voltage-gated K^+ channels and has been shown to be responsible for the I_{Kr} [3]. HERG is composed of four identical alpha subunits (1159 amino acids) which co-assembles to form the full HERG channel. Each alpha subunit itself has six transmembrane domains, intracellular N- and C-termini, and a pore loop which links domains S5 and S6. Positive charges in the S4 domain act as voltage sensors. In the alpha subunits of the HERG channel, the S6 segment contains two aromatic amino acids (tyrosine-Tyr and phenylalanine-Phe). These are very important as they participate in the binding site of most of the drugs involved in QT prolongation.

In most K^+ channels, the selectivity filter is formed from the carbonyl atoms of a Gly-Tyr-Gly (GYG) sequence; however, in HERG channels the sequence is Gly-Phe-Gly (GFG) [3]. The central cavity is lined by the four S6 segments and is wide because these segments lack the bend found in other K^+ channels. This may explain why drugs of many different chemical structures can block HERG channels. The slow activation and rapid inactivation kinetics cause the HERG channel to pass significant current in the inward direction but little current in the outward direction (inward rectifier function). HERG mutations cause a reduction in outward K^+ current through multiple mechanisms—nonfunctional channel generation and mutations that affect intracellular trafficking of channel proteins [3].

The electrophysiological properties of the HERG potassium channel are important in many physiological processes and they may have different roles depending on where they are in the body [34]:

- Heart: they are the molecular basis for the cardiac muscles to rapidly produce I_{Kr} currents. Functional abnormality is related to long-QT syndrome (LQTS) and short QT syndrome (SQTS).
- Nervous system: they are involved in regulating spike-frequency adaptation and controlling resting potential. Abnormal expression is associated with the onset of schizophrenia.
- Cell proliferation and differentiation: they regulate apoptosis, and their abnormal expression is related to diseases such as cancer.
- Other: They are involved in regulating the secretory activity of pancreatic β cells and chromaffin cells. They also regulate the contractility of smooth-muscle cells in the portal vein, the jejunum, and the epididymal duct [34].

Most HERG-blocking drugs are compounds that cross the lipid bilayer as neutral molecules, equilibrate in the cytosol as positively charged molecules, and bind to the channel only in the open or inactivated state [3].

Tyr652 and Phe656 are the most important drug-binding sites. These high-affinity binding sites are located in the central cavity of the channel between the selectivity filter and the activation gate [3]. An inactivation-associated reorientation of Tyr652 and Phe656 during closure of the activation gate (formed by the crisscrossing of the S6 helical bundles) may cause drugs to be trapped inside the central cavity after inactivation. This process increases HERG channel drug sensitivity. On subsequent depolarization, because the drug remains bound, the channel is unable to conduct K^+ ions [3].

33.3.2 Repolarization Heterogeneity

There is intrinsic transmural heterogeneity in the density of the various ion channels, which has different effects on the action potential duration of the four cell types: subepicardial myocytes, midmyocardial M cells, subendocardial myocytes, and Purkinje cells [3]. Hence, drugs that only impair I_{Kr} preferentially prolong the action potential more in midmyocardium and Purkinje cells (which have lower densities of the other channels, such as I_{Ks} and I_{Na}). Thus, they increase heterogeneity of myocardium repolarization, which results in greater TdP risk. Amiodarone can produce marked prolongation of QTc without inducing TdP because it can block other ion channels, such as I_{Ca}, and I_{Na}, causing homogeneous prolongation of the action potential. More selective I_{Kr}-blocking drugs can increase heterogeneity in repolarization between the subepicardium and the endocardium [3]. This means that at a certain point the action potential in one location (e.g., the subepicardium) ends and action potential can be triggered by a new stimulus. However, in another location (e.g., the subendocardium) the cells are in early phase 3 and refractory, thus triggering reentry. It has been proposed that the last fragment of the T wave (T peak–T end) is a predictor of ventricular repolarization heterogeneity [3].

33.3.3 Mechanisms of Proarrhythmia in QT Prolongation

QT prolongation alone is not sufficient to result in TdP. Indeed, amiodarone usually results in significant QT prolongation, but TdP from amiodarone is rare [35,36]. Repolarization heterogeneity across cell types within the ventricular myocardium (see above) is being increasingly recognized as one explanation for the lack of direct link between QT prolongation and arrhythmias. The action potentials of the epicardial cells, midmyocardial (M) cells

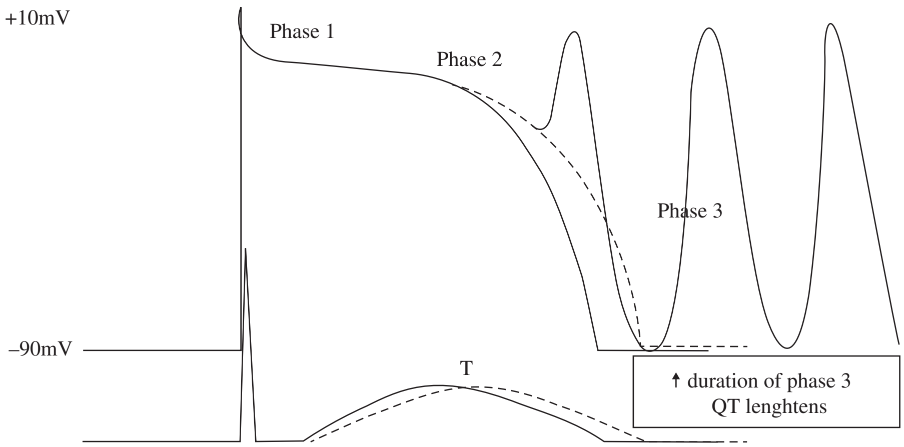

FIGURE 33.4 **Multiple EADs from progressively more negative transmembrane potential.** Prolonged repolarization can cause early after depolarizations (EADs) due to activation of inward depolarizing currents (L-type calcium channels or sodium-calcium exchange current), that appear as depolarizing oscillations in membrane voltage during phases 2 and 3 of the action potential. *Source: From Kallergis et al.* [121].

and endocardial cells differ in morphology and duration. These differences in turn are due to ion channel variations in the three cell types. To further complicate matters the action potential in each type responds differently to alterations in heart rate and to drugs [36].

This difference across the ventricular wall, otherwise known as transmural dispersion of repolarization, is physiologic; however, if exaggerated, it may increase TdP risk. Conversely, if transmural dispersion is reduced, as with the drug amiodarone which prolongs repolarization in all three cell types, this will lower the likelihood of TdP. The interval from the peak to the end of the T-wave on the surface ECG correlates with transmural dispersion of repolarization. Given the above information, this interval may signify a more specific ECG indicator of TdP risk in the presence of a long-QT interval [36].

Change in amplitude or polarity of the T-wave on alternating beats, otherwise known as T-wave alternans, is thought to result from alternation of the M-cell AP duration. It has been observed in LQTS as a TdP precursor because T-wave alternans leads to exaggeration of transmural repolarization dispersion during alternate beats, thus increasing the risk of TdP [37]. Another indicator of TdP risk is a change in QT duration on alternating beats or beat-to-beat QT variability. In an animal study, sotalol was used in a dose-dependent fashion to elicit TdP. Both low- and high-dose sotalol produced similar QT prolongation, however, "short-term" variability of the QT interval was increased only at the high dosage. This was accompanied by a high rate of TdP. In the same model, while amiodarone did prolong the QT interval, it did not increase short-term variability or result in TdP [36].

Action potential prolongation can lead to the development of early after depolarization (EAD) oscillations in the membrane potential during repolarization (see Figure 33.4). The danger inherent in a prolonged QT is that, if excessive, it carries a risk of sudden cardiac death (SCD) due to TdP. An EAD can result in an ectopic beat if it reaches a critical threshold in a large area of the myocardium. This ectopic beat is usually followed by a long pause, with a subsequent sinus beat showing marked QT prolongation. In the presence of exaggerated heterogeneity of action potential duration across the myocardium, the ectopic beat can induce reentrant excitation and TdP (see Figures 33.2 and 33.4). In contrast, TdP in its congenital form often follows a sudden adrenergic surge such as exercise or arousal [38].

EADs are thought to result from the reopening of either L-type calcium channels or sodium channels, and can result in ectopic beats if occurring in a large enough region of the heart. Triggered upstrokes from EADs are a likely initiating mechanism for TdP [36]. Proarrhythmia results indirectly from I_{Kr} blockade, which enables activation or reactivation of inward currents underlying EADs. This partly explains why verapamil, even though it is a potent I_{Kr} blocker, rarely causes TdP [6]. It has been shown to reduce EADs in LQTS, presumably by blocking the inward calcium current [39]. In a model of acquired TdP from a combined I_{Ks}–I_{Kr} blockade, verapamil has been found to shorten the QT interval, reduce transmural dispersion of refractoriness, and reduce EADs and TdP incidence [36]. A role for Ca/calmodulin-dependent protein kinase II (CaM kinase) in the development of TdP has also been demonstrated. Sparfloxacin was used to induce EADs in isolated rabbit Purkinje fibers, and was associated with severe prolongation of action potential duration and an increase in short-term repolarization instability. A CaM kinase block, caused by the calmodulin antagonist W-7, had no effect on action potential duration but did inhibit sparfloxacin-induced EADs in a concentration-dependent manner [36]. This decreased beat-to-beat repolarization instability.

33.3.4 Reduced Repolarization Reserve

The concept of "reduced repolarization reserve" suggests that multiple, often redundant, mechanisms maintain normal repolarization [6]. Minor alterations in function may not be obvious at baseline. A reduction in repolarizing current (e.g., as a result of a genetic variant that causes a small reduction in an important repolarizing ion channel), may not have any effect normally because other mechanisms maintain a normal QT interval [6]. The reduced reserve may, however, become more apparent when other factors influencing repolarization are added (e.g., slow heart rate, hypokalemia, or drug challenge). See Figure 33.5.

Initial findings leading to the concept of repolarization reserve began with the observation of quinidine syncope caused by TdP at a low plasma quinidine concentration [40]. There was no apparent explanation for this happening in a specific individual. In contrast, using sotalol therapy as an example, the risk of TdP was clearly increased as dose increased [4]. QT-interval prolongation reflects prolongation of at least some action potentials in the ventricular myocardium. Action potential prolongation must arise from an increase in inward current (e.g., sodium or calcium channels) or a decrease in outward current (e.g., through potassium channels) during the action potential [4]. Quinidine blocks both the transient outward and delayed rectifier components of the potassium current.

The two currents I_{Kr} and I_{Ks} have different activation, inactivation, and deactivation characteristics and different sensitivities to blocking drugs. In a later study, they were found to be the result of the expression of different genes—mutations that we now recognize as the common causes of congenital long-QT syndrome. Virtually all drugs that produce TdP are high-potency I_{Kr} blockers. Subsequent studies have identified molecular mechanisms underlying the susceptibility of this particular potassium channel to blocking by many structurally different compounds. There are only a few exceptions. For example, some studies have suggested that ibutilide prolongs QT interval and causes TdP by enhancing sodium entry into cells during the plateau [4].

The separation of I_{Kr} and I_{Ks} provided an explanation for unusual sensitivity to low concentrations of quinidine. The therapeutic range for quinidine is 2–5 $\mathrm{ug\,mL^{-1}}$ or ~6–20 $\mathrm{umol\,L^{-1}}$, and drug concentrations in the 5–10 $\mathrm{umol\,L^{-1}}$ range block multiple potassium currents as well as the inward sodium current [4,41–43]. However, when the effects of quinidine on the components of I_K were examined there was a difference: the concentration blocking 50% of I_{Kr} was 1 $\mathrm{umol\,L^{-1}}$, while I_{Ks} required 30–50 $\mathrm{umol\,L^{-1}}$ for a 50% block [4]. When extracellular potassium was lowered from 4 $\mathrm{mmol\,L^{-1}}$ to 1 $\mathrm{mmol\,L^{-1}}$, low drug concentrations of 0.4 $\mathrm{umol\,L^{-1}}$ (0.15 $\mathrm{ug\,mL^{-1}}$) were sufficient to produce a 50% I_{Kr} block. Quinidine's I_{Kr}-blocking actions are manifest at low concentrations; indeed, in some experimental settings increasing quinidine concentration blunts action potential prolongation. This might reflect superimposition of a sodium (or even calcium) channel block [44].

The principle that an I_{Kr}-blocking drug may not necessarily prolong action potentials if it also blocks inward current applies to other drugs such as the calcium channel blocker verapamil (as previously mentioned in Section 33.3.3). It is recognized as a potent I_{Kr} blocker but is not associated with QT prolongation or TdP [4]. Amiodarone also blocks I_{Kr} and prolongs QT interval [45,46]. However, amiodarone-induced TdP is unusual, presumably because it also blocks inward currents [35]. These findings support the idea that variability in the extent to which nonselective ion channel blockers like quinidine (or verapamil or amiodarone) prolong QT interval and generate TdP depends on their effects on other ion channels [4].

The data also suggested that the extent to which any I_{Kr} blocker prolongs QT may depend on the amplitude of other

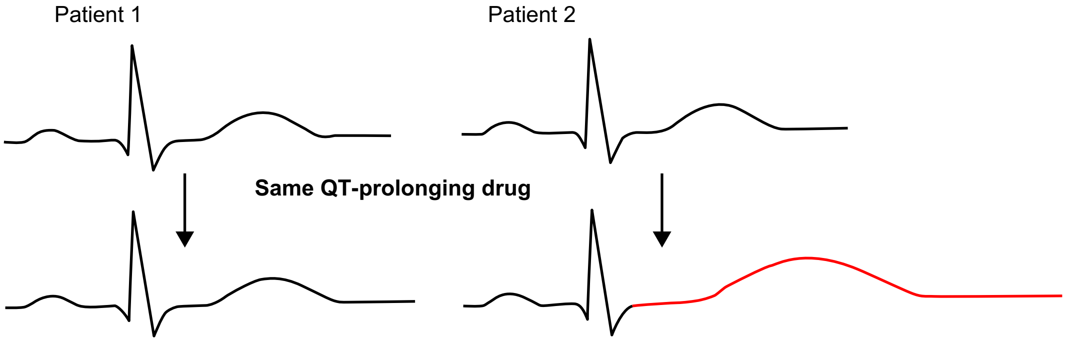

FIGURE 33.5 **Reduced repolarization reserve.** The concept of reduced repolarization reserve. Patient 1 is prescribed a QT-prolonging drug and has minimal or no prolongation of the QT interval. In contrast, patient 2, given the same QT-prolonging drug at the same dosage, develops marked prolongation of the QT interval. This has been termed "reduced repolarization reserve". Repolarization is a physiologically redundant process such that I_{Kr} block will not result in markedly prolonged repolarization; that is, the system displays some "reserve." However, otherwise subclinical lesions in other components of the repolarization system, such as reduction of I_{Ks} as a result of genetic factors or hypokalemia, may become apparent as marked QT prolongation when I_{Kr} is reduced. *Source: From Kannankeril et al.* [6] *with permission.*

ion currents, notably I_{Ks} [4]. Therefore, individuals with defective I_{Ks} might display normal QT interval because of a robust I_{Kr}, but are predicted to display marked QT prolongation when challenged with an I_{Kr}-blocking drug.

Roden summarizes well that the concept of repolarization reserve provides a "unifying framework for analysis of these risk factors and their clinical mechanisms" [4]. It is suggested that the normal heart includes multiple redundant mechanisms to accomplish normal repolarization, and that a lesion in just one of these mechanisms may not be enough to elicit a LQTS phenotype. However, the presence of subclinical lesions in the repolarization process means that superimposition of an I_{Kr}-blocking drug can produce marked action potential prolongation [4]. This can result in the pathophysiological cascade of engagement of inward current, increasing heterogeneities of action potential duration and EADs that culminate in TdP. This is a specific example of the idea that physiological redundancies in biological systems protect against extreme perturbations. Unusually high drug concentrations and toxicity are much more likely with drugs that are metabolized by a single (i.e., nonredundant) pathway than with drugs that are metabolized by multiple pathways [4].

Some patients may have very long QT intervals, and yet the vast majority of their heartbeats do not precipitate TdP. Therefore, (in keeping with the concept of repolarization reserve), in addition to genetic (or other) modulators of baseline QT interval and of the extent to which the QT interval is prolonged during drug exposure, it is also possible that genetic or environmental factors play a role in modulating the pro-arrhythmic pathophysiology that generates TdP when the QT interval is prolonged [4].

33.3.5 QTc Prolongation–Inducing Drugs—A Closer Look

The first recognition of drug-induced "acquired long-QT syndrome" came with the observation of syncope on quinidine therapy initiation (as mentioned in the previous section). This was recognized shortly after the introduction of the drug in the 1920s [4]. The first electrocardiographically documented case of acquired LQTS is thought to be the subject of a 1935 report in which hypomagnesemia was implicated [4]. Continuous electrocardiographic monitoring allowed for documentation of episodes of polymorphic VT in the 1960s, as reported for a series of patients on quinidine therapy [31]. Studies in the 1980s which revealed that quinidine blocks both the transient outward and the delayed rectifier components of potassium current [47,48]. and the identification of the delayed rectifier's two components, I_{Kr} and I_{Ks}, were key advancements in knowledge [49,50].

Most patients with diLQTS have had at least one of the risk factors listed in Table 33.4, in addition to drug exposure itself. Holter monitor studies of drug-induced TdP report an increase in the underlying sinus heart rate in the minutes prior to an event, suggesting that a pause in the setting of heightened sympathetic activation and long QT intervals may be especially arrhythmogenic [4].

The 2–3-fold female preponderance of QT prolongation [51] may be explained by the protective effect of testosterone. Electrocardiographical studies suggest that at puberty the QT interval shortens markedly in males and testosterone has been implicated as the major factor in the lowering of male TdP risk. Work in a prepubertal rabbit model reveals that an I_{Kr} blocker results in greater AP duration prolongation in males compared with females, and causes ventricular tachycardia in males only [6,36]. These findings may explain the higher risk of events in male children with congenital LQTS; however, other age- and gender-dependent factors may also contribute to diLQTS risk.

For the vast majority of drugs, risk increases with higher concentrations. Indeed, drug overdose and impaired drug elimination caused by genetic factors, disease, along with drug interactions, have been implicated as key mediators of TdP risk [4]. An interesting example is thioridazine, metabolized almost exclusively by cytochrome P450 CYP2D6 [52], which is functionally absent in 5–10% of Caucasians and African Americans and so results in higher plasma concentrations and elevated TdP risk. Here we discuss some more examples of drug-induced QT prolongation and TdP. See Table 33.5 for more information.

Antiarrhythmics

Antiarrhythmic agents are the leading cause of drug-induced TdP, and class IA agents (quinidine, procainamide, and disopyramide) block both Na^+ and K^+ channels and as previously discussed TdP can occur at either therapeutic or subtherapeutic doses [53]. Quinidine prolongs QT interval by an average of 10–15% within a week of therapy initiation and carries a 1.5% risk of inducing TdP [54]. TdP development on antiarrhythmic therapy is often precipitated by electrolyte disturbances, such as hypokalemia or hypomagnesemia. Potassium infusion has been found to reverse quinidine-induced QT prolongation [55]. Mortality increases threefold when quinidine is used in atrial fibrillation for rhythm control. Indeed, the incidence of quinidine-induced TdP ranges from 2.9-8.8% in patients with atrial flutter or atrial fibrillation and TdP tended to occur after conversion to sinus rhythm [55]. Due to its predominant Na^+-blocking effect, procainamide is less likely to induce TdP. However, in patients with renal dysfunction or in rapid acetylators, it can induce TdP through its active metabolite, N-acetyl procainamide (NAPA), which has a potent K^+-blocking effect [56]. Disopyramide, contraindicated in patients with heart failure and liver or renal dysfunction, has also been implicated in TdP [53].

Class III agents are potent I_{Kr} blockers and tend to prolong QT interval in a dose-dependent manner.[53], Ibutilide, dofetilide, and sotalol carry the highest risk for TdP, whereas amiodarone carries the lowest risk. Sotalol causes TdP in 2–4% of patients, with a higher risk seen in

TABLE 33.5 Drugs Reported to be Associated with QT Prolongation and/or TdP with Postulated Risk

Drug Group	High Risk (Frequent Reports of DITdP)	Moderate Risk (Reported to Cause diTdP)	Low Risk (diTdP likely Only with Overdose, Culprit Drug, or Concomitant Risk Factors)	Low Risk (QT Prolongation Only or Rarely with diTdP, Usually with Other Risk Factors)
Antiarrhythmics				
Class I	Quinidine,[a] procainamide,[a] Disopyramide, dihydroquinidine[a]	Flecainide, propafenone, pirmenol, [a] cibenzoline, [a] ajmaline[a]		
Class III	Sotalol, d-sotalol,[a] dofetilide,[a] azimilide,[a] Ibutilide,[a] sematilide,[a] ersentilide,[a] almokalant,[a] nifekalant,[a] terikalant[a]	Amiodarone	Dronedarone	
Antianginals and vasodilators	Prenylamine,[a] terodiline,[a] lidoflazine,[a] bepridil[a]			Vardenafil, ranolazine
Antihypertensives		Indapamide		Nicardipine, isradipine, moexipril/hydrochlorothiazide
Anti-histamines	Terfenadine,[a] astemizole[a]	Ebastine[a]	Diphenhydramine	Mizolastine, bilastine
Serotonin agonists and antagonists	Cisapride,[a] ketanserin[a]	Dolasetron		Ondansetron, granisetron
Antimicrobials				
Macrolides	Erythromycin, spiramycin	Azithromycin, clarithromycin	Roxithromycin[a]	Telithromycin
		Gatifloxacin,[a] levofloxacin, Sparfloxacin,[a] moxifloxacin, grepafloxacin[a]		
Fluoroquinolones			Ciprofloxacin	Gemifloxacin,[a] ofloxacin, gatifloxacin
Antifungals			Ketoconazole, fluconazole, itraconazole, voriconazole	Posaconazole
Antimalarials	Halofantrine[a]	Chloroquine	Quinine	artemether with lumefantrine,
Others	Pentamidine		Amantadine, cotrimoxazole,	Foscarnet, atazanavir,
			Trimethoprim, ritonavir	Saquinavir, telaprevir
Psychiatric				
Tricyclic antidepressants			Amitriptyline, nortriptyline, desipramine,[a] clomipramine, imipramine, trimipramine, doxepin, protriptyline[a]	

TABLE 33.5 Continued

Drug Group	High Risk (Frequent Reports of DITdP)	Moderate Risk (Reported to Cause diTdP)	Low Risk (diTdP likely Only with Overdose, Culprit Drug, or Concomitant Risk Factors)	Low Risk (QT Prolongation Only or Rarely with diTdP, Usually with Other Risk Factors)
Serotonin reuptake inhibitors		Citalopram	Fluoxetine, paroxetine, sertraline, zimeldine,[a] amoxapine[a]	Venlafaxine, escitalopram
Antipsychotics	Thioridazine,[a] chlorpromazine, haloperidol, droperidol[a]	Pimozide, mesoridazine, sertindole	Amisulpride, ziprasidone, risperidone	Trifluoperazine, prochlorperazine, Paliperidone, quetiapine, flepentixol, fluphenazine, zuclopenthixol
Others			Maprotiline,trazodone	Lithium
Anticancer	Arsenic trioxide	Tacrolimus, geldanamycin,[a] vandetanib		Nilotinib, tamoxifen, sunitib, lapatinib, vinflunine, erubilin, pazopanib, fingolimob, capecitabine
Others	Probucol, domperidone, cisapride, methadone	Vasopressin, tizanidine, alfuzosin, amantadine, levomethadyl,[a] lofexidine	Organophosphates,[a] galantamine, solifenacin, clobutinol,[a] chloral hydrate, sevoflurane	Felbamate,[a] fosphenytoin, degarelix, perflutren, octreotide, oxytocin, galantamine, retigabine, tizanidine, tolterodine, alfuzosin, isolfurane

women [57]. The incidence of TdP with Dofetilide is 2.1%, with increased risk in renal failure patients, and intravenous ibutilide carries a TdP risk of 1–3% [58], with a higher incidence in patients with structural heart disease, heart failure, and electrolyte disturbance. The incidence of TdP with amiodarone is rare despite its QT-prolonging effect [53].

Antihistamines

Only a few nonsedating antihistamines have been implicated in significant arrhythmogenicity. Due to their potent I_{Kr}-blocking effect even at low doses, terfenadine and astemizole have been withdrawn from the market because of their high TdP risk. Most antihistamines are metabolized by the cytochrome P450 enzyme CYP3A4. Patients with liver dysfunction or who are co-administered drugs or food (such as grapefruit) that inhibit CYP3A4 can show higher drug levels. The newer nonsedating antihistamines such as desloratadine, cetirizine, levocetirizine, and fexofenadine seem to be safer than previous versions [53,59].

Antipsychotics and antidepressants

Antipsychotic medications prolong QT interval in a dose-dependent manner [53]. Haloperidol (a butyrophenone) is used to treat schizophrenia and severe agitation and is known to be a potent blocker of the I_{Kr} channel. This effect is amplified in the presence of risk factors (see Table 33.4). Haloperidol has been reported as prolonging the QT interval by up to 15–30 ms [53] and in 2007, the US Food and Drug Administration (FDA) released an alert recommending ECG monitoring with intravenous haloperidol use. Droperidol has an effect similar to that of haloperidol and, in patients with risk factors, clinicians must pay careful attention and consider whether ECG monitoring may also be appropriate with its use.

Phenothiazines such as chlorpromazine have a combination of both antipsychotic and antiemetic effects [53]. Indeed, both chlorpromazine and thioridazine have been implicated in QT prolongation and TdP due to their K^+-blocking effect. Atypical antipsychotics can cause dose-dependent prolongation of the QT interval associated with variations in their potency. QT prolongation is highest with ziprasidone and lowest with olanzapine [60]. In 1998, sertindole was withdrawn from the market due to the risk of TdP and sudden death. Zimelidine and citalopram have also been related to TdP in high doses [53].

Tricyclic antidepressants (TCAs) are more commonly associated with QTc-interval prolongation than selective serotonin-reuptake inhibitors (SSRIs) [61]. The mechanism by which TCAs prolong the QTc is blockade of the Na^+ channel. The effect is exaggerated when there is co-administration of a potassium channel–blocking agent [53]. Amitriptyline, desipramine, and imipramine have all been implicated in TdP, and toxic doses of TCA, as seen in TCA overdose, can result in various ECG changes such as QRS complexes widening, QT prolongation, and TdP [53]. All such cases should have ECG monitoring when being assessed in the acute phase. SSRIs prolong the QT interval by inhibiting the I_{Kr} channel, and citalopram and escitalopram have been associated with QT prolongation [53].

Antibiotics and antimalarials

As Nachimuthu et al. state [53], fluoroquinolones have a variable effect on the QTc interval and bring with them a very low incidence of TdP. Grepafloxacin and sparfloxacin delay repolarization more profoundly than gatifloxacin, levofloxacin, and moxifloxacin, with ciprofloxacin and ofloxacin having the least effect on the I_{Kr} channel [53]. Indeed, both grepafloxacin and sparfloxacin were discontinued in the preliminary drug development. The rest of the fluoroquinolones are relatively safe, but caution must be exercised if there are any underlying risk factors or if they are co-administered with other QT-prolonging drugs [62].

Macrolides, (e.g. clarithromycin and erythromycin), have also been associated with QT prolongation and TdP [61]. In animal studies, erythromycin was found to have similar effects to those of class III antiarrhythmic agents, with prolongation of QT interval and EAD induction (see Figure 33.4.). Both erythromycin and clarithromycin are CYP3A4 inhibitors which can unsurprisingly lead to significant toxicity if co-administered with another CYP3A4 inhibitor or with drugs metabolized by CYP3A4 [53]. TdP has also been reported with the use of azithromycin, although the drug is considered to be safe [63].

The true incidence of QT prolongation and TdP with antimalarial agents is largely unknown. This is because of underreporting on a worldwide level [53]. Quinine, which is an optical isomer of quinidine, has a weak effect on the QT interval and rarely has been associated with TdP. However, chloroquine and halofantrine can prolong the QT interval and so have been linked to TdP. Halofantrine the most potent, has been found to have repolarization properties similar to those of quinidine and Class III antiarrhythmic agents [53,64].

Others

Pentamidine is an anti-protozoal drug that is used for *Pneumocystis carinii* pneumonia treatment [53]. It has structural similarity to procainamide and while its electrophysiological properties are not known, intravenous use can lead to TdP. Inhalation is considered safe. The proarrhythmic risk of IV use is related to idiosyncratic reaction rather than the effect of dose [65].

The systemic azole group of antifungal agents have both pharmacodynamic and pharmacokinetic characteristics that may trigger TdP [53]. Attention should be paid when using these agents, especially in patients who have underlying risk factors for QT prolongation (see Table 33.4).

Cisapride, the gastrointestinal promotility agent used for delayed gastric emptying and gastroesophageal reflux disease [53] is also structurally similar to procainamide and has demonstrated both I_{Kr-} and I_{Ks-} blocking effects. Cisapride use has been related to the greatest number of TdP cases next to antiarrhythmic agents [66] which ultimately led to its withdrawal from US market in July 2000.

33.3.6 Pharmacokinetic and Pharmacodynamic Factors

Pharmacokinetic and pharmacodynamic interactions might increase the risk of TdP of torsadogenic drugs. Pharmacokinetic interactions occur mainly because of the inhibition or induction of cytochrome P450 enzymes [3]. Pharmacokinetic interactions may occur if one drug reduces the clearance of the other or if both drugs compete for the same hepatic enzyme. Co-administering a drug with cytochrome CYP3A4 inhibitors such as -azoles, -mycins, or grapefruit juice will increase its level. Haloperidol and thioridazine share the same enzyme, CYP2D6, for clearance, resulting in increased levels of both [53,66,67].

Terfenadine undergoes near-complete presystemic metabolism by CYP3A4 (and the closely related isoform CYP35) in the intestine and liver. As a result, plasma concentrations of the drug are low, and most of its antihistamine actions are mediated by generation of an active metabolite, fexofenadine (now on the market as Allegra) [4]; unlike with CYP2D6, patients with no CYP3A activity on a genetic basis have not been recognized. Terfenadine itself is a potent I_{Kr} blocker and, with inhibition of CYP3A, causes markedly elevated plasma concentrations and TdP risk [4].

TdP-related pharmacodynamic interactions are easier to detect because they occur when two drugs act on the same or a distinct target and induce the same adverse drug effect, such as QT prolongation (e.g., antipsychotics and tricyclic antidepressants) [3]. Other mechanisms include the combination of a QT-prolonging drug with another drug that influences a variable that increases QT prolongation risk. Examples of such drugs include those that produce hypokalemia, such as beta 2 agonists, diuretics, amphotericin B, and insulin.

33.3.7 Prevention, Monitoring and Treatment of Drug-Induced LQTS

QT-prolonging drugs should be avoided in patients with preexisting heart disease, with a history of ventricular arrhythmias or with metabolic abnormalities such as hypokalemia (see Table 33.4). Hospitalized patients are at a higher risk for developing TdP than outpatients with the same QT-prolonging drugs [53]. This is because hospitalized patients are often elderly with underlying heart disease, who may also have renal or hepatic dysfunction, electrolyte abnormalities, and bradycardia, to whom drugs need to be administered intravenously and rapidly [68]. Co-morbidities act as, or enhance, risk factors for TdP. Concomitant administration of drugs that inhibit the cytochrome P450, especially imidazole antifungals, and macrolide antibiotics or those that can prolong the QT interval or cause electrolyte disturbance, should be avoided [53]. Surveillance ECGs are recommended before and after initiation of QT-prolonging drugs. Routine electrolyte monitoring, especially for potassium, is also recommended in those who are on QT-prolonging drugs and diuretics. For example, methadone has been associated with TdP in women if the dose is >100 mg/day [69]. Methadone guidelines recommend a pretreatment ECG for QTc-interval screening and a follow-up ECG within 30 days and then annually [53,70].

ECG monitoring of the QT interval in the hospital setting is indicated for the following reasons: (1) initiation of a drug known to cause TdP; (2) overdose from potentially proarrhythmic agents; (3) new-onset bradyarrhythmias; and (4) severe hypokalemia or hypomagnesemia [53]. If drug-induced TdP has occurred, a careful review of the patient's personal/family history must be obtained in order to identify the possibility of congenital LQTS. If a history of unexplained syncope or premature sudden death is discovered, 12-lead ECG is recommended for all first-degree relatives and genetic testing for congenital LQTS should be considered in the family.

In cases of TdP which have degenerated into ventricular fibrillation, immediate direct current cardioversion should be performed [53]. In those with TdP who are otherwise stable, the following treatments should be considered: intravenous magnesium, intravenous potassium, overdrive transvenous pacing. A detailed review of the patient's medication list should be carried out. Permanent pacemakers should be inserted if the patient has chronic bradycardia e.g. AV block or sick sinus syndrome, however, implantable cardioverter defibrillators (ICDs) should also be considered, and the case should therefore be discussed with an expert in the field.

33.3.8 Detecting Drug-Induced Effects on Repolarization

There are many models to detect if a drug can potentially prolong QT [3]. Several examples of *in vitro* models are described to evaluate their effects on repolarization. Some examples are heterologous expression systems (in studying ion currents), disaggregated cells (also in studying ion currents), isolated tissue (in screening large numbers of compounds), and isolated intact heart (also in screening large numbers of compounds) [3].

In vivo models include multi-lead ECG in conscious or anesthetized guinea pigs, rabbits, dogs or pigs. The QT should be measured from at least three successive beats. However, there is no single, standardized, uniform method for preclinical screening of drug effects on cardiac repolarization [3].

33.3.9 Congenital LQTS Genes in Drug-Induced LQTS

The accumulation of case series of diTdP has identified small numbers of subjects in whom the diagnosis of congenital LQTS was made only after culprit drug exposure and arrhythmia [71]. This is consistent with the concept that some patients with congenital LQTS have little QT prolongation at baseline but may be more susceptible to a markedly prolonged QT interval on exposure to a QT-prolonging drug [5,23]. Around 10% of subjects with diLQTS have rare variants in the cLQTS disease genes and are thought to represent incompletely penetrant cLQTS. Studies on this focused on the more common disease genes in cLQTS [72,73], such as *KCNQ1* and *KCNH2* and not on the rarer, more recently identified genes. In some recent studies, individuals with subclinical cLQTS or genetic polymorphisms have been found to be more predisposed to drug-induced or hypokalemia-induced arrhythmia [74]. In cLQTS, *KCNQ1* mutations are most common, and, as we know (see Table 33.2) this gene encodes I_{Ks}. Loss of I_{Ks} function may not be apparent until superimposition of I_{Kr} block. Genetic polymorphisms that have been found in the sodium channel produce subtle changes in sodium channel activation until the I_{Kr} blocker is superimposed, at which point exaggerated action potential prolongation and EADs are manifest [4,74].

33.3.10 *KCNH2* Polymorphisms and Disease Susceptibility

Since the early finding in 1995 that functional deficits of HERG potassium channels are related to cLQTS [34], over 293 LQTS-related *KCNH2* mutations have been reported in the literature, including a new frameshift mutation recently discovered by Mihic et al. (P1086fs+32X, 3256InsG) [75]. The Arg744Pro mutation found by Aidery et al. [76] and the Gly816Val mutation reported by Krishnan et al. [77] are both associated with cLQTS. Copy number variation (CNV) in *KCNH2* may also be involved in LQTS. For example, Barc et al. [78] recently reported that *KCNQ1* and *KCNH2* CNVs might account for 3% of LQTS occurrence.

The clinical symptoms of aLQTS are similar to those of cLQTS. aLQTS is caused by environmental factors, including cardiomyopathy, abnormal metabolism, and, most commonly, drugs. It manifests as prolonged QT interval, sometimes accompanied by TdP and ventricular fibrillation [34]. Susceptibility to aLQTS significantly correlates with gene polymorphisms. For example, the mutation Pro347Ser is related to cisapride- and clarithromycin-induced TdP; Arg784Trp, with amiodarone-induced TdP.

33.4 PUBLIC HEALTH IMPACT

Long-QT syndrome is a significant public health problem, especially given the large number of drugs that can prolong the QT interval and its risk of perhaps a fatal outcome. Vast numbers of patients worldwide are exposed to potentially QT-prolonging agents every day, and while the actual number of those suffering adverse outcomes is small, the severity of outcome in those affected keep this issue a priority. It is for this reason that the QT interval is thoroughly evaluated as part of the drug safety and development process (see Section 33.5).

TdP arising during antiarrhythmic drug therapy is an important consideration when balancing risk and benefit in individual patients and in large numbers of subjects exposed to these drugs in clinical trials and practice. The risk of TdP versus the potential benefit of anti-arrhythmic therapy was the centerpiece of the FDA advisory panel debates over ibutilide, dofetilide, and sotalol [4]. D-sotalol, which is the dextrorotatory isomer of sotalol, was developed as a non-beta-blocking "pure" class III anti-arrhythmic. However, it was abandoned when the SWORD (Survival With Oral D-Sotalol) study demonstrated increased mortality with the drug versus placebo [4]. Drug-induced TdP was one possibility. Mibefradil, a drug with L- and T-type calcium channel–blocking properties, increased mortality in patients with heart failure, compared with placebo [79]; the fact that there was an increased risk among female patients receiving diuretics, raises the possibility that TdP may have been implicated.

The possibility that TdP also occurs during drug therapy not destined for cardiovascular indications was recognized early in the 1970s, with antipsychotic agents [80], and in the 1990s, with the very widely used antihistamine terfenadine [81,82]. By the time the potential for TdP was recognized, terfenadine had been used in tens of millions of patients and had generated such a good safety record that over-the-counter status was being considered [4]. It was the recognition of a single case of TdP, associated with the concomitant use of terfenadine and ketoconazole, that prompted a review of the FDA voluntary reporting postmarketing database, which identified several dozen more cases. A common feature of these cases was co-administration of drugs known to inhibit certain pathways of drug metabolism (e.g. CYP3A4) [4].

Initial attempts to deal with the problem focused on educational programs to prevent co-prescription of terfenadine with known inhibitors such as erythromycin and ketoconazole, but these programs were not sufficiently effective and the drug was withdrawn [4]. While terfenadine, and other drugs since, have received considerable attention in the press, the incidence of documented TdP associated with these drugs remains much lower than that associated with anti-arrhythmic drugs. However, as in the case of terfenadine, given that there were effective alternative therapies and that the indication for therapy was not in itself life-threatening, even a very small risk of TdP was considered to be unacceptable.

The absolute numbers of individuals exposed to diTdP risk are significant as up to 3% of all prescriptions worldwide include potentially pro-arrhythmic medications [83]. Therefore, diTdP has become a very important public health and regulatory issue and has led to the withdrawal of a number of widely prescribed drugs from the market, such as, cisapride and thioridazine, along with terfenadine. It has also led to restricted use of others (e.g., citalopram, droperidol, haloperidol, sertindole) [5,84].

Some pro-arrhythmic drugs that are essential to medical practice have not been withdrawn, such as macrolide antibiotics in penicillin-sensitive individuals and halofantrine in drug-resistant malaria [5]. Several neuroleptic drugs, vital in the treatment of psychotic illnesses also remain in use.

With the recognition of terfenadine-induced TdP came the increasing scrutiny of other drugs and it is now routine for all new drug entities to be screened for their ability to block I_{Kr} *in vitro* and to prolong QT intervals in early human trials. Although this has imposed a new hurdle in drug development, screening studies will reduce the likelihood of any new drug unexpectedly causing TdP by blocking I_{Kr} [5,8,83–85].

Clinicians are often faced with decisions regarding alternative medications for individuals with a prolonged QT interval. However, cardiovascular screening prior to prescription of potentially QT-prolonging drugs seems unlikely to be cost effective or widely adopted. Still, clinicians should be conscious of cardiac-related aspects of the patient history and should consider any potential increased risks prior to commencing such therapies.

Specific groups of patients, particularly those with risk factors as mentioned in Table 33.4, should be observed prior to therapy with potentially QT-prolonging agents, ideally in a medical setting. Also, patients whose family history includes sudden cardiac death or those on complex medical regimes that may give rise to issues of drug elimination should be treated with caution. In reality, this is often not possible, and when one considers the great number of patients fulfilling such criteria who are treated every day, both in hospital and in the community, versus the number who will suffer an episode of TdP, it may be difficult to justify such extra measures on a cost-effective basis.

Nevertheless, if therapy with a potentially QT-prolonging agent is commenced, the patient should be warned to promptly report any unusual symptoms, particularly any cardiac-related symptoms such as palpitations and syncope [30]. It is also important to remember that other intercurrent symptoms may alter electrolytes and predispose to cardiac events—for example, gastroenteritis, which may lower serum potassium levels. An ECG during treatment may detect the asymptomatic prolongation of the QTc to >500 ms or an increase in the QTc of >50 ms on treatment. In this, education programs about co-prescribing have not been sufficiently effective [4]. It is hoped that increased awareness among clinicians (especially family doctors, who are generally the first-line prescribers) and patients themselves may result in greater exposure to highly informative sources such as www.qtdrugs.org. A higher profile for cardiac-related and sudden death charities (and the information they provide) on social networking sites may prove to be beneficial in the long term. Improved clinician education and awareness of the proarrhythmic potential of noncardiac drugs alone is probably not sufficient in preventing adverse outcomes, and computer-assisted strategies can offer another level of safeguarding. Electronic prescribing allows for sophisticated systems with automatic alerts and this will add an extra level of defense against prescribing medications which may be proarrhythmic in combination, or in conjunction with a patient's current medical history e.g. temporary electrolyte imbalance whilst a hospital inpatient. Systems which can combine a patient's past medical history with their current "real time" medical experience e.g. hypokalaemia or heart failure would be most beneficial.

A major concern is always the fact that rare and poorly understood side effects can occur with many highly effective drugs, and that the withdrawal of these medications from the market altogether would probably harm more patients than it would help. The very real risk of serious adverse events in the minority must be weighed against the clear therapeutic benefits in the vast majority.

33.5 QTc IN NEW DRUG DISCOVERY AND DRUG SAFETY

As Nachimuthu et al. summarize well, it has now become common practice for pharmaceutical and biotechnology companies to screen compounds for HERG channel activity early in preclinical safety assessment [53]. Indeed, in Europe and the United States all new molecules must undergo evaluation in both pre-clinical and clinical settings to assess their effects on repolarization. An example of this in practice is the "Thorough QT/QTc (TQT) study", intended to confidently identify drugs that may cause QT prolongation [53]. This study has evolved as a key component of all clinical development programs for new molecular entities; it employs a double-blinded, randomized design with a placebo and a positive control arm that is strictly powered to exclude an effect on the QTc interval exceeding 10 ms. It aims to determine whether the new chemical entity prolongs the QTc interval, and if so, whether the effect is dependent on the dose or the concentration. It is conducted using healthy volunteers once the tolerability and the pharmacokinetics of the drug have been established. During a TQT study, RR interval, heart rate, QT interval corrected using both Bazett's and Fridericia's correction are collected. ECG interval measurement methods are either fully manual or use some degree of manual adjudication (e.g. computer-based algorithmic measurements are reviewed and corrected as needed) [53].

The role of the positive control is to demonstrate the study's ability (i.e., assay sensitivity) to detect a small effect on the QT interval—in this case, QT prolongation of slightly more than 5 ms. If the study can detect such a small QT prolongation by the control, then a finding of a lesser QT effect for the test drug should indicate that the drug does not significantly prolong the QT interval. Moxifloxacin, a fluoroquinoline antibiotic with a mild QT-prolonging effect is used in most of these studies [53]. Moxifloxacin 400 mg has been associated with an observed 7.5–12.5 ms increase in the mean placebo- and baseline-corrected QTc interval, which supports its appropriateness a positive control in TQT studies [86].

A TQT study usually results in three clinical scenarios [53]:

1. The studied drug prolongs the mean QTc interval by ≤10 ms and therefore does not appear to cause TdP.
2. The studied drug prolongs the mean QTc interval by >10 ms but ≤20 ms and has an "uncertain" risk of TdP.
3. The studied drug prolongs the mean QT/QTc interval by >20 ms and may have a "high" risk for causing clinically important arrhythmic events.

To fully evaluate the risk of QT prolongation, it is important to include patients in these analyses with additional TdP risk factors such as those with electrolyte abnormalities (e.g., hypokalemia), congestive heart failure, impaired drug-metabolizing capacity or clearance (e.g., renal or

TRENDS in Molecular Medicine

FIGURE 33.6 **HERG subunit.** Shown here is a single HERG subunit containing six α-helical transmembrane domains (S1–S6), a pore-forming loop (between S5 and S6), a C-terminal cyclic nucleotide-binding domain (cNBD), and a N-terminal Per-Arnt-Sim (PAS) domain. There are at least 30 *KCNH2* SNPs shown associated with HERG potassium channel sensitivity to about 70 drugs; polymorphisms leading to changes in the channel properties are highlighted. *Source: From He et al.* [34] *with permission.*

hepatic impairment, drug interactions), female patients, and patients aged <16 years and >65 years.

Recent studies have indicated that fully or partially automated methods of QT interval measurements using computer algorithms, compared with labor-intensive manual methods, produce similar results when tested on drugs with a known QT-prolonging effect [87]. It is expected that use of automated QT algorithms in the evaluation of new medications will not only replace manual QT measurements but will also improve detection of subtle T-wave changes [53,88].

33.6 PHARMACOGENOMIC STUDIES

33.6.1 HERG Potassium Channels, *KCNH2* Polymorphisms, and Drug-Induced LQTS

Figure 33.6, by He et al. [34] shows a single HERG subunit, with 30 *KCNH2* single-nucleotide polymorphisms (SNPs) that are associated with HERG potassium channel sensitivity to about 70 drugs [34]. These drugs include antiarrhythmic agents, antidepressants, and antibiotics. The following Sections 33.6.1–33.6.3 describe the relationship between *KCNH2* polymorphisms and drug-induced QT-interval abnormalities according to the literature reported and summarized by He et al. [34].

Current studies on HERG potassium channel polymorphisms and drug-induced LQTS began with finding drugs related to QT interval prolongation. *In vitro* patch-clamp techniques were then used to determine the effect of these drugs on I_{Kr} currents in recombinant cells which had different HERG potassium channel genotypes. In this way, the relationship between *KCNH2* polymorphisms and drug-induced QT abnormalities could be evaluated. However, one must accept that drug-induced malignant arrhythmia is rare and the numbers of LQTS patients are relatively small [34]. Nevertheless, with new technological developments such as induced pluripotent stem cells (iPSCs) [34,89], cell models that closely mimic the electrophysiological properties of cardiac-muscle cells can be employed to evaluate the effects of HERG potassium channels more objectively.

At present, *in vitro* studies have demonstrated that the majority of LQTS-related drugs block HERG potassium channels, and HERG potassium channel polymorphisms affect the sensitivities of these drugs [34]. In particular, the Tyr652Ala and Phe656Ala mutations in the S6 pore region of HERG potassium channels are the key to drug sensitivity [34]; however, these results have not as yet been clinically proven. Interestingly, natural plant monomers, such as berberine, nicotine and papaverine can lead to prolonged QT intervals or action potential duration (APD), and *KCNH2* polymorphisms are related to the sensitivity of these traditional Chinese medicines [34].

33.6.2 Functional Deficits Caused by HERG Channel Mutations

Congenital LQTS induced by *KCNH2* polymorphisms is mainly caused by functional deficits or transfer deficits of HERG potassium channels [34]. Mutations at the C terminus of HERG potassium channels can cause misfolding, transfer deficit, and abnormal positioning and thus disturb the ion distribution density needed for these channels to function normally. This can lead to LQTS (e.g., the Asn470Asp mutation) [34]. However, ion channel functional deficits or transfer deficits caused by these mutations can be repaired by HERG blockers or by low temperature. For example, Harley et al. [90] found that the transfer deficits caused by nine mutations in the PAS region of HERG potassium channels could be rescued by low temperature [34].

Delisle et al. [91] found that thapsigargin can selectively rescue the transfer deficit of HERG potassium channels caused by Gly601Ser and Phe805Cys mutations. It was also found that the HERG blocker E4031 can repair deficits caused by Asn470Asp and Gly601Ser [34]. Yao et al. showed that current density decreases caused by Arg1014X and Trp927X mutations could be partially repaired by gentamicin [34,92]. Rajamani et al. found that, although rescuing the transfer deficits caused by Asn470Asp and Gly601Ser mutations does not depend on the HERG-blocking effect of terfenadine and fexofenadine, the transfer deficit caused by Val822Met mutation could not be repaired [34,93].

Gong et al. [34,94] showed that morpholino oligonucleotides can counteract downregulation of the mRNA level induced by the HERG Gln1070X mutation and increase HERG protein expression. The researchers indicated that investigating *KCNH2* polymorphisms and QT syndromes will be of clinical value in developing individualized treatments.

33.6.3 Distribution of Drug Sensitivity–Related *KCNH2* Polymorphisms

Studies on the frequency distribution of *KCNH2* polymorphisms in human populations have been rare. Also, there are only a few studies on the polymorphisms related to the drugs that act on HERG potassium channels. Mutations in HERG that correlate with drug sensitivity are many, but there have been only a few studies on the frequency distribution of *KCNH2* polymorphisms in human populations [34].

The reported drug sensitivity–related *KCNH2* polymorphisms show substantial racial differences, which suggests that studies on genes related to HERG drug sensitivity in human populations are important [34].

HERG polymorphisms are associated with cLQTS, tumors, schizophrenia, cardiovascular diseases, epilepsy, and skeletal muscle dystrophy, and studies over the past 10 years show that drugs with risk of LQTS are mainly antiarrhythmics, antihypertensives, and drugs for psychiatric disorders, epilepsy, or cancer [34]. In-depth study of the relationships between HERG potassium channel polymorphisms and diseases or adverse drug reactions can provide new insights into disease prevention and treatment. It can also hopefully present new targets for drug development and offer a new platform for re-evaluating drugs that have been withdrawn from the market due to severe adverse effects. This is important as such drugs might still have a lot to offer us and be valuable in a wide range of clinical applications [34].

33.6.3.1 HERG in the Clinical Application of New Drugs

Studies have shown that HERG blocking may be related to the treatment effect of the drugs. For example, Parkman et al. studied 48 patients with gastroparesis and found that the *KCNH2* polymorphism (rs3815459), an allele, correlated with the therapeutic effect of domperidone in treating this condition [34]. This suggests that proper HERG blocking may be another important approach for gastroparesis treatment.

Pharmacogenomic studies on HERG provide warnings during early-stage drug development, helping to avoid the withdrawal of useful compounds only because of their adverse effects on patients with genetic defects. To some extent, such studies may play an important role in providing more information for drug structural analysis. For example, erythromycin shows a blocking effect on HERG with an IC_{50} of approximately 59.3 uM; the Tyr652Ala mutation does not affect HERG sensitivity to erythromycin, whereas the Phe656Ala substitution does so slightly, suggesting that the blocking of HERG by erythromycin is due to its size [34].

New opportunities for the clinical application of drugs can be pieced together by pharmacogenomic studies, offering a basis for safety evaluation and individualized use [34]. Studies have shown that functional deficits can be repaired by HERG channel blockers, and that structurally different HERG blockers can selectively repair functional deficits caused by mutations at different sites (e.g., fexofenadine) [34]. However, the mechanism of these repair functions remains unclear. It is possible that HERG blockers function by repairing the unstable conformations caused by mutations. This suggests that HERG channel blockers can be used to treat cLQTS. However, such treatment should be based on an individualized diagnosis and related pharmacogenomic assays to ensure that it is safe and effective. Investigations into the relationship between HERG channel polymorphisms and drug sensitivity have all been performed *in vitro* [34].

Many studies have explored the effect of Tyr652Ala on drug sensitivity and have found that this amino acid mutation significantly decreases the blocking effects of most drugs, and it may reduce the risks of adverse effects for drugs that can induce QT interval abnormality. Drugs with LQTS risks may be safe and effective in populations that carry this site mutation. The Tyr652Ala polymorphism shows clear differences in racial and gender distribution. Overall, its clinical significance certainly merits further investigation [34].

The relationships between CYP2B6 and *KCNH2* polymorphisms and the effects of methadone are yet to be investigated in detail, but will be of important clinical value [34]. Eap et al. [34,95] studied 179 subjects and found that, in CYP2B6*6 carriers vs noncarriers, the risk of methadone-induced QT interval prolongation was increased 4.5-fold. *In vitro* studies have found that the blocking effect of S-methadone on HERG is 3.5-fold that of R-methadone, but there has been no research into the relationship between *KCNH2* polymorphisms and the HERG effects of these two methadone isomers. Some *in vitro* studies have suggested that *KCNH2* polymorphisms affect channel drug sensitivity and enhance the risk of QT abnormality syndromes; however, this needs to be verified with large clinical trials.

In addition, amino acid mutations at position 652 of the HERG potassium channel may not always affect HERG blocker sensitivity [34]. For example, mutations at this position have been found to increase the blocking effect of capsaicin on HERG I_{Kr} current, decreasing the IC_{50} to about a quarter of the value for the wild- type channel. Contrary to this, amino acid mutations at position 656 showed no difference compared with wild type [34]. The physiological functions of HERG potassium channels, their role in regulating disease occurrence and development, and their relationship with adverse as well as treatment effects of drugs merits further studies.

Pharmacogenomic studies on HERG potassium channels can provide a new basis for reevaluating drugs that are of value in a wide range of clinical applications but have been withdrawn merely because of their rarely occurring adverse effects [34]. Such studies can also offer new insight into the development of individualized clinical treatment services. Although at the present time the results of such studies have not been clinically applied, they are of great importance in individualized applications of drugs carrying QT abnormality risks, in evaluating the safety of withdrawn drugs, and those during early-stage development [34].

33.6.4 Rare Mutations

With the identification of rare mutations in ion channel genes underlying cLQTS and with the investigation of large pedigrees, the phenomenon of incomplete penetrance has become apparent, as previously discussed [6,23]. In a given pedigree, people with a LQTS mutation but normal QT intervals at baseline can be described as "subclinical" and may experience TdP after exposure to a QT-prolonging drug. When cLQTS disease genes are screened for, mutations are identified in ~10% of diLQTS subjects [73].

33.6.5 Common Variants and Common Polymorphisms in Ion Channel Genes

More common polymorphisms in ion channel and other genes have been described that have minor functional effects at baseline yet, when compounded with a QT-prolonging drug, may increase TdP risk. In one study of patients treated with dofetilide, the common *SCN5A* polymorphism H558R was over-represented in those with TdP (37.5%) compared with those without (14.4%) [6,96]. Other common ion channel polymorphisms implicated in small diLQTS studies include *KCNH2* R1047L and *KCNE2* T8A and Q9E [97]. A survey of a large collection of diLTQS patients compared with drug-exposed patients with minimal QT prolongation and with population controls revealed that the polymorphism D85N in *KCNE1* (an important subunit for I_{Ks} function) was a risk factor [98]. The allele frequency of D85N was ~8% among subjects with diTdP and 1–2% in controls [5].

Most variants studied to date have been "nonsynonymous" and data comparing the function of wild-type channels to that of variant channels can often be generated *in vitro* [5]. One variant that is relatively common in African subjects, with a minor allele frequency of ~13%, results in S1103Y (substitution of tyrosine for serine at position 1103 in the cardiac sodium channel). However, this variant is unusual in subjects of other ethnicities [99].

33.6.6 Genome-Wide Association Studies

Genome-wide association studies (GWAS) have been used to study variability in the baseline QT interval [100–102]. Such studies encompassed tens of thousands of individuals, identified multiple loci at which common variation influences variability in the QT interval [5]. Some of these are in ion channel genes, suggesting that rare variants in these genes can cause diseases like cLQTS, whereas common variants modulate the baseline QT interval. The QTc interval is known to be influenced by genetic factors and heritability estimates are between 25% and 52% [103–105]. In the Twins UK study [106], a UK-based sample of mostly female twins of European ancestry, the proportions of additive genetic influences have been estimated as 55% for resting heart rate, 60% for uncorrected QT interval and 50% for QTc.

As Jamshidi et al. [105] describe, until recently, research into genetic factors influencing QT interval was limited to candidate genes known to have a role in arrhythmogenesis. This was on the basis of their involvement in the congenital monogenic diseases LQTS and short QT syndrome [105,107,108]. However, advances in biotechnology have now made genome-wide association studies (GWAS) possible. GWAS have the potential to identify loci that had not previously been targeted as having a role in the trait or disease, thereby highlighting potentially novel biological pathways [109]. This is in contrast to candidate gene studies in which genes are selected on the basis of known or suspected disease mechanisms. An early GWAS for the QTc interval [100] based on selection of individuals from the extreme tails of the population-based QTc interval distribution identified a common variant in the nitric oxide synthase 1 adaptor protein (*NOS1AP*) gene region, and this was consistently confirmed in later studies [101,102,110–113]. The *NOS1AP* variant has been estimated to explain up to only 1.5% of QTc variance [100,105] suggesting the need for more studies with the potential to detect additional common genetic variants, which are likely to be of modest effect size.

Recent advances include meta-analyses of GWAS investigating QT interval duration in population-based cohorts by a number of consortia [101,102]. The QTGEN and QTSCD [101,102] consortia found that common variants in a number of genes previously known to cause congenital LQTS (*KCNQ1*, *KCNH2*, *KCNE1*, and *KCNJ2*) and short QT syndrome (*SCN5A*) were among the most strongly associated with the QT interval in these population-based cohorts. These studies have contributed many newly associated loci to this complex trait, and have suggested a cumulative effect of individual variants on QT interval [105]. Two of the novel loci contained genes with established electrophysiological function (*ATP1B1* and *PLN*) and a third locus on 16q21 was near the genes *GINS3* and *NDRG4*. These genes have been associated with myocardial repolarization in zebrafish experiments [105].

Indeed, one of the strongest signals to emerge from GWAS analysis of the baseline QT interval is variation at the nitric oxide synthase 1 adaptor protein (*NOS1AP*) locus on chromosome 1, which encodes a protein for neuronal nitric oxide synthase. *In vitro* and *in vivo* studies suggest that it modulates both potassium and calcium current function [5,114]. Following from this is the investigation of the role of QT-modulating genes in diTdP and other traits. There is some evidence that *NOS1AP* variants can act as modulators of arrhythmia risk in cLQTS [115,116] and are implicated in sudden death in the general population [117]. Further evidence for the role of the *NOS1AP* locus in diTdP was provided by a study that found a 5-fold increase in diTdP risk in patients in whom amiodarone was the culprit drug [5,118].

33.7 FUTURE DIRECTIONS

33.7.1 Screening, Stratification, Personalization

Despite substantial advances in the field since potentially proarrhythmic drugs were first described, it has become clear that there are several factors which contribute to an individual's personal risk of diLQTS and TdP. The known clinical risk factors for acquired and drug-induced TdP can serve to separate patients into high- or low-risk subgroups for development of this life-threatening arrhythmia; however, they cannot identify risk on an individual level.

For more accurate risk stratification, the genomic contribution to drug-induced TdP risk must be further evaluated and refined, as it appears that here lies more of the unpredictability of this condition. Indeed, the fact that small studies have uncovered first-degree relatives of patients with diTdP who themselves have a prolonged QTc interval on exposure to a QT-prolonging drug [119] supports the role of a genetic component in risk.

In the future, additional coding and noncoding modifier variants are likely to be discovered as novel technologies, such as exome and whole genome sequencing, are used to genotype LQTS patients. The incorporation of these variants into risk stratification algorithms is likely to have a significant impact on LQTS management [120]. Other future directions for LQTS studies include the functional effects of mutations and their correlation with risk—for example, using induced pluripotent stem cells (iPSC) derived directly from patient samples.

The potential role of rare variants in diTdP can be further examined by some of the newer approaches to sequencing [5]. In comparison with background rates ascertained by the 1000 Genomes and the Exome Sequencing projects a recent study [72] sequenced 79 candidate arrhythmia genes in a small number of subjects with diLQTS and identified a high proportion of individuals with rare variants. Ascertaining the role of genetic variation in diTdP will require gathering together a large number of well-phenotyped cases across different ethnic groups and will cover several different drugs and drug classes.

It is a realistic prospect that, in the future, we will include clinically relevant information on pharmacogenetic variation in patient records. With the decreasing costs of genotyping and sequencing, future limiting factors, other than cost, are more likely to be data interpretation and wider ethical issues resulting from the identification of variants of uncertain clinical significance. The turnaround time for results will also have to be rapid and reliable, but with advice limited in some cases to enhanced risk than a definitive "yes" or "no." Thus, some clinicians may be less inclined to support adoption of pharmacogenomic testing for diTdP on a wide scale.

Pharmacogenetic data may influence the clinical management of patients in the future—for example, by focusing on those who should be monitored more closely on treatment, those in whom drug dosage should be altered, or those for whom a particular therapy should be avoided altogether. However, before such genotype-based healthcare can be implemented, several significant issues must be addressed such as: the strength of the evidence associating genetic variation with variable drug outcomes; interaction with nongenetic risk; variable effects of genetic variants across ethnicities; reliability of genotyping assays; the development of electronic medical-records systems; and the attitudes of both patients and their clinicians [5].

33.7.2 Proposed Methods of Risk Stratification

Short-term QT interval variability (as measured from 30 consecutive beats) is increased in patients with a history of drug-induced long-QT syndrome, suggesting that this variability could prove to be a useful noninvasive, easily obtainable parameter for aiding the identification of patient at risk for potentially life-threatening arrhythmia in the context of drugs with QT-prolonging potential [121].

The development of a torsadogenic score to assess proarrhythmic drug risk would be most beneficial and this is the ultimate goal of the ARITMO (Arrhythmogenic Potential of Drugs) project [122]. In this study, the FDA Adverse Event Reporting System (FAERS) is used to detect signals of increased torsadogenic risk. The population is large (including all US reports and serious/unexpected adverse drug reactions from other countries) and this feature makes the FAERS an incredibly useful resource for exploring more rare adverse drug reactions (ADRs) such as TdP [122]. FAERS's initial findings will need to be further validated by integrating data from other sources of clinical data. However, it is important to bear in mind the limitations of current methods and to remind ourselves that, for more recently marketed drugs, careful monitoring should be maintained. It appears that *in vitro/in vivo* assays and thorough QT studies strengthen the role of postmarketing surveillance in early and timely detection of safety signals [122].

33.7.3 Unanswered Questions and Priority Areas for Research

Understanding the nature and extent of variability among human genomes will allow prediction of individual susceptibility to disease, adverse drug reactions, and even beneficial drug effects. Achieving this vision of personalized medicine requires in-depth understanding of the number of variants in specific candidate genes and across the genome, the way in which these variants affect individual gene function, and the ways in which they may be analyzable. There are enormous challenges in executing this vision. These include the requirement for new technologies for rapid genotyping; the development of approaches to organization and analysis of very large data sets; associated ethical issues; and cost and commercialization [4].

These challenges are balanced by a set of opportunities including the true possibility of delivering improved care and developing new therapies through a better understanding biology. The key first step in this research is clear definition and identification of target phenotypes, so it is essential that clinicians be educated to become leaders in this new field.

In considering priority areas for future research, we must consider not only what would happen in an ideal world but also what might realistically be readily absorbed into the general clinical workflow and be ethically acceptable. As we look to the future, we must address significant issues before genotype-based healthcare can be implemented. Most important is how to analyze the huge amounts of data generated and how to deal with that information. Ethical considerations, which even now are the subject of heated worldwide debate, must not be underestimated.

With advances in personal genomics, high-accuracy risk prediction for adverse drug effects is a real prospect. Understanding the mechanisms underlying drug actions, especially toxicities such as diLQTS, remains the best way forward in choosing the most appropriate therapies for individual patients, and in developing new, safe, and effective treatments.

GLOSSARY

Andersen-Tawil syndrome	a condition characterized by episodic paralysis, ventricular arrhythmias, and prolonged QT interval
Cascade screening	method of ascertaining gene carriers by testing the patient's close family members
Copy number variant	form of DNA variation in which a certain sequence is present in differing numbers of copies, and is different across individuals. Many CNVs are nonpathogenic common variants
Genome-wide association study (GWAS)	a study in which SNPs are tested for association with a disease in a case-control design
Monogenic	pertaining to a disorder occurring as a direct consequence of single gene defects
Penetrance	probability of a characteristic being present given a certain genotype
Phenotype	measurable characteristics of an organism. These may derive from the genotype, the environment, or their combination
Single nucleotide polymorphism (SNP)	any polymorphic variation at a single nucleotide
Syncope	transient loss of consciousness

Timothy syndrome rare childhood condition that leads to cardiac arrhythmia, a spectrum of neurological and developmental abnormalities, and syndactyly

Torsades de Pointes (TdP) distinctive form of polymorphic ventricular tachycardia characterized by twisting of the QRS complexes around the isoelectric line. It is associated with QT prolongation

Ventricular fibrillation (VF) rapid, chaotic, nonrepetitive waveform in which there is uncoordinated contraction of the cardiac muscle of the ventricles. VF is clinically associated with loss of effective blood circulation and, if not immediately treated, death

Ventricular tachycardia (VT) sequence of three or more beats in a row, with wide QRS complex (QRS >120 ms) at a ventricular rate exceeding 100 beats/min

ACRONYMS AND ABBREVIATIONS

GWAS	genome-wide association study
NME	new molecular entity
SNP	Single-nucleotide polymorphism
ECG	electrocardiogram
APD	action potential duration
EAD	early after depolarization
I_{Kr}	rapid delayed rectifier potassium current
I_{Ks}	slow delayed rectifier potassium current
KCNQ1	potassium voltage-gated channel, KQT-like subfamily, member 1
RWS	Romano-Ward syndrome
JLNS	Jervell and Lange-Nielsen syndrome
KCNH2	potassium voltage-gated channel, subfamily H, member 2
SCN5A	sodium voltage-gated channel, type V, α-subunit
ANK2	ankyrin 2
KCNE1	potassium voltage-gated channel, I_{SK}-related subfamily, member1
KCNE2	potassium voltage-gated channel, I_{SK}-related subfamily, member 2
KCNJ2	potassium channel, inwardly rectifying, subfamily J, member 2
CACNA1C	calcium voltage-dependent channel, L-type, α-1C subunit
CAV3	caveolin 3
SCN4B	sodium voltage-gated channel, type IV, β subunit
AKAP9	A-kinase anchor protein 9
SNTA1	syntrophin α1
KCNJ5	potassium channel, inwardly rectifying, subfamily J, member 5

34.1 OVERVIEW

Pancreatic cancer (PC) is the fourth leading cause of cancer-related death in Western societies, including the United Kingdom, with an overall five-year survival rate of less than 5%—a figure that has not changed in 50 years [1]. Surgical resection remains the only chance of cure, with chemotherapy adding a modest benefit. With a few exceptions, most clinical trials have not shown a statistically significant or clinically meaningful survival benefit. This is perhaps not surprising, as recent genomic sequencing studies revealed that, apart from the few well-known mutations that cannot be effectively targeted, most mutations occur at a rate of less than 5%, making PC one of the most heterogeneous cancers [2,3]. This likely hampers clinical trials given that the responsive phenotype of a particular therapeutic regimen would most likely fall below the detection threshold of a conventional randomized controlled trial design.

This heterogeneity makes PC an ideal disease to explore a stratified approach through matching the right treatment to the right patient. Stratification would improve overall outcomes and quality of life by selecting the treatment most likely to be effective and minimizing unnecessary side effects from ineffective therapies. Furthermore, it would reduce the cost of ineffective drugs and their associated toxicities, as well as the cost of drug development. In 2012, three-quarters of worldwide pharmaceutical investment did not achieve the desired efficacy, resulting in high costs for healthcare providers. For example, Tarceva®, a USFDA-approved agent for PC, has a price tag of greater than US $600,000 per quality-adjusted life year.

34.2 CURRENT TREATMENT PARADIGM

Current classification and management of PC are based on morphology (Figure 34.1). After diagnosis, the patient undergoes staging investigations, followed by a stage-specific treatment pathway. Generally, patients are categorized as having resectable or unresectable disease. Patients

Handbook of Pharmacogenomics and Stratified Medicine. http://dx.doi.org/10.1016/B978-0-12-386882-4.00034-7

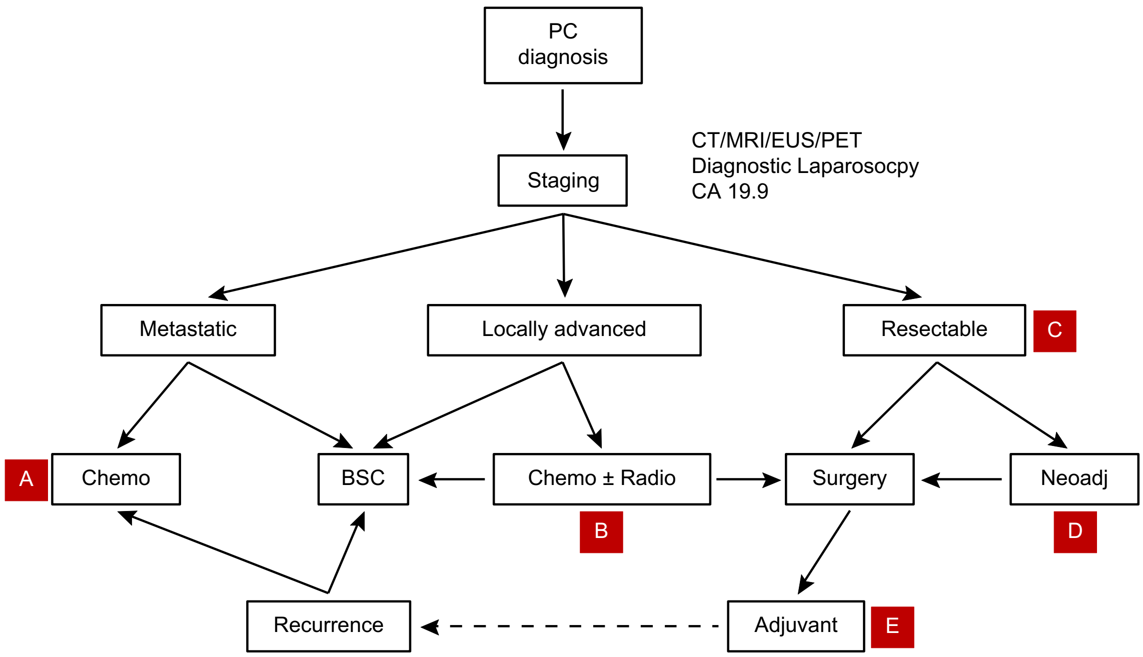

FIGURE 34.1 **Current management approach for pancreatic cancer based on morphology.** Stratification points A–E, in red, identify where biomarkers may be used to refine current management using stratification. PC—pancreatic cancer; CT—computer tomography; MRI—magnetic resonance imaging; EUS—endoscopic ultrasound; PET—positron emission tomography; BSC—best supportive care; chemo—chemotherapy; radio—radiotherapy; neoadj—neoadjuvant therapy.

with resectable PC undergo surgery or, more increasingly common, neoadjuvant chemotherapy, either as institutional policy or based on individual clinician preference. Following surgery, patients undergo chemotherapy in the adjuvant setting. For patients with unresectable PC, treatment consists of palliative chemotherapy or best supportive care depending on the individual's performance status. A wide variety of chemotherapy regimens are potentially available, including gemcitabine, 5-FU, FOLFIRINOX, and many other combinations that depend on patient fitness and clinician preferences. Radiotherapy is used sporadically in various settings.

34.3 STRATIFIED THERAPEUTIC APPROACH

34.3.1 Metastatic Pancreatic Cancer

More than 50% of patients with PC present with metastatic disease at diagnosis. The therapeutic options for these patients are either best supportive care or palliative chemotherapy. These patients are often frail as a result of cancer cachexia, and the majority are not chemotherapy candidates because of their poor performance status. Even for patients who are candidates for chemotherapy, the overall response rates have been generally disappointing, with rapidly diminishing numbers that are eligible for second- or third-line chemotherapy because of accumulating toxicity and increasing cachexia. Despite low overall response rates, palliative chemotherapy appears to be effective in an undefined subgroup of patients [4,5]. Better selection may therefore improve response rates in this subgroup and avoid ineffective chemotherapy in the remainder. This has become more relevant in recent years, with the increasing number of available chemotherapeutic options.

Better selection of patients based on predictive biomarkers of therapeutic responsiveness is the modern paradigm of clinical oncology. Through the efforts of the authors' group and others, several actionable phenotypes of therapeutic responsiveness have been proposed (Figure 34.1, stratification point A). Despite low recurrent mutation rates, it is possible to map putative actionable molecular genotypes/phenotypes in PC using a variety of tissue- and genomic-based assays. For the purpose of this review, we concentrate only on actionable molecular genotypes/phenotypes with drugs currently approved for PC or other cancer types (Table 34.1). Other emerging actionable molecular genotypes/phenotypes using repurposed or novel therapeutics are in development.

34.3.1.1 Gemcitabine

Until recently, gemcitabine was the only option for advanced PC [6]. The putative biomarkers of gemcitabine responsiveness include nucleoside transporters such as hENT1, hCNT1/3, and kinases involved in gemcitabine metabolism, such as deoxycytidine kinase (dCK) [7,8].

TABLE 34.1 PC Actionable Molecular Genotypes/Phenotypes

Actionable Genotype (Molecular Phenotype)	Therapeutic	Rationale	Molecular Characterization/ Proposed Biomarkers	Overall Prevalence
Gemcitabine responsive	Gemcitabine	Phase III clinical trial data	High *hENT1*, *hCNT1*, *hCNT3*	~14%
DDR deficient	Platinum; MMC; PARPi	Case reports; clinical trial signals FOLFIRINOX trial	*BRCA2/PALB2* mutations	8%
nab-paclitaxel responsive	*nab*-paclitaxel	Clinical trial; preclinical models	*SPARC* expression	10%
Fluoropyrimidine responsive	5-fluorouracil; capecitabine	Phase III clinical trials	Unknown	3%
Anti-EGFR responsive	Erlotinib	Phase III clinical trial data (PA3)	*KRAS* wild type	7%
Irinotecan responsive	Irinotecan	FOLFIRINOX trial	Topoisomerase 1 over expression	2%
HER2 amplified	Trastuzumab	Rescuing	*HER2* amplification	2%

Note: Data are for drugs approved for PC or other cancer type, defined using tissue- and genomic-based assays.

The most studied biomarker of therapeutic responsiveness in PC is hENT1, a membranous equilibrative nucleoside transporter encoded by the *SLC29A1* gene. There is evidence to support the role of hENT1 in gemcitabine responsiveness in PC cells both *in vitro* and *in vivo*, but its precise function as a predictive biomarker in the clinic is yet to be established. Small cohort studies and retrospective analysis of large phase III randomized control trials (RCTs), such as RTOG 9704 and ESPAC 1/3, have supported hENT1 as a predictive biomarker of adjuvant gemcitabine responsiveness [9,10]. However, a recent phase II RCT stratified by hENT1 expression, comparing gemcitabine versus CO-101 (lipophilic gemcitabine) in metastatic PC, failed to demonstrate this in metastatic disease [11]. Though the reasons for this are still unclear, the discrepancy may be due to the use of different hENT1 antibodies for immunohistochemistry; or it may be that the significance of hENT1 as a predictive biomarker is different in the metastatic as compared to the adjuvant setting; or, finally, it may be that hENT1 is not a predictive biomarker of gemcitabine responsiveness.

34.3.1.2 DNA-Damaging Agents

Perhaps the most striking cellular hallmark of cancers with mutations in the Fanconi anaemia/BRCA homologous recombination pathway is their hypersensitivity to DNA-damaging agents, such as mitomycin C and platinum, or to PARP inhibitors [12,13]. Anecdotal evidence for the potential use of DNA-damaging agents in PC that harbor these defects is mounting.

Platinum-based therapies in PC have had mixed results in clinical trials of unselected patients [14], although a recent meta-analysis of clinical trials [15] and efficacy of the FOLFIRINOX regimen [4] suggest activity in subgroups of patients. The efficacy of FOLFIRINOX in PC was demonstrated by the PRODIGE4/ACCORD 11 study [4] (overall median survival 11.1 versus 6.8 months; $p < 0.001$). FOLFIRINOX is a combination of 5-fluorouracil, irinotecan, and oxaliplatin, and can be associated with significant drug-related toxicity. Therefore, predicting responders prior to therapy could significantly improve overall outcomes. In addition, most evidence suggests that the predominant active agent in this combination is oxaliplatin, as similar response rates are seen despite dose reduction in 5-FU and irinotecan [16,17]. This implies that defining patients whose tumors harbor defects in DNA damage repair and replication (DDR) may facilitate better patient selection and remove the necessity for other drugs. While irinotecan may have synergistic activity with platinums, many consider that 5-FU adds little considering the cost of associated toxicity. Putative biomarkers of DNA-damaging agent responsiveness have not been well characterized because of complex interactions between a large number of genes involved in DNA maintenance machinery.

Platinum agents and PARP inhibitors are currently in clinical trials for the treatment of hereditary breast and ovarian cancers [13,18], recruited based on germline defects or variants in Fanconi anemia genes. However, there is increasing evidence to suggest that the responsive phenotype may be greater than just the patients harboring tumors with germline and/or somatic mutations in known DNA maintenance genes. The majority of these patients have either germline or somatic known pathogenic mutations in genes involved in DNA maintenance; however, up to 30% of them have novel mutations of unknown significance in known DNA maintenance genes or mutations in novel genes that have not been implicated in DNA maintenance.

In a collaborative effort led by the Sanger Institute to which the Australian Pancreatic Cancer Genome Initiative (APGI) contributed, an analysis of 4,942,984 mutations from 7042 cancers extracted more than 20 distinct mutational signatures [19]. The results revealed four signatures in PC that infer known biological processes: older age, *BRCA*-mediated defects in DNA damage repair, DNA mismatch repair deficiency, and a signature associated with the APOBEC family of cytidine deaminases. As a consequence, mutational signatures associated with specific defects in DNA maintenance may also be clinically useful in defining a DNA-damaging agent responsive phenotype and may have utility for patient selection in the future.

34.3.1.3 Nab-Paclitaxel

Secreted Protein Acid and Rich in Cysteine (SPARC, also known as osteonectin) regulates extracellular matrix modeling and deposition and may act as a tumor suppressor or an oncogenic driver depending on differential expression in epithelial and stromal components in different cancer types [20]. High stromal and low epithelial SPARC expression is a poor prognostic biomarker in PC [21,22]; based on its hypothesized function as an albumin "sticker," it was developed as a therapeutic target for *nab*-paclitaxel (Abraxane®) to enable "stromal depletion" and, in turn, improve drug delivery.

A phase I/II study of gemcitabine plus *nab*-paclitaxel demonstrated SPARC expression in the stroma but not in the epithelium, cosegregated with improved survival, and hence a candidate predictive biomarker for *nab*-paclitaxel responsiveness [23]. This led to the phase III MPACT (Metastatic Pancreatic Adenocarcinoma Clinical Trial) RCT, which compared gemcitabine versus gemcitabine plus Abraxane. This trial demonstrated that the addition of Abraxane conferred significant survival benefit over gemcitabine alone in patients with metastatic PC (median overall survival 8.5 versus 6.7 months; $p<0.001$) [5]; however, data concerning SPARC as a predictive biomarker are not currently available. Although the relationship between SPARC expression and *nab*-paclitaxel responsiveness is still evolving, these proof-of-concept data warrant further exploration of SPARC as a biomarker that can potentially better select patients for *nab*-paclitaxel treatment.

34.3.1.4 Erlotinib Responsiveness

In the NCIC CTG PA.3 study, the combination of erlotinib and gemcitabine demonstrated a modest but statistically significant survival advantage over gemcitabine alone in advanced PC [24]. However, in patients with Grade ≥2 skin rash, the median survival was 10.5 months—double that of those without a rash [24]. A retrospective molecular analysis of the trial did not demonstrate either *KRAS* mutation status or *EGFR* gene copy number as predictive biomarkers of erlotinib responsiveness [25]. The NCIC study was limited because tissue was available for analysis in only 32% of the patients, and even fewer patients had available *KRAS* and *EGFR* results (26% and 15%, respectively). The proportion of *KRAS* wild-type tumors (21%) was also much higher than the 7% reported in large sequencing studies using next-generation technology [2]. It remains unclear if anti-EGFR therapy can be guided by the mutation status of *KRAS*, as it is in colon cancer, where activating mutations are associated with resistance to therapy.

34.3.1.5 HER2 Amplification

HER2 amplification has been used as a predictive biomarker of trastuzumab responsiveness in breast and gastric cancer [26,27]. Preclinical PC data support the efficacy of anti-*HER2* therapy in HER2 over expressing PC [28,29]. Activation of *HER2* also transforms *HPDE* ("normal" pancreatic cell line) with activated *KRAS* and inactivated *p16/p14* and *SMAD4*, suggesting that *HER2* may be an important oncogenic driver in PC [30]. Results from trastuzumab clinical trials have been somewhat disappointing [31,32]; however, this may be a consequence of the nonstandardized assays that were used for patient selection leading to the overestimation of *HER2* amplified patients and thus the underpowering of the studies. The reported HER2 positive rates range between 0 and 80% in the literature because of different assays and cut-points. The authors' group observed only 2% *HER2* amplification (IHC 2/3+ and FISH positive) in a cohort of 469 PC patients using standardized assays performed in a national reference laboratory [33]. We also observed that *HER2*-amplified PC may be a different clinical entity that is characterized by the lack of liver metastases and the preponderance of lung and brain metastases [33].

34.3.1.6 Individualized Molecular Pancreatic Cancer Therapy Trial

In order to test the preceding actionable molecular genotypes/phenotypes, an Individualized Molecular Pancreatic Cancer Therapy (IMPaCT) trial has been established (Australian New Zealand Clinical Trial Registry ID: ACTRN12612000777897; see Figure 34.2). IMPaCT is a phase II prospective trial that randomized patients between standard therapy and stratified treatment in a first-line

metastatic setting after screening for actionable genotypes/phenotypes.

The initial three subgroups of interest were HER2 positive (*HER2/neu*-amplified), DNA-damaging agent–responsive (germline *BRCA1/2* or *PALB2* mutations), and anti-EGFR responsive (*KRAS* wild-type or *KRAS* codon 13 mutation). This trial was designed to be "adaptive" so that additional arms can be added as emerging and novel actionable molecular genotypes/phenotypes become better defined.

34.3.2 Locally Advanced Pancreatic Cancer

About 40% of patients present with nonmetastatic PC, but are unresectable. They include (1) patients with unresectable disease due to local invasion of surrounding structures, and (2) patients with borderline resectable disease, where R0 resection (microscopic clear surgical margin) is unlikely to be achieved. Evidence to define the best treatment approach for this group of patients, who have the potential for surgical resection, is lacking. The key goals are to (1) detect and recognize occult metastatic disease so that nonbeneficial surgery and other locoregional treatment modalities (e.g., radiotherapy) can be avoided, and (2) achieve R0 resection for patients who do eventually come to surgery. To achieve these goals, it is generally believed that induction chemotherapy should precede chemoradiation to prevent systemic progression and to select for nonprogressive patients who would benefit from subsequent radiotherapy. Building on this principle, the most effective chemotherapy would ideally be selected based on the actionable molecular genotypes/phenotypes discussed; other biologically relevant biomarkers that have been associated with a metastatic phenotype may be tested to tailor locoregional therapy in a trial setting (Figure 34.1, stratification point B).

Although yet to be proven, candidates include high expression of S100A2 and CXCR4 and loss of SMAD4, both of which have been associated with poor prognosis in patients with resectable disease and a distant relapse pattern rather than local recurrence [34–36]. If patients with tumors that possess a metastatic phenotype could be correctly defined, then prior knowledge that this subgroup would not otherwise benefit from the addition of radiotherapy would be beneficial. On the contrary, exploration of more aggressive surgical options could be justified in patients with truly localized disease.

34.3.3 Resectable Pancreatic Cancer

34.3.3.1 Neoadjuvant Therapy versus Surgery Upfront

Only about 10–15% of patients have "clearly resectable" disease on imaging at presentation. However, up to 30% of patients deemed "clearly resectable" after staging, suffer recurrences within six months after resection, and up to 60% succumb to disease within the first 20 months after surgery [37,38]. The pattern of failure as suggested by autopsy studies is primarily metastatic, with fewer than 30% of patients having local recurrence only [36,39]. The goals of treatment for this group are to (1) detect and recognize, or predict, occult metastatic disease so that nonbeneficial surgery and other locoregional treatment modalities (e.g., radiotherapy) can be avoided, and (2) achieve a prolonged disease-free survival after surgical resection. In order to identify patients with occult metastatic disease leading to early post-resection failure, some favor a neoadjuvant approach. Although neoadjuvant treatment in an unselected fashion may identify early progressors, it is not without associated complications. Better selection of patients for specific neoadjuvant therapies may improve overall outcomes (Figure 34.1, stratification points C and D).

Prognosis prediction tools, such as nomograms, have been developed for many cancer types in an effort to better predict prognosis and inform treatment decisions for individual patients. The most widely used tool in resected PC is the prognostic nomogram from the Memorial Sloane-Kettering Cancer Center [40], which has been tested and validated in multiple patient cohorts [41–43]. It is superior to the AJCC staging system because it segregates patients into more homogeneous prognostic groups [43], and it can be used to predict poor post-resection prognosis due to early recurrence. However, prognostic nomograms can be used only postoperatively as they include clinico-pathological variables that become available only after pathological assessment of resected specimens, by which time patients have already undergone extensive surgery of uncertain benefit.

To circumvent this, the authors' group developed a preoperative prognostic nomogram using only variables that can be measured preoperatively [44]. These include patient age, tumor size, tumor location, and tumor expression of two biologically relevant molecular biomarkers: the S100A2 and S100A4 calcium-binding proteins. The prognostic significance of these two prometastatic S100 proteins has been tested and validated in multiple patient cohorts of resectable PC ($n > 1000$), (See Chang et al., submitted for publication) and proof-of-concept data suggest that biomarker expression can be assessed in preoperative endoscopic ultrasound, fine-needle biopsy cell block samples. Our preoperative prognostic nomogram has the potential to better select patients for neoadjuvant therapy. Systemic inflammatory measures of advanced disease have also been explored, including CRP, albumin, and tumor inflammatory cell infiltrate, which may also be used to identify patients with occult metastatic disease [45–48].

34.3.3.2 Adjuvant Chemotherapy

Various large phase III RCTs have shown adjuvant chemotherapy to be beneficial [49,50], with single-agent gemcitabine having similar efficacy to that of 5-FU in unselected patients [51,52]. Questions remaining include the following: (1) Do all patients require adjuvant chemotherapy, as the prognosis of a cancer-free patient cannot be improved with chemotherapy? (2) What is the most effective chemotherapy regimen for an individual? Extrapolating from experience in the metastatic setting, there is no reason that an actionable molecular genotype/phenotype-driven adjuvant chemotherapeutic regime selection cannot be tested. The question remains as to how we can better select patients needing adjuvant chemotherapy and/or radiotherapy. The current decision for adjuvant chemotherapy is based on fitness following surgery and not on probability of residual disease. Tools such as postoperative and preoperative prognostic nomograms, described earlier, and molecular biomarkers of a metastatic phenotype can potentially be used to better select and target patients for adjuvant treatment (Figure 34.1, stratification point E).

34.3.3.3 Adjuvant Radiotherapy

Currently adjuvant radiotherapy is used sporadically, as evidence from RCTs is mixed. This is perhaps not surprising given that the majority of patients with resected PC succumb to distant metastases often with no evidence of local recurrence, which makes studies on the efficacy of radiotherapy grossly underpowered. These assertions are further supported by evidence from a meta-analysis showing that only margin-positive patients benefit from radiotherapy in addition to adjuvant chemotherapy [53].

The authors' group have demonstrated that the degree of surgical margin clearance is important for long-term survival in a subgroup of patients; this criterion can be used to identify patients who will benefit from adjuvant radiotherapy [37,38]. Molecular biomarkers of a metastatic phenotype, discussed previously, can potentially be used to select patients who are less likely to have metastatic disease and are hence more likely to benefit from more aggressive locoregional therapy.

34.4 PRECLINICAL MODELS OF PANCREATIC CANCER

Preclinical genetically engineered mouse models (GEMM) of cancer have been invaluable in contributing to our understanding of disease pathogenesis in recent years. Based on the Hingorani et al. [54] GEMM, which expresses a mutant $Kras^{G12D}$ targeted to the pancreas using Cre-Lox technology, many other models that harbor other known and novel oncogenic drivers in PC have been generated. These models closely mimic their human counterpart and can be generated to mimic actionable molecular genotypes identified in the human disease.

The GEMMs and cell lines generated are ideal resources for assessing the efficacies of predicted therapy of the putative genotype both *in vivo* and *in vitro*. In addition, the number of patient-derived xenografts (PDX) and cell lines (PDCL) that are "-omically" characterized is growing. These models have been successfully used as mouse "avatars" of the human disease that they were derived from, which can be used to test a stratified genotype-guided approach [55,56]. These preclinical models are ideal platforms to test, define, and develop novel actionable molecular genotype/phenotype and drug combinations and may serve as a basis to guide further clinical trial design and chemotherapeutic decision making when the same actionable genotype/phenotype is seen in another patient.

34.5 CENTRAL KNOWLEDGE DATABASE

With the dramatic increase in genomic sequencing facilities and the corresponding decrease in cost, the number of cancer genomes available for analysis is exponentially increasing. To tackle the complexity and heterogeneity of the cancer genome, as well as the various therapeutic regimens either on or off clinical trials, a central database of genomic sequences and treatment responses is a potential approach. As this database builds over time, evidence for the treatment of even the rarest cancer genotype may be better defined and understood. More than 100 research organizations and healthcare providers around the world have joined together to form The Global Alliance for Genomics and Health (GA4GH) to develop such a framework [57], which may potentially be incorporated into databases that match patients' molecular genotype/phenotype to all available clinical trials.

34.6 BIOREPOSITORY AND PRIVACY ISSUES

Although beyond the scope of this review, some of the greatest challenges in genotype-driven stratified medicine are those concerning privacy and biospecimen acquisition and processing. Without adequate sample acquisition, even the simplest histopathological examination cannot be performed and is often overlooked. The other highly contentious issue in the genomic era is privacy. How should the research community and healthcare providers protect patient privacy but at the same time share enough information globally to advance medical research and discovery, and in turn provide better healthcare?

34.7 CONCLUSION

In this review, we have presented an overall concept for a stratified therapeutic approach to the management of pancreatic cancer (Figure 34.1, stratification points A–E). This will continue to be an evolving area, and will need to be tested in appropriate clinical trials. It is expected that high-throughput technologies, such as massively parallel genomic sequencing, will play a key role in the future provision of stratified medicine for cancer.

Chapter Outline

35.1 Overview 815
35.2 Pharmacokinetic Pharmacogenetics In Anesthesia 815
35.2.1 Transport Proteins 815
35.2.2 Metabolism 816
35.3 Pharmacodynamics 820
35.3.1 Defective Enzymes and Anesthesia 820
35.3.2 Abnormalities in Butyrylcholinesterase 821
35.3.3 Malignant Hyperthermia 822
35.3.4 Pharmacogenetics of Specific Drugs in Anesthesia 825
35.3.5 Inhalational Anesthetic Agents 827
35.3.6 Neuromuscular Blocking Agents 828
35.3.7 Opioids 828
35.3.8 Nonsteroidal Anti-Inflammatory Drugs 830
35.4 Conclusion 830
References 830

35.1 OVERVIEW

Rare pharmacogenetic adverse effects—for example, induced apnea, malignant hyperthermia, and thiopentone-induced acute porphyria—are well recognized. As early as the 1950s, Kalow and Gunn described how an inherited variation in drug metabolism involving the enzyme butyrylcholinesterase affects the response to succinylcholine [1]. However, expanding pharmacogenetic knowledge of variable efficacy and adverse effects related to other commonly prescribed agents (e.g., analgesics, antiemetics, beta-blockers) will have a major impact on anesthetic practice in the future [2–4]. In February 2013, for example, the FDA issued a box warning against codeine for pain relief following tonsillectomies in children. Using the database of the Adverse Events Reporting System (AERS) from 1969 to 2012, the FDA identified ten deaths and three overdoses associated with Codeine [5]

In this chapter, we describe how genetic variations have a major impact on efficacy and toxicity of drugs commonly used in anesthesia.

35.2 PHARMACOKINETIC PHARMACOGENETICS IN ANESTHESIA

Many important examples in pharmacogenetics relate to pharmacokinetic parameters associated with variable drug uptake, metabolism, or elimination (see Chapter 17).

35.2.1 Transport Proteins

Transmembrane proteins carry either endogenous compounds or xenobiotics across biological membranes. They can be classified as either efflux or uptake proteins, depending on the direction of transport. The extent of expression of genes coding for transmembrane proteins can have a profound effect on the bioavailability and pharmacokinetics of various drugs. Transmembrane proteins, particularly of the gut, liver, kidney, and blood–brain barrier, have been implicated in multidrug resistance in epilepsy and cancer chemotherapy.

There are two superfamilies of transport proteins that have important effects on the absorption, distribution, and excretion of drugs. These are the ATP-binding cassette

Handbook of Pharmacogenomics and Stratified Medicine. http://dx.doi.org/10.1016/B978-0-12-386882-4.00035-9

(ABC) and the solute-carriers (SLCs). ABC transporters are present in cellular and intracellular membranes and can be responsible for either importing or removing (efflux) substances from cells and tissues. They often transport substances against a concentration gradient using energy from the hydrolysis of ATP to drive the transport. There are at least 49 ABC transporter genes, of which ABCB1 is of importance to anesthesia. ABCB1 codes for a glycosylated membrane protein commonly referred to as P-glycoprotein (P-gp), PGY1, or multidrug resistance protein-1 (MDR1).

35.2.1.1 P-glycoprotein and Anesthesia

ABCB1/MDR1 was the first recognized and most extensively studied ABC transporter encoding a polypeptide (P-glycoprotein). P-glycoprotein (P-gp) is one of the main efflux transporters (pump) proteins and is expressed in multiple normal tissues with excretory or protective functions, including intestine, kidney, liver, blood–brain barrier, spinal cord, testes, and placenta [6,7]. The expression of ABCB1 on the apical surface of enterocytes and the canalicular part of the hepatocyte has been shown to influence intestinal drug absorption and limit oral bioavailability of a wide variety of structurally diverse drugs.

ABCB1 appears to have a superior effect on decreasing drug cellular uptake from the blood into the brain as well as from the intestinal lumen into the epithelial cells, as opposed to increasing drug elimination from hepatocytes and renal tubules into adjacent luminal spaces. ABCB1 is highly polymorphic, with more than 50 SNPs and three insertion/deletion polymorphisms reported [8–10]. There is a broad overlap in substrate specificity and tissue distribution of P-gp with cytochrome P450 3A4 (CYP3A4), as discussed later in the chapter.

This broad specificity, coupled with the tissue localization and function of both proteins, has led to the hypothesis that P-gp and P450 3A4 work in concert, protecting the body from absorption of harmful compounds by acting synergistically in the small intestine. There is considerable interindividual variability (2–8-fold) in human P-gp expression, and numerous polymorphisms and haplotypes in humans have been identified [11]. The frequencies of these SNPs in a population can vary according to racial/ethnic background and gender. For instance, hepatic P-gp levels are 2–2.4-fold lower in females than in males. Thus, females may have not only increased response but also increased toxicity.

Some opioid analgesics, such as morphine, methadone, sufentanil, and fentanyl, are substrates for P-gp. Absence or blockade of this protein can lead to an increased response to substrate drugs [12]. Clinically, simultaneous administration of P-gp inhibitors and oral morphine can increase the plasma concentration and analgesic effect of morphine. Investigation into MDR-1 polymorphisms may promote understanding of variability in the effect of drugs that are P-gp substrates [13]. Various cancers tend to display low initial P-gp, with expression increasing after chemotherapy and relapse. This may explain why these patients need higher doses of oral opioids and suffer from the side effects like constipation, nausea, and vomiting.

In their preoperative assessment of patients, anesthetists may come across many drugs that the patient may be on for various illnesses that are P-gp substrates. These include protease inhibitors, immunosuppressants, calcium channel blockers, beta-blockers, statins, steroids, antihistamines, anticonvulsants, and antidepressants. The importance of P-gp for pharmacotherapy has led to great interest in its pharmacogenomics.

35.2.2 Metabolism

35.2.2.1 Phase I Enzymes

Many phase I reactions, particularly oxidative pathways, occur in the liver because of a nonspecific mixed-function oxidase system in the endoplasmic reticulum. This is the cytochrome P450 system (CYP), named after the wavelength (in nm) of its enzymes' maximal absorption of light when the reduced state is combined with carbon monoxide. However, the cytochrome P450 system is not unique to the liver; its enzymes are also found in gut mucosa, lung, brain, and kidney. CYPs are responsible for 70–80% of phase 1 metabolism of medications [14].

CYPs are a superfamily of drug-metabolizing enzymes and are classified into families and subfamilies by their degree of shared amino acid sequences. Fifty-seven CYP genes have been identified in humans, but only a relatively small number of the encoded proteins, primarily the CYP1, CYP2, and CYP3 families, appear to contribute to drug metabolism. The clinical relevance of the inherited variations associated with CYP enzymes is dependent on many environmental factors, such as disease, drugs, surgery, nutritional status, and biological variations. The frequency of variant alleles is also significantly varied depending on race and ethnic background [15].

CYPs that share >40% amino acid sequence are grouped in a family, which is designated by a number (e.g., CYP2); those with >55% homology are grouped in a subfamily, which is designated by a letter (e.g., CYP2A). In simple terms, families and subfamilies respectively share 40% and 55% of the amino acid sequence. Subfamilies are further divided into isoforms, which are identified by a third number (e.g., CYP2A6). Allelic variants are designated by an asterisk (*) and a number following the protein identifier (e.g., CYP2A6*1). The majority of drugs are metabolized by CYPs 1, 2, and 3—mainly CYPs 2C, 2D6, and 3A. CYP2C9 and CYP2D6 both demonstrate significant genetic polymorphism; other cytochromes have variants as well, but these two are clinically important. Many drugs are metabolized by more than one isozyme (e.g., diazepam by CYP3A4 and CYP3A5) [14,16,17].

CYP2EI

CYP2E1 is responsible for the metabolism of inhalational agents and paracetamol [3,18]. Variability has not been associated with genetic polymorphism as such but rather with body mass, diet, alcohol consumption, and age.

CYP3A

The CYP3A family of CYPs is responsible for the oxidative metabolism of more than 50% of all therapeutic medications that undergo phase I metabolism. In adults this enzyme comprises CYP3A4 and CYP3A5. CYP3A4 is found in large quantities in the epithelial layer of the small intestine and in the liver (~30% of all CYPs).

CYP3A4 has the ability to metabolize a variety of drugs from many different classes: opioids, benzodiazepines, local anesthetics, immunosuppressants, calcium channel anatagonists, and aantihistamines [2,3]. This enzyme exhibits wide variability in activity and continuous unimodal distribution. Although dose adjustments are generally not needed for CYP3A4 polymorphisms, drugs metabolized through CYP3A4 are subject to inhibitors such as cimetidine, ketoconazole, and grapefruit juice. This inhibition leads to reduced CYP3A4 activity.

CYP3A5

CYP3A5 is similar to CYP3A4 and metabolizes similar substrates, but its activity is diminished. Recent findings suggest that hepatic (and intestinal) CYP3A5 expression may be much higher than what was once believed (>50% of hepatic CYP3A). Individuals expressing CYP3A5 along with 3A4 may have greater metabolism of CYP3A drugs.

CYP2D

CYP2D is another important member of the CYP family of which two isoforms, CYP2D6 and 2D9, are of importance to anesthesia. Even though it accounts for only 2–5% of all the CYPs, CYP2D6 metabolizes ~25% of phase I drug reactions. This enzyme is noted for extensive variability and for its effects on the metabolism of many anesthetic drugs. There may be as much as a 1000-fold difference in metabolism by CYP2D6 between phenotypes, which may result in adverse drug reactions in patients with a polymorphism of the CYP2D6 enzyme. The CYP2D6 enzyme is responsible for metabolism of many antiemetics (5HT-3 antagonists), beta-blockers, opioids that undergo CYP2D6-mediated O-demethylation (codeine, dihydrocodeine, tramadol, oxycodone, and hydroxycodone), antipsychotics, anti depressants (SSRIs), neuroleptics, and antiarrhythmics [2–4,19–22].

Polymorphic variation in CYP2D6 can result in patients being classified as poor (PM), intermediate (IM), extensive (EM, wild-type), and ultrarapid (UM) metabolizers. Although testing may be beneficial in anesthesia, associated adjustments in dosing and clear recommendations have not been fully developed and have not become standard practice. Patients with poor metabolism have nonfunctional or nonexistent CYP2D6 enzymes, and those with ultrarapid metabolism have overactive enzymes, requiring a modification of drug dose depending on whether the drug is activated or metabolized by the enzyme [22].

The overall frequency of PM is 7–8% in Caucasians, 2% in African Americans, and <1% in Asians. More than 20 mutant CYP2D6 alleles have been identified. Most code for inactive proteins, and homozygotes are PMs. However, some alleles that are particularly frequent in Asians code for a protein with reduced activity. Ultrarapid metabolism is caused by gene duplication, with up to 13 copies. The frequency of UMs is 20% in Ethiopians, 7% in Spanish, and 1% in Scandinavians, generally requiring substantially higher drug doses. There is even a spectrum of CYP2D6 activity in EMs owing to the diversity of 2D6 alleles [4,22–24].

The role of pharmacogenetics in interindividual variability in drug disposition and response is well illustrated by codeine, a prodrug requiring CYP2D6-mediated metabolic activation (O-demethylation) to the μ (mu) agonist morphine, and even greater bioactivation to the more potent agonist morphine-6-glucuronide. Patients who rapidly convert codeine into morphine usually have at least one wild-type CYP2D6 allele, known as CYP2D6*1. In contrast, poor codeine metabolizers tend to express combinations of the *4, *5, and *6 alleles and are virtually immune to codeine's analgesic effects [25]. Interestingly, the severity of the adverse effects of codeine does not seem to be associated with the CYP2D6 genotype, thus explaining how codeine can impair driving ability even when the driver's blood does not contain detectable morphine concentrations [26].

CYP2D9

Drugs metabolized by CYP2D9 include pheyntoin, NSAIDS, celecoxib, and warfarin. Testing is available for this enzyme, and several studies have shown that performing and evaluating CYP2D9 genotyping can be helpful in providing safe, more personalized warfarin treatment and in reaching therapeutic levels sooner, at the same time reducing potentially life-threatening side effects [2,27].

CYP2C

The CYP2C gene family consists of CYPs 2C8, 2C9, 2C18, and 2C19, which together account for ~25% of total hepatic CYP and metabolize 15–20% of all therapeutic drugs. CYP2C9 is the major 2C isoform in human liver. The best known CYP2C9 substrates are (S)-warfarin, phenytoin, tolbutamide, diclofenac, and several NSAIDs [3,20,28,29]. Several variant 2C9 proteins with substantially decreased activity (as low as 20%) have been identified. These mutant alleles occur more commonly in Caucasians (10–20%) than in Asians and African Americans (<5%). Warfarin is an excellent example of pharmacogenetics and its application in modern therapeutics. Patients with CYP2C9 variants have higher warfarin plasma concentrations and are more susceptible to over-anticoagulation, serious or life-threatening bleeding complications, and longer hospitalizations [27].

CYP2C19

CYP2C19 is a minor CYP, but it has been well studied. Its substrates include barbiturates, diazepam, phenytoin, amitryptyline, and proton pump inhibitors. Individuals are classified as EM or PM, with a PM frequency of 2–5% in Caucasians, 2% in African Americans, 18–23% in Japanese, and 15–17% in Chinese. The CYP2C19 polymorphism is important in the disposition and clinical effect of diazepam, particularly in PM homozygotes. PM diazepam clearance is half that in EMs, with dose requirements correspondingly less; heterozygotes are IMs, which is thought to account for lower diazepam dose requirements in Chinese patients [17].

35.2.2.2 Modified Drug Metabolism

The hepatic CYP system is particularly subject to enzyme induction. In other words, exposure to environmental substances or drugs can increase expression of the gene coding for the enzyme and thus the amount of the enzyme present. This is one of the most important mechanisms of drug interaction.

Induction may be of one or several of the CYP subtypes, and it may increase metabolism of the inducing substance or of another drug, thus increasing its excretion and reducing its effect. There are several examples of the relevance of induction to anesthetic practice. The toxicity of pethidine may be enhanced by barbiturates, increasing its metabolism to the toxic metabolite norpethidine. Monoamine oxidase inhibition (MAO-I) and alanine (Ala) synthase induction in porphyria are other examples.

Inhibition of metabolism may also occur that may be due to inhibition of enzymes or, more commonly, to competition between drugs for the same metabolic pathway. With most drugs that are eliminated by processes obeying first-order kinetics, competition rarely causes significant metabolism inhibition, but competition is more important in drugs eliminated by zero-order kinetics, where the enzyme system is easily saturated. For example, omeprazole can inhibit the metabolism of drugs metabolized mainly by the cytochrome P-450 enzyme subfamily 2C (diazepam, phenytoin), but not that of drugs metabolized by subfamilies 1A (caffeine, theophylline), 2D (metoprolol, propranolol), and 3A (ciclosporin, lidocaine (lignocaine), quinidine). Since relatively few drugs are metabolized mainly by the 2C compared with the 2D and 3A families, the potential for omeprazole to interfere with the metabolism of other drugs appears to be limited, but the half-life of diazepam and phenytoin is prolonged as much as by cimetidine [30,31].

35.2.2.3 Non-CYP Enzymes

The CYP system is not responsible for all of phase I metabolism. Many non-CYP enzymes are involved in the metabolism of drugs used in anesthesia.

Catechol-O-methyltransferase

The monoamines (adrenaline, noradrenaline, dopamine) are metabolized by the mitochondrial enzyme monoamine oxidase. Individual genetic variation, or the presence of exogenous inhibitors of this breakdown pathway, can result in high levels of monoamines in the circulation, causing severe cardiovascular effects. Catechol-O-methyltransferase (COMT) regulates the metabolism of catecholamines such as norepinephrine, epinephrine, and dopamine; thus, mutations in the COMT gene can effect the perception of pain. Reduced COMT activity leads to higher levels of catecholamine neurotransmitters and increased pain sensitivity in animal models of pain [32]. A common human polymorphism in the COMT gene, p.V158M (Val158Met), leads to a 3–4-fold variation in COMT activity, with p.158MM homozygous individuals demonstrating the lowest activity and subsequent reduced activation of the endogenous opioid system and compensatory up-regulation of opioid receptor expression [33]. Although low COMT activity is associated with increased pain sensitivity in some patients, clinical studies of COMT polymorphisms suggest that these individuals require smaller opioid doses, possibly because of up-regulation of opioid receptors. Among the cancer population, carriers of the COMT, p.158VV, and p.158VM genotype have been shown to require 63% and 23% higher doses of morphine compared with carriers of the p.158MM genotype. In the postoperative pain setting, Kim and colleagues failed to show a significant association between COMT polymorphisms and pain response, although a low frequency of some polymorphisms and lack of statistical power may have contributed to this result [34].

Carboxylesterases

Carboxylesterases (CESs) have a wide tissue distribution and are found in the greatest amounts in the liver and in the gastrointestinal tract, brain, and possibly blood. CESs belongs to the class of serine hydrolases that include acetylcholinesterase, which is primarily found in the blood and neural synapses. They are categorized as phase I drug-metabolizing enzymes that can hydrolyze a variety of ester-containing drugs and prodrugs, such as angiotensin-converting enzyme inhibitors (ACE-I) and opioids (cocaine, heroin, and pethidine). It is thought that CESs are one of the major determinants for pharmacokinetics and pharmacodynamics of ester drugs or ester prodrugs. There are numerous polymorphisms in the gene, but none result in altered enzyme activity [35].

Butyrylcholinesterase

A major human cholinesterase, butyrylcholinesterase (also known as pseudocholinesterase, plasma cholinesterase, serum cholinesterase, and nonspecific cholinesterase), is found in plasma as well as liver and other tissues. Plasma cholinesterase was one of the early enzymes for which pharmacogenetic variation was elucidated based on observed heritable variability in response to succinylcholine. (discussed in detail later in the chapter). The level and quality of butyrylcholinesterase (BChE) in a patient determines the duration of action of succinylcholine and mivacurium. Inherited deficiency or reduced efficacy of plasma cholinesterase results in prolonged muscle relaxation after succinylcholine [36]. This was the first documented example of inherited variation in anesthetic drug effect [1,37–40]. Plasma cholinesterase also metabolizes the three ester local anesthetics: cocaine, procaine, and chloroprocaine. Heroin undergoes extensive deacetylation in blood to 6-monoacetylmorphine and then to morphine. The former reaction is catalyzed rapidly by plasma cholinesterase and more slowly by erythrocyte AchE, although the latter reaction accounts for most hydrolysis *in vivo* and only erythrocyte AchE can convert 6-monoacetylmorphine to morphine [1,41].

Like succinylcholine, esmolol and remifentanil also undergo extensive metabolic inactivation in blood; their metabolism is catalyzed exclusively by erythrocyte AchE. Plasma cholinesterase, which catalyzes succinylcholine, has no role to play; thus, neither remifentanil nor esmolol elimination is altered by pseudocholinesterase deficiency [13].

35.2.2.4 Phase II Enzymes

Phase II reactions are conjugation reactions in which the drug or its metabolite is attached to a water-soluble molecule or group, such as glucuronic acid, glutathione, sulfate, acetyl group, methyl group, or glucosamine, making the whole complex more hydrophilic for excretion via the renal system. The role of phase II enzyme polymorphisms in the metabolism of anesthetic drugs is largely unknown, but some of the important drugs administered to patients in the perioperative period by anesthetists undergo phase II reactions.

N-acetylransferases

N-acetyltransferases (NAT1 and NAT2) are key enzymes in the conjugation (phase II reaction) of certain drugs and other xenobiotics with an arylamine structure [42]. These enzymes have historical significance as they were the first drug-metabolizing enzymes for which genetic polymorphisms were discovered (fast and slow acetylators for isoniazid). Slow acetylators show a greater therapeutic response than fast acetylators to several drugs (e.g., isoniazid, hydralazine, dapsone) and may also be more susceptible to the side effects mediated by acetylated metabolites, such as isoniazid hepatotoxicity and lupus-like syndrome after hydralazine or procainamide. Fast acetylators, on the other hand, may not reach therapeutic levels with treatment and require greater doses [43].

Polymorphisms in NAT2 have long been recognized to modulate toxicity produced by the antitubercular drug isoniazid, with molecular epidemiologic studies suggesting a link between the acetylator phenotype and increased risk for bladder cancer. Polymorphisms in the NAT2 gene are responsible for the N-acetylation polymorphism that divides human populations into rapid, intermediate, and slow acetylator phenotypes. Multiple NAT2 alleles (NAT2*5, *6, *7, and *14) have substantially decreased acetylation activity and are common in Caucasians and populations of African descent. Polymorphisms in NAT1 are generally associated with relatively minor effects on acetylation function and less interindividual variability than seen with NAT2 polymorphisms [44,45].

UDP-glucuronosyltransferases and Glutathione S-Transferases

UDP-glucuronosyltransferases (UGTs) and glutathione S-transferases (GSTs) are present predominantly in the gastrointestinal tract, especially in the liver; however, they have also been distinguished in extrahepatic tissues, including skin, kidney, intestine, and many other organs. UGTs and GSTs are important families of detoxification enzymes. UGTs catalyze the conjugation of a wide variety of exogenous compounds (e.g., drugs, pesticides, components of tobacco smoke) and endogenous compounds (e.g., bilirubin, bile acids, steroid hormones) to glucuronic acid, while GSTs catalyze the reaction of glutathione with exogenous electrophiles (e.g., polycyclic aromatic hydrocarbons, heterocyclic amines) and endogenous products of oxidative stress. The metabolites formed by these reactions are generally less toxic and more water-soluble, which facilitates their biliary and renal excretion. Polymorphic variations in these detoxification enzymes may influence the rates of conversion of toxic or carcinogenic compounds [46,47].

In humans, UGT have been mainly classified into two families: UGT1A and UGT2. So far, nine functional UGT1A isoenzymes (UGT1A1, UGT1A3–UGT1A10) have been characterized, all deriving from a single gene locus on chromosome 2. UGT1A enzymes are involved mainly in the metabolism of exogenous compounds; although this is not strictly the case, as bilirubin and steroid hormones are important endogenous substrates. UGT2 isoenzymes 2A1, 2B4, 2B7, 2B10, 2B11, 2B15, and 2B17 are involved mainly in the glucuronidation of endogenous compounds. Several functional polymorphisms in the UGT1A family of isoenzymes have been identified. In Caucasians, polymorphisms in this family result in significantly reduced hepatic bilirubin UGT enzyme activity, leading to a mild form of hyperbilirubinemia known as Gilbert's syndrome [48,49].

Glucuronidation is an important pathway for certain drugs used in anesthesia. Propofol is mainly eliminated via glucuronidation by human UGT1A9. Many opioids such as morphine, codeine, naloxone, nalorphine, buprenorphine, oxymorphone, and hydromorphone undergo glucuronidation by UGT2B7. Glucuronidation of morphine to morphine 6-glucuronide (M6G) is important since this metabolite is more potent than its parent drug. The finding that UGT2B7 is also present in human brain suggests that in situ formation of M6G may play an important role in analgesia [50]. Midazolam is metabolized to 1-hydroxymidazolam by glucuronidation and is pharmacologically active. It is excreted renally and may be responsible for the prolonged effects of midazolam in patients with renal insufficiency when used for ITU sedation [3].

In humans, the GST family comprises four main classes (alpha, mu, pi, theta), whose genes are mapped on different chromosomes. These enzymes catalyze the reaction of the tripeptide glutathione with a diverse array of drugs and toxins, and they are primarily a defensive system for detoxification. There is considerable polymorphism in GST expression; however, this enzyme is of little relevance to anesthesia (except in the metabolism of the sevoflurane degradation product “compound A” [3,49].

35.3 PHARMACODYNAMICS

Pharmacodynamic polymorphisms are generally attributable to variants in cell-surface receptors or intracellular signaling pathways Compared with genetic influences on drug disposition, less information is currently available about genetic influences on pharmacodynamics. There are, however, several notable examples. Malignant hyperthermia is due to polymorphism in the skeletal-muscle calcium release channel (ryanodine receptor) gene.

Anesthetists are well aware of the interindividual variability of response to morphine, and it is of considerable interest that this may be due to opioid receptor polymorphisms in a certain group of patients [50]. Among the numerous candidate genes that have been considered important in opioid response, the μ-opioid receptor gene (OPRM1, p.118A/G), the catechol-O-methyltransferase gene (COMT, Val158Met), several variants of the ATP-binding cassette, subfamily B member 1 gene (ABCB1), and the CYP family of enzymes have been extensively reviewed.

The level of evidence linking gene variation to morphine response is moderate. In patients with the A118G μ opioid receptor polymorphism, some but not all studies show decreased A118G μ receptor affinity for ß-endorphin and morphine. Some have shown a 2–3-fold decrease in the potency of morphine and morphine-6-glucuronide, while others have shown no difference. Some have shown a 1.5–2-fold increase in postoperative morphine PCA requirements in A118G homozygotes (but not heterozygotes), while others suggest no major difference [32,33,51–55].

In the past decade, the use of β-blockers has become a standard of care in at-risk patients, with the goal of improving perioperative outcomes. However, despite numerous *in vitro* studies that have extensively defined the biological effects of the multiple genetic variants of the β1-adrenergic receptor gene (ADRB1) and the β2-adrenergic receptor gene (ADRB2), the clinical relevance of most of the numerous pharmacogenetic results for β-blockers is still inconclusive [2,56].

Several nonsynonymous polymorphisms in adrenergic receptors have been identified, although their functional significance awaits full determination. Some ß-adrenergic receptor polymorphisms have been implicated in the response to asthma therapy, and it is speculated that they are involved in the response to drugs used for hypertension and congestive heart failure [2].

35.3.1 Defective Enzymes and Anesthesia

A different type of problem arises when there are genetically determined defects in enzyme activity, as in porphyria, or defects at the receptor or intracellular level as in malignant hyperpyrexia. A detailed description of these conditions can be found in any standard anesthesia textbook or in review articles.

35.3.1.1 Porphyria

Porphyria comprises a group of metabolic disorders resulting from partial enzyme deficiency in the haem-biosynthesis pathway that are characterized by acute neurovisceral symptoms, skin lesions, or both. Acute porphyrias (acute intermittent porphyria, variegate porphyria, or hereditary coproporphyria) can be precipitated by drugs used in anesthesia and present with acute attacks, typically consisting of severe abdominal pain, nausea, constipation, confusion, and seizure. They can be life-threatening [57].

The control of haem production is tightly regulated through feedback inhibition of ALA synthesis so that the levels of haem closely match demand. The implications of this for the anesthetist is that the disease may be dormant until periods of stress occur, caused by surgery and illness or by the administration of drugs, in particular barbiturates (thiopentone). Acute intermittent porphyria (AIP) is caused by a deficiency in porphobilinogen PBG deaminase. It is an autosomal dominant disease with the gene loci on chromosome 11. AIP is of primary importance to the anesthetist because it is the porphyria in which an acute attack is most likely to prove fatal. Variegate porphyria is due to a deficiency in protopophyrinogen oxidase. The gene for this enzyme is found on chromosome 1. The genes encoding the deficient enzymes in hereditary and plumboporphyria are both situated on chromosome 9 [57,58].

Anesthetic Drugs and Porphyria

Barbiturates are the classic example of drugs that are dangerous in patients with porphyria. Propofol is the best choice at present for intravenous induction, although there is some doubt about its use as an infusion. From long use, halothane has proven safe, and isoflurane is probably so; enflurane should be avoided, and information on sevoflurane and desflurane is insufficient. Opioids, such as morphine and fentanyl, are safe, whereas there is not sufficient data on some other analgesics to be sure of their position. All muscle relaxants are probably safe, although, again, there are not enough data about most to be completely sure; on the other hand, atropine and neostigmine are known to be safe. Drugs that are unsafe or probably so include barbiturates, etomidate, enflurane, alcuronium, mepivacaine, pentazocine, some benzodiazepines (temazepam is safe; others are less certain), calcium channel blockers, and aminophylline [59,60].

In the event of an acute crisis, it is vital to assess muscle strength and bulbar function because severe disease may cause respiratory failure and risk of aspiration. Postoperative ventilation may be necessary. All possible precipitants must be withdrawn and adequate hydration must be ensured. Haematin is the only specific treatment that probably has an effect by supplementing the free haem pool and suppressing ALA synthetase. However, it may cause renal failure, coagulopathy, and thrombophlebitis. Haem arginate is a suitable alternative that is devoid of the side effects associated with haematin [61]. β-blockers have a dual role, both in controlling tachycardia and in decreasing ALA synthase activity. In the ICU setting, it is recommended that high carbohydrate intake be instituted because carbohydrate loading can suppress porphyrin synthesis [62].

Diagnosis is essential to enable specific treatments to be started as soon as possible. Screening of families to identify presymptomatic carriers is crucial to decrease the risk of overt acute porphyrias through counseling on avoidance of potential precipitants [62].

35.3.2 Abnormalities in Butyrylcholinesterase

Succinylcholine-induced neuromuscular blockade can be significantly prolonged if the patient has an abnormal genetic variant of butyrylcholinesterase (BChe). Kalow and Genest found this variant to respond to dibucaine differently from how normal butyrylcholinesterase responds. Dibucaine inhibits normal butyrylcholinesterase to a far greater extent than it inhibits the abnormal enzyme. This observation led to development of the test for dibucaine number [38]. The prevalence of BChE deficiency is highest in the Caucasian population, with 3.4–4% displaying a partial enzyme deficiency leading to slightly prolonged apnea (between 5 minutes and 1 hour) and 1 in 2500 individuals showing a prolongation of more than 1 hour. Individuals with undetectable levels of BChE activity display a severe prolongation lasting more than 8 hours. The prevalence of this severe form is estimated at 1 in 100,000 individuals [37,63].

The molecular biology of butyrylcholinesterase is well understood. Heterozygous (single-allele) expression is responsible for all plasma cholinesterase variants. The plasma cholinesterase gene lies on the long (q) arm of chromosome 3. The amino acid sequence of the enzyme is known, and the coding errors responsible for most genetic variations have been identified (more than 50 mutations). Most variants are due to a single amino acid substitution error or sequencing error at or near the active site of the enzyme [40].

35.3.2.1 Quantitative Variants

The K variant is caused by a point mutation resulting in the substitution of alanine by threonine at position 539 in the amino acid sequence of the subunit. It is the most common clinically significant BChE variant. It was recently shown that patients with a K variant have a significantly prolonged duration of mivacurium action—30–40% if they are of the U/K genotype. The J variant is associated with a 33% reduced BChE concentration.

35.3.2.2 Qualitative Variants

The A variant is a result of a point mutation resulting in aspartamine being substituted by glycine at position 70. Patients who are homozygous for the A variant are very sensitive to mivacurium and suxamethoium, and an extremely long duration of action has been reported after 0.12–0.2 mg/kg—the time for full spontaneous recovery of neuromuscular function is 6–8 hours compared to 30 minutes in patients with normal BChE. In the case of suxamethonium, the effect may persist for more than 2 hours. The F allele has reduced activity *in vivo* and demonstrates fluoride inhibition.

The S variant results from a stop codon. It occurs because of multiple mutations and has no activity. Neuromuscular blockade may last for several hours in the homozygote.

Butyrylcholinesterase activity is expressed as dibucaine number. The activity of atypical cholinesterase is decreased by 70%. Homozygotes are very sensitive to succinylcholine, and the frequency of this variant is about 2%. A small number of patients (0.3%), however, express a fluoride-resistant enzyme whose activity is decreased by 60% and who are moderately sensitive to succinylcholine. Patients with the silent variant (0.03%) have no enzyme activity. Succinylcholine hydrolysis is rapid (90% within one minute) and robust (70% reduction in enzyme activity only moderately prolongs neuromuscular blockade) [37,38,40,63]. (See Figure 35.1.)

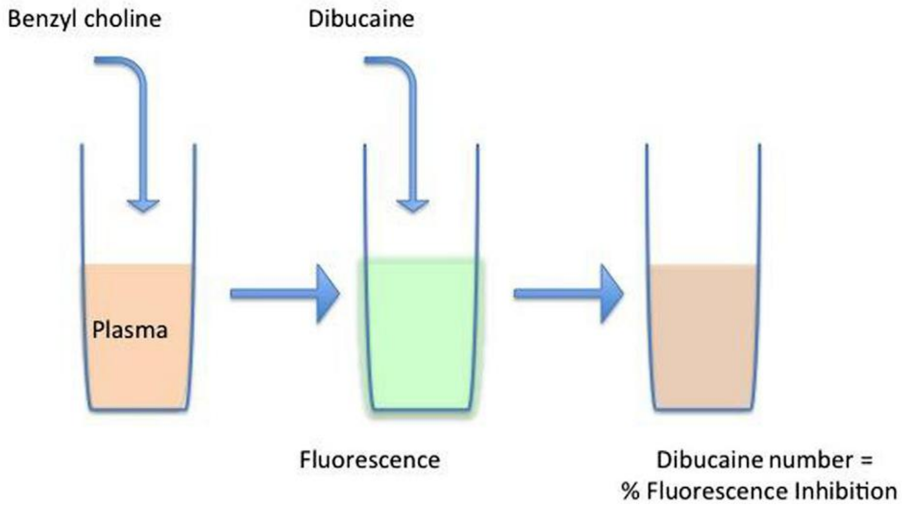

FIGURE 35.1 Dibucaine inhibits normal butyrylcholinesterase to a far greater extent than it inhibits the abnormal enzyme. Under standardized test conditions, dibucaine inhibits expression of the normal enzyme by about 80%; the abnormal enzyme, by about 20%.

Mivacurium is also hydrolyzed by plasma cholinesterase, at a rate 70–90% of succinylcholine hydrolysis. Patients with cholinesterase variants respond similarly to mivacurium and succinylcholine. Recovery of neuromuscular function can be prolonged up to 60-fold in atypical cholinesterase homozygotes [41].

Although the dibucaine number indicates an individual's genetic makeup with respect to butyrylcholinesterase, it does not measure the concentration of the enzyme in plasma nor does it indicate the efficiency of the enzyme in hydrolyzing a substrate such as succinylcholine or mivacurium. Both of the latter factors are determined by measuring butyrylcholinesterase activity, which may be influenced by genotype. DNA analysis, although not carried out routinely, can be used to identify heterozygous carriers of atypical alleles [41].

35.3.3 Malignant Hyperthermia

Malignant hyperthermia (MH) was one of the earliest potentially fatal pharmacogenetic disorders and was first described in the 1960s. The major intracellular store of calcium (Ca^{2+}) is the sarcoplasmic reticulum (SR). The T-tubule membranes are invaginations of sarcolemma and represent approximately 80% of the plasma membrane of a skeletal muscle fiber. On excitation, the action potential generated at the neuromuscular junction spreads over the muscle fiber membrane and propagates into the interior through the T tubules. T-tubule depolarization permits the release of Ca^{2+} from the SR, which is in close association with the T tubules. T tubule–mediated SR calcium release results in what is known as excitation–contraction (EC) coupling of skeletal muscle. Thus, T-tubule membranes represent an essential element in the EC-coupling process.

EC coupling is the process by which muscle fiber depolarization initiates contraction. The action potential is transmitted to all fibrils in the fiber via the T system. It triggers the release of Ca^{2+} from the terminal cisterns—the lateral sacs of the SR next to the T system. Depolarization of the T-tubule membrane activates the sarcoplasmic reticulum via dihydropyridine receptors (DHPRs), named for the drug dihydropyridine, which blocks them. DHPRs are voltage-gated Ca^{2+} channels in the T-tubule membrane. In cardiac muscle, influx of Ca^{2+} via these channels triggers the release of Ca^{2+} stored in the SR (calcium-induced calcium release) by activating the ryanodine receptor (RyR).

The RyR is named after the plant alkaloid ryanodine, which was used in its discovery. It is a ligand-gated Ca^{2+} channel with Ca^{2+} as its natural ligand. In skeletal muscle, Ca^{2+} entry from the extracellular fluid (ECF) by this route is not required for Ca^{2+} release. Instead, the DHPR that serves as the voltage sensor allows the release of Ca^{2+} from the nearby SR via physical interaction with the RyR. The released Ca^{2+} is quickly amplified through calcium-induced calcium release. Ca^{2+} is reduced in the muscle cell by the sarcoplasmic or endoplasmic reticulum Ca^{2+} ATPase (SERCA) pump.

The SERCA pump uses energy from ATP hydrolysis to remove Ca^{2+} from the cytosol back into the terminal cisterns, where it is stored until released by the next action potential. Once the Ca^{2+} concentration outside the reticulum has been lowered sufficiently, chemical interaction between myosin and actin ceases and the muscle relaxes. Note that ATP provides the energy for both contraction (at the myosin head) and relaxation (via SERCA). If Ca^{2+} transport into the reticulum is inhibited, relaxation does not occur, even though there are no more action potentials; the resulting sustained contraction is called a contracture [64]. (See Figure 35.2.)

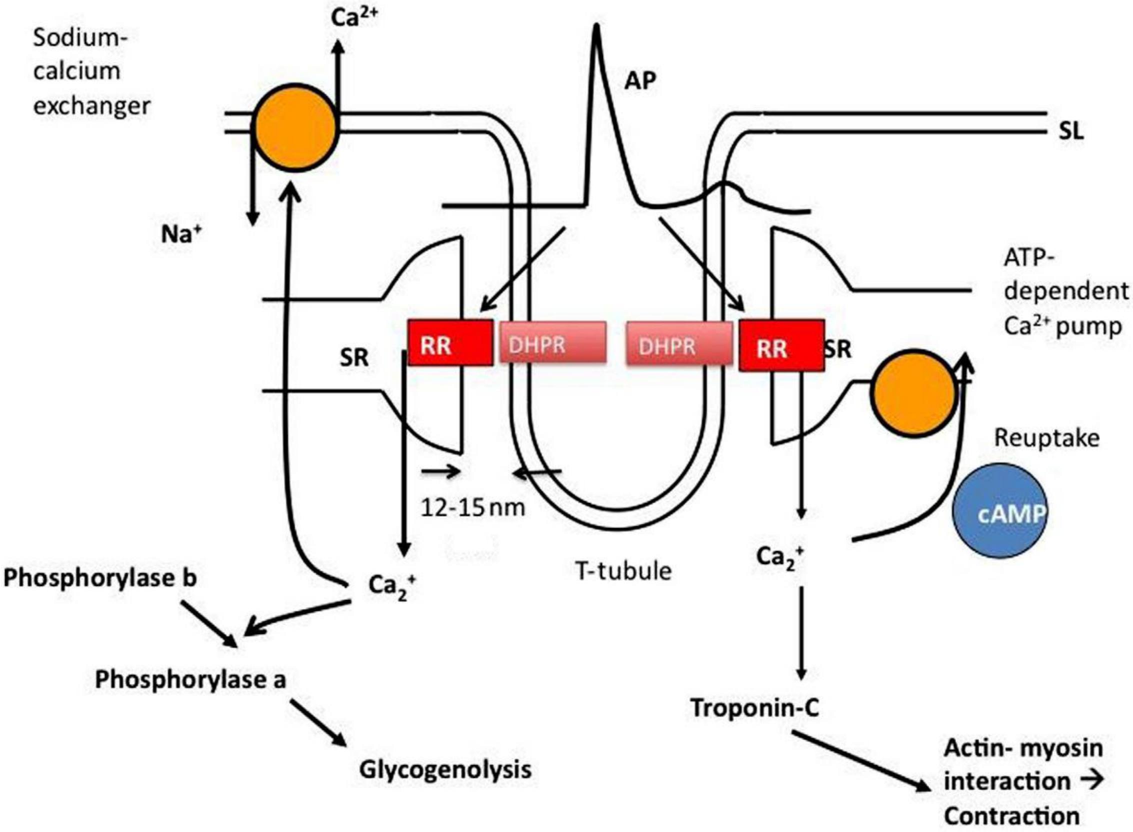

FIGURE 35.2 Calcium is released directly from the sarcoplasmic reticulum (SR) by the action potential (AP), through the ryanodine receptor (RR). Increased intracellular Ca^{2+} removes inhibition of the contractile elements by troponin, and the muscle contracts. The sodium–calcium exchanger on the sarcolemma (SL) and the cyclic AMP AMP– (cAMP-) regulated pump on the SR remove calcium from the myofibril, terminating contraction. Ca^{2+} simultaneously activates glycogenolysis to provide energy for contraction. The T tubules contain the highest concentration of dihydropyridine binding sites in the body. The dihydropyridine receptors (DHPRs) of skeletal muscle do not function as Ca^{2+} channels, but instead act as voltage sensors, transducing the sarcolemmal action potential into the release of Ca^{2+} from the SR.

MH has been described in patients of all racial groups. The majority of MH reactions occur in children and young adults, with a 2:1 male preponderance. In the United Kingdom, the MH Investigation Unit estimated that an MH reaction occurs with 1 in 20,000 to 1 in 80,000 anesthetics, depending on patient age. However, this may be a conservative estimate, as Ording reported that MH reactions occur in 1 in 15,000 anesthetics in Denmark [65]. The European MH group consensus estimate for the prevalence of genetic susceptibility to MH is about 1 in 10,000 [66].

The recognized modes of inheritance for MH susceptibility are autosomal dominant with reduced penetrance and variable expression, autosomal recessive, or multifactorial and unclassified. Reduced penetrance means that fewer offspring are affected than would be predicted by a perfectly dominant pattern. Variable expression refers to a difference of susceptibility between families with little variation within the same family. The gene for MH is located on human chromosome 19, which is also the genetic coding site for the calcium release channels of skeletal muscle SR (ryanodine receptor RyR1 locus). It is presumed that a defect in the calcium release channels results in MH susceptibility. The presence of RyR1 mutation in patients does not always relate to a positive *in vitro* contracture in response to halothane. MH in humans is not a single disease but a syndrome with multiple sites of causation and multiple mutations at them [64,67].

Even the presentation of MH is not the same in all patients. Some 30% of MH patients have had up to three uneventful anesthetics. A spectrum can occur from minor reactions to rapid temperature increase, muscle rigidity, acidosis, arrhythmias, and death. Some reactions have greater latency to onset and may not manifest until the postoperative period. MH may not always occur in response to triggering agents. Thus, there may be different genes causing MH in different families, or there may be other predisposing factors that are expressed differently in patients or families. MH may be described as a heterogeneous genetic disorder with a highly variable clinical presentation. There are no MH-specific clinical features, and the diagnosis depends on knowledge of features that can occur during an episode. MH is characterized by signs and symptoms of hypermetabolism (up to 10 times normal).

The earliest signs of MH are related to enormous increases in the patient's metabolic rate, reflecting the ability of triggering drugs to cause an imbalance in calcium homeostasis in skeletal muscle cells. In some patients, metabolic stimulation is evident clinically within 10 minutes of administration of volatile anesthetics, whereas in others several hours may elapse. Hypermetabolism leads to increased carbon dioxide production with associated tachypnea. In addition, lactic acidosis develops, and the presence of mixed respiratory and metabolic acidosis stimulates sympathetic nervous system activity with associated tachycardia. Increased carbon dioxide production occurs early, emphasizing the value of continuous capnography. Temperature rise may be a late sign, but core temperature may increase as early as 15 minutes after exposure to a triggering agent. Cardiac dysrhythmias, such as ventricular bigeminy, multifocal ventricular premature beats, and ventricular tachycardia, may also occur, especially with hyperkalemia resulting from rhabdomyolysis and sympathetic nervous system stimulation. Other complications are hemolysis, myoglobinuria, rhabdomyolysis, and renal failure [64,66,68].

Successful treatment of MH depends on early diagnosis and a preplanned therapeutic regimen. Treatment can be categorized as causal or symptomatic. Causal treatment is directed at correcting the underlying causative mechanisms. Symptomatic treatment is directed toward maintaining renal function and correcting hyperthermia, acidosis, and arterial hypoxemia.

Once MH is recognized it is imperative to act quickly: (1) discontinue the inhalational agent, (2) hyperventilate with 100% oxygen and administer dantrolene, (3) cool the patient and treat symptoms. Dantrolene, administered intravenously, is the only drug that is reliably effective in treating MH. It decreases the release of calcium from the SR, restoring the balance between release and reuptake. Active cooling may entail surface cooling and intracavitary lavage of the stomach and bladder using cold saline solutions infused through peripheral intravenous catheters; they should also be cooled. Cooling is discontinued when body temperature decreases to 38°C.

Other symptomatic therapy includes intravenous administration of sodium bicarbonate to correct metabolic acidosis and hyperkalemia, hydration with saline, and maintenance of urine output using osmotic or tubular diuretics. Intravenous administration of glucose-insulin helps drive potassium intracellularly and provides an exogenous energy source with which to replace depleted cerebral metabolic substrates [64,66,68].

More than 100 variants of RyR1 have been reported, although the RyR1 gene mutation on chromosome 19 is predominant. Of variants that are predicted to lead to an amino acid chain in the ryanodine receptor protein, 50 have been detected in UK MH families. More than 20 mutations have been functionally characterized in experimental systems—an essential step in identifying a mutation as potentially MH causative. These functional mutations have the potential to be used in diagnosis. However, in a minority of families (approximately 10–20%), no RyR1 defect can be found, even after coding the entire sequence of the gene [64,69].

Genetic linkage studies have implicated five other chromosomal candidate loci, but a mutation has been found in only one of them (the alpha-1 subunit of the dihydropyridine receptor), and in this case only two mutations in two different families have been reported worldwide [70,71]. The likelihood that defects in other genes contribute to MH susceptibility is high [72]. The inability to find an RyR1 mutation does not exclude the possibility of MH even when a mutation found in other members of the family is not present. An individual who does not have the familial mutation, however, has an approximately 5% chance of actually being susceptible to MH; his or her status must therefore be confirmed by *in vitro* contracture testing before being administered MH-triggering drugs [66–68,73,74].

Determining MH linkage with other diseases has been problematic—only central core disease appears to be truly linked, and most families with central core disease have a mutation at the RyR1 locus [74]. Other syndromes associated with multicore myopathy are Evan's myopathy and the King-Denborough syndrome/phenotype. In Duchenne's muscular dystrophy, the balance of opinion has shifted from an association with MH to an one with anesthesia-induced rhabdomyolysis.

The contracture halothane caffeine test is the most common method of diagnosing MH. This test requires muscle biopsy and measures contracture in response to caffeine and halothane. The test is very sensitive, meaning that most patients with a risk of and susceptibility to MH will be identified. Problems with it include the requirement for a fresh sample at the testing site, the invasiveness and expense of the test, and limited biopsy centers. MH centers offer patients (and their families) genetic testing if they have a positive result from the caffeine halothane contracture test; the centers screen for the 17 most common RyR1 mutations. Although the test is very specific, only about 25% of individuals at risk for MH are detected because of the multiple areas of MH mutation [66,68,75].

Mortality from MH has decreased from 80% thirty years ago to less than 5% today. In the future, DNA testing will replace the *in vitro* contracture test for high-risk individuals. When DNA testing achieves 100% sensitivity and specificity, it will be suitable for population screening, but this requires that all gene defects contributing to MH susceptibility be identified [4,64,76,77].

35.3.4 Pharmacogenetics of Specific Drugs in Anesthesia

The following subsections focus on drugs directly related to the administration of anesthesia related to anxiolysis, analgesia, and muscle relaxation, which are integral to anesthesia administration (See Tables 35.1–35.3). Other drugs that the anesthetist may come across are discussed elsewhere in this book.

35.3.4.1 Benzodiazepines

Benzodiazepeines (BDZs) are commonly used preoperatively as anxiolytic agents for control of seizures. Their administration is concomitant with induction of anesthesia agents. Most benzodiazepines are metabolized by hepatic cytochrome P450 enzymes to more polar metabolites and are excreted in bile and urine. The relative antianxiety potencies of the different BDZs correlate with their relative potencies as agonists at the BDZ receptor. The resultant inhibitory effects in the brain are responsible for BDZs' anti-anxiety, sedative, and anticonvulsant effects. The inhibition of the spinal pathways results in skeletal muscle relaxation. The therapeutic use of particular BDZs is as much related to their potency and solubility as to their inherent pharmacokinetic differences. Given orally at normal therapeutic doses, they have little effect on cardiovascular, respiratory, or autonomic function. Respiratory depression and reduced systolic blood pressure may occur, but these are seen principally with intravenous administration or overdose.

Temazepam, midazolam, and diazepam are the preferred drugs for preoperative anxiolysis because they are rapidly absorbed by the oral route and short-acting after single doses. The choice of drug varies according to local practice and to the availability of oral preparations. Lorazepam is also used for preoperative anxiolysis, particularly when it is desirable to dampen sympathetic outputs before major cardiac surgery. In these circumstances, lorazepam may be given the evening before the operation as well as in the morning.

TABLE 35.1 Major CYP Enzymes and their Substrates in Anesthetic Practice

CYP2B6	CYP2C9	CYP2C19	CYP2D6	CYP2E1	CYP3A4	CYP3A5
Propofol	Propofol	Diazepam	Codeine	Sevoflurane	Diazepam	Diazepam
	Parecoxib	Barbiturates		Halothane	Midazolam	
		Omeparzole		Isoflurane	Temazepam	
		Pantoprazole		Paracetamol	Fenatanyl	
					Alfentanil	
					Lignocaine	
					Vecuronium

TABLE 35.2 Abnormalities of Butyrylcholinesterases

Patient	Genotype	Incidence	Dibucaine number	Block Duration with Mivacurium and Suxamethonium
Homozygous typical	E1u: E1u	96%	>70	No change
Heterozygous atypical	E1u: E1a	1:500	40–70	20–30 minutes
Homozygous atypical	E1a: E1a	1:3200	<20	4–8 hours
Homozygous fluoride-resistant	E1f: E1f	1:32,000	70–80	1 hour
Homozygous silent	E1s: E1s	1:100,000	-	>6 hours

Source: Data from Jensen et al. [37], Staron [39], and Kalow [40].

TABLE 35.3 Example Genotypes Linked to Individual Differences in Metabolism, Efficacy, and Side Effects of Commonly Used Anesthetic Agents

Drug	Gene	Effects
Volatile anesthetics		
Halothane, other inhalational anesthetics	CYP2E1	Hepatitis
Halothane, isoflurane	RyR1	Malignant hyperthermia syndrome
Muscle relaxants		
Succinylcholine, mivacurium	Plasma butyrylcholinesterase	Prolonged muscle relaxation
Succinylcholine	RyR1	Malignant hyperthermia syndrome
Benzodiazepines		
Diazepam	CYP2C19	Increased half-life, prolonged sedation, greater likelihood of unconsciousness
Midazolam	CYP3A4	Reduced clearance of systemic (but not oral) midazolam
Midazolam	CYP3A5	Reduced clearance of systemic (but not oral) Midazolam
Opioids		
Morphine, morphine-6-glucuronide	μ opioid receptor	Reduced nausea, vomiting, sedation, drowsiness
Morphine	Uridine diphosphate glycosyl transferase	More rapid glucuronidation
Codeine	CYP2D6	Slower conversion to morphine; reduced analgesic effect (but no adverse effects)
Tramadol	CYP2D6	Slower conversion to O- and N-demethyltramadol; greater need for rescue analgesics after surgery
Methadone	CYP2D6	Slower metabolic clearance (although not consistently)
NSAIDs and Others		
Celecoxib, naproxen, piroxicam, ibuprofen, flurbiprofen	CYP2c9	Slower metabolism
Paracetamol	CYP2e1	Accelerated elimination rate
Acetaminophen	Tumor necrosis factor β	Lower risk of encephalopathy in patients with acetaminophen-induced acute liver failure
Various NSAIDs	HLA-DRB1	Higher risk of anaphylactoid reaction

Source: Adapted from Palmer et al. [3].

CYP—cytochrome P450; HLA—human leukocyte antigen; NSAID—nonsteroidal anti-inflammatory drug; RyR1—ryanodine receptor.

The BDZ of choice for intravenous sedation is midazolam, the only water-soluble benzodiazepine. It is preferred for sedation in intensive care patients and is particularly useful when given in combination with other drugs, such as alfentanil and propofol. Although the duration of action after bolus injection is short due to rapid redistribution, when administered to critically ill patients as a continuous infusion for longer than 24 hours, its clinical effect is often prolonged due to accumulation and possibly also due to α-hydroxymidazolam, midazolam's active metabolite.

Alphahydroxymidazolam is 60–80% as potent as midazolam, with an elimination half-life of about 1 hour in patients with normal renal function. The clinical effects of midazolam may be increased in patients with renal failure owing to α-hydroxymidazolam accumulation. Diazepam is less suitable as an infusion on account of its longer half-life and the even longer half-life of its principal metabolite. Given intravenously, both diazepam and midazolam are effective first-line treatments for status epilepticus. For intractable status epilepticus, clonazepam, a longer-acting alternative, which can also be given by intravenous infusion, is often used.

35.3.4.2 Diazepam

The half-life of diazepam in individuals homozygous for the A allele of the cytochrome CYP2C19 G681A polymorphism is four times longer than individuals homozygous for the major (G) allele, presumably because of markedly decreased CYP2C19 metabolic activity. Individuals heterozygous for the A allele have a diazepam half-life somewhere between these two extremes. These genetic differences may manifest clinically as prolonged sedation or unconsciousness after diazepam administration [78,79].

35.3.4.3 Midazolam

Midazolam is metabolized by two different enzymes (CYP 3A4, CYP3A5) present in both the liver and the intestine. So far, there is no evidence that polymorphisms in either of these enzymes cause any effect on drug action when given orally. However, coadministration of midazolam and fentanyl can prolong the action of fentanyl due to inhibition of fentanyl metabolism by midazolam's competing metabolism at the liver enzyme CYP3A4 [80].

35.3.5 Inhalational Anesthetic Agents

Volatile anesthetics or inhalational agents are used mostly for maintenance and occasionally for induction of anesthesia. The commonly used inhalational anesthetic agents in current practice are isoflurane, sevoflurane, and desflurane. Halothane is still used in developing countries, but in the developed world it has been superseded by the newer volatile anesthetics just mentioned. Two main pharmacogenetic conditions of particular relevance to anesthesia are malignant hyperthermia and halothane- (and sevoflurane-) induced hepatitis.

Individual sensitivity to volatile anesthetics based on genetics has not been well studied or defined. Based on research by Liem et al., we know that many redheads have distinct polymorphisms in the melanocortin-1 receptor that make them less sensitive to desflurane (requiring more drug to achieve the mean alveolar concentration, or MAC) [81]. Other than this study, there is little to show that any genetic variability causes a change in sensitivity to individual volatile agents.

Halothane-induced hepatitis, which has been widely studied, seems to result from an immune response to halothane metabolites processed by the cytochrome enzyme CYP2E1. Halothane-induced hepatitis occurs in approximately 1 in 10,000 patients. Although its tendency to occur within families suggests that it is hereditary, the genetic mechanisms involved are not entirely clear. This is because CYP2E1 activity depends as much on body mass, diet, alcohol consumption, and age as it does on any polymorphisms discovered to date. Mechanisms of halothane toxicity are idiosyncratic reaction, immuno-allergic type; the protein adducts formed in the initial toxic reaction provide the hapten for the formation of antibodies, which augments damage on re-exposure. Covalent binding of halothane metabolites to tissue proteins has been well described. Up to one-third of inhaled halothane may be oxidatively metabolized by CYP2E1 and 2A6.

Trifluoroacetyl chloride, which has a strong ability to acetylate liver proteins, is formed during the synthesis of trifluoroacetic acid (TFA). Only a small amount of halothane (~%1) is metabolized through the reductive pathway by CYP2A6 and 3A4. This pathway is favored under hypoxic conditions, resulting in the release of bromide and fluoride ions and in the formation of other volatile organic metabolites. Several drugs or chemicals have been shown to induce hepatitis with autoimmune involvement. Adduct formation of an activated metabolite is believed to act as a trigger and to induce a specific immune response.

Two types of halothane-mediated hepatotoxicity have been defined. The first, type I, occurs postoperatively and is mild and self-limiting, with a mild form of hepatocellular injury that can be observed in about 20% of patients. The mild hepatic injury is assumed to result from the direct action of halothane on liver cells. Two clinically detectable factors appear to contribute to this. The first is a transient elevation of liver enzymes and the second is alteration of cellular integrity, which can be detected by electron microscopy. Lesions result from intracellular degradation of halothane via its anaerobic and aerobic pathways, in combination with local hypoxia caused by an alteration of the hepatic oxygen demand–supply relationship.

The second type of halothane-mediated hepatotoxicity is type II—halothane hepatitis. The incidence of type II hepatotoxicity after halothane administration is one in 10,000–30,000 adult patients. Its probable mechanism is an immune-mediated hepatotoxicity, in which antibodies are directed against modified liver microsomal proteins on hepatocyte surfaces. There is strong evidence that the fulminant form of halothane hepatitis is mediated by the patient's own immune system. Besides signs of mild cellular injury, tissue acetylation is usually found due to the generation of reactive intermediates from halothane metabolism. The acetylation of intacellular proteins is considered the first step in the pathogenesis of the severe type of hepatic injury. The second step involves the formation of antibodies directed toward these acetylated neo-antigens.

The consequence of the immune response with regard to hepatic injury is severe and sometimes fatal. CYP2E1 is a major catalyst in the formation of trifluoroacetylated proteins, which have been implicated as target antigens in the mechanism of halothane hepatitis. Patients with halothane hepatitis or severe hepatic damage caused by other halogenated anesthetics produce metabolites against several liver trifluoroacetylated microsomal proteins [82].

There are reports of hepatoxicity following exposure to sevoflurane. Sevoflurane is a widely used volatile anesthetic agent in both adult and pediatric patients, with rapid onset and washout. Because of its rapid onset of action and lack of irritability to the airways, sevoflurane can be used for both induction and maintenance of anesthesia. Prospective, serial blood tests have often demonstrated minor transient elevations in serum aminotransferase (ALT) levels 1–2 weeks following major surgery.

Clinically apparent, severe hepatic injury from sevoflurane is very rare, with only isolated case reports having been published. The injury is marked by acute elevations in serum ALT levels (5–50-fold) and the appearance of jaundice 2–21 days after surgery. There are usually minimal increases in alkaline phosphatase and gammaglutamyl transpeptidase levels. Jaundice is usually preceded by a day or two of fever and may be accompanied by rash and eosinophilia.

Acute liver injury may be self-limiting and resolve in 4–8 weeks, but it can also be severe and associated with acute liver failure. A strong risk factor is previous exposure to any of the halogenated anesthetics and particularly a history of halothane hepatitis or unexplained fever and rash after anesthesia with one of these agents. The differential diagnosis of acute liver injury after surgery and anesthesia is sometimes difficult, and a clinical picture similar to sevoflurane-induced hepatitis can be caused by shock or ischemia, sepsis, other idiosyncratic forms of drug-induced liver injury, and acute viral or herpes hepatitis [83–85].

The mechanism of sevoflurane hepatotoxicity is suspected to be similar to that of halothane and to be associated with creation of reactive intermediates. Sevoflurane is metabolized, to a small extent, by the microsomal drug-metabolizing enzyme CYP 2E1 to a TFA-reactive intermediate that is capable of binding to multiple intracytoplasmic proteins, forming potentially immunogenic adducts. The TFA adducts induce antibodies that can be detected in patients with sevoflurane as well as halothane hepatotoxicity and are also found in a proportion of healthcare workers exposed to the volatile anesthetics [84,85].

Among approximately 50,000 liver transplants performed in the United States between 1990 and 2002, 137 [0.2%] were because of idiosyncratic drug-induced acute liver failure. Three of these were attributed to halothane, one to isoflurane, and none to other halogenated anesthetics.

35.3.6 Neuromuscular Blocking Agents

Most of the commonly used neuromuscular blocking drugs (NMBDs) are quaternary ammonium compounds. They are structurally related to acetylcholine (ACh), which contains a quaternary nitrogen group ($N^+(CH3)_3$). As with ACh, the positive nitrogen atoms of NMBDs are attracted to the α-subunits of the postsynaptic nicotinic receptor.

35.3.6.1 Depolarizing Muscle Relaxants

Depolarizing muscle relaxants (DMRs) are agonists located at ACh receptors. Succinylcholine is the only DMR in clinical use. Recovery from neuromuscular block occurs as succinylcholine diffuses away from the neuromuscular junction and down a concentration gradient in association with decline in its plasma levels. In the plasma, it is metabolized by butyrylcholinesterase. As discussed earlier, reduced/absent butyrylcholinesterase activity, a result of inherited or acquired factors, may alter the duration of action of succinylcholine and lead to prolonged paralysis [1,40,41].

35.3.6.2 Nondepolarizing Muscle Relaxants

Nondepolarizing muscle relaxants (NMDRs) antagonize the action of ACh in a competitive manner at the postsynaptic nicotinic receptor. Unlike depolarizing drugs, they do not produce conformational changes in the receptor. Binding to one or both α-subunits prevents access by ACh to depolarize the receptor. The binding of antagonists to receptors is dynamic, with repeated association and dissociation. If the concentration of ACh is increased, it has a higher chance than the antagonist of occupying the receptor sites. Except for mivacurium, which is metabolized by butyrylcholinesterase, no genetic factors have been implicated in prolonged duration of NMDR action. Prolonged duration of action results from reduced or absent butyrylcholinesterase activity [41,86,87].

35.3.7 Opioids

Opioids—the most common drugs used by anesthetists worldwide for analgesia and sedation in perioperative and intensive-care settings—exert their pharmacological effects by binding to specific cellular receptors. At least three distinct receptor subtypes (μ, κ, and δ) have been identified and studied extensively; they are primarily responsible for opiods' observed pharmacological effects. Binding to (or blockade of) these receptors alters many clinically important physiological functions. Most of the clinical effects observed are mediated by the μ receptor.

A newer receptor known as nociceptin/orphanin FQ peptide (NOP) and variants of μ-receptor genes have been identified; however, their impact on pharmacotherapy requires further research and understanding. Opioid action is very difficult to characterize by single polymorphisms.

The pharmacogenomics of opioid action can be explained by categorizing the variables into receptor polymorphism, drug transport polymorphism, and metabolism [4].

35.3.7.1 μ Receptor Polymorphism

The μ receptor is the principal site of opioid action. Its two common variants, present in 5–10% of Caucasians, are A118G and the promotor polymorphism G-172T. Although the G118 allele has no apparent relation to a patient's analgesic response to morphine (nor does its active metabolite morphine-6-glucouronide), preliminary data suggest that this allele is associated with reduced severity of opiod adverse effects, which include nausea, vomiting, pupil dilation, and sedation. Therefore, G118 allele carriers may tolerate higher opiate doses than noncarriers [51–53,55,88–91].

35.3.7.2 Drug Transport Polymorphisms

Morphine, methadone, fentanyl, and meperidine are all transported (e.g., across cell membranes, to the brain) by the ABC transporters, specifically the ABCB1 efflux transporter. Research on this transporter is just beginning, although investigations carried out so far show that patients with two copies of the relevant polymorphisms may require as much as a 2-fold increase in opioid dosage [8,12,13,91].

35.3.7.3 Metabolism

Opioid metabolism by cytochrome P450 enzymes and by enzymes that regulate glucuronidation to active metabolites influence the concentration of drug available at the effect site and therefore its clinical efficacy [91]. Genes encoding enzymes responsible for these metabolic pathways exhibit considerable polymorphism, which results in wide variability in interindividual responses to some opioids. The clinical effects of the weaker opioids, codeine, dihydrocodeine, tramadol, oxycodone, and hydrocodone, rely on the formation of more potent hydroxyl metabolites (such as morphine, dihydromorphine, and oxymorphone) via a metabolic pathway mediated by the cytochrome P450 enzyme CYP2D6.

The gene encoding CYP2D6 exhibits significant polymorphism, with 100 variant alleles identified. Variant allele expression results in a number of clinical phenotypes: poor metabolizers express two nonfunctional alleles (e.g., 4*, 5*, and 6*), intermediate metabolizers express at least one reduced functional allele (e.g., 9*, 10*, and 41*), and extensive metabolizers express at least one functional allele [22]. A fourth phenotype, the ultrarapid metabolizer, develops when a gene duplication event results in the individual having multiple copies of the functional allele. Approximate frequencies of these phenotypes for the Caucasian population are poor metabolizers 5–10%, intermediate metabolizers 10–15%, extensive metabolizers 65–80%, and ultrarapid metabolizers 5–10%. The prevalence of variant alleles differs considerably according to ethnicity—for example, the frequency of CYP2D6 gene duplication associated with ultrarapid metabolism ranges from 0.5% in China to 29% in Ethiopia [16,22,91,92].

35.3.7.4 Morphine

Multiple liver cytochromes influence the morphine metabolism. Morphine glucoronidation is the major path of first-pass metabolism. An alteration in the genotype of UDGT causes increased glucoronidation. Surgical patients homozygous for the C161T and C802T UDGT gene polymorphisms (which are always inherited together) demonstrate more rapid morphine glucuronidation than do patients who are heterozygous or wild type, therefore causing a decrease in morphine effectiveness. Most recently, it was found that CYP2D6 poor and ultrarapid metabolizers have very poor analgesia with morphine when compared to extensive and intermediate metabolizers [2,51,58,93,94].

35.3.7.5 Codeine

Codeine has a minimal clinical effect until it is metabolized to morphine in the liver by CYP2D6 (about 10% of the drug) [95–97]. Approximately 5–10% of Caucasian patients (poor metabolizers) are unlikely to gain full benefit from codeine administration, although they are just as likely to suffer codeine-related side effects [98]. In children, this number may be as high as 36% [99]. The effect may be compounded by low drug absorption.

There is a small population of individuals, most commonly those of East African descent, who are ultrarapid metabolizers and convert the majority of codeine into morphine. For these patients, respiratory depression and apnea are very real possibilities after even a single dose. This is of particular concern in nursing mothers [100]. Interestingly, the severity of codeine's adverse effects does not seem to be associated with the CYP2D6 genotype, thus explaining how codeine can impair driving ability even when the driver's blood does not contain detectable morphine concentrations [25].

35.3.7.6 Methadone

CYP2D6 poor metabolizers have decreased methadone clearance, although this decrease is not always consistent [101]. It may be secondary to the influence of CY2B6 and CY3A4 in methadone metabolism. CYP3A4 is important in the metabolism of several other opiates, such as fentanyl, alfentanil, and sufentanil. Interestingly, CYP3A4-mediated metabolism is 40% more rapid in females than in males. The clinical implication is that females have a 3-fold higher incidence of awareness during total intravenous anesthesia and have a more rapid awakening [50,102].

35.3.7.7 Tramadol

Tramadol is an opiate that is metabolized to O- and N-demethyltramadol by the CYP2D6 enzyme system. Poor metabolizers maintain high tramadol levels for an extended period of time. Because this actually results in a diminishment of drug effectiveness, the percentage of tramadol nonresponders is significantly higher in the poor metabolizer group (46.7%) compared with the normal (extensive metabolizer) group (21.6%). In contrast, CYP2D6*1 allele carriers were found to be twice as likely to require additional postoperative analgesics because of increased tramadol metabolism [50,103–105].

35.3.8 Nonsteroidal Anti-Inflammatory Drugs

Nonsteroidal anti-inflammatory drugs (NSAIDs) are commonly used to treat various types of pain. Their mode of action is inhibition of the cyclo-oxygenase enzyme system. Many NSAIDs are metabolized by the cytochrome enzyme CYP2C9. Celecoxib, naproxen, piroxicam, ibuprofen, and flurbiprofen are more slowly metabolized in individuals with CYP2C9*3 than in those without it [98,106,107]. This reduction in metabolism tends to be greater in *3 homozygotes than in heterozygotes, which suggests that *3 carriers may experience either more clinical benefit or greater adverse effects from NSAIDs, or both. However, no studies have yet confirmed this. In contrast, metabolism of diclofenac seems largely unrelated to the CYP2C9 genotype [28,29].

Preliminary evidence indicates that the *11 allele of the gene for the human leukocyte antigen HLA-DRB1, which is involved in immune response, may be associated with anaphylactoid reactions to various NSAIDs. However, there is no evidence to suggest any association between NSAID activity and cyclooxygenase-2 gene polymorphisms. This is surprising, given that cyclooxygenase-2 inhibition is the NSAID mechanism of action. It has been suggested that the cyclooxygenase-2 enzyme is so important for maintaining body homeostasis that any polymorphisms that might significantly alter its function have been suppressed by natural selection. This seems an unlikely explanation because the G-765C polymorphism of the cyclooxygenase-2 gene was recently shown to be independently associated with a decreased risk of myocardial infarction and stroke.

35.3.8.1 Paracetamol

In therapeutic doses, paracetamol (acetaminophen) is one of the most effective and well-tolerated drugs in adults and children. It has been in use in clinical practice for more than 50 years and has been the cornerstone of pain and fever management. Although paracetamol has been used for the last century, its mechanism of action is still unknown; however, it is generally considered to be a weak inhibitor of prostaglandin (PG) synthesis. *In vivo*, paracetamol's effects are similar to those of selective COX-2 inhibitors. Although it decreases PGs, it does not reduce inflammation in conditions like rheumatoid arthritis, as the COX-2 inhibitors do.

Paracetamol metabolism involves CYP2E1. Individuals who are homozygous for the CYP2E1 c2 allele (which lacks a DNA segment that limits protein manufacture in the wild-type c1 allele) metabolize paracetamol twice as fast as do heterozygous or wild-type individuals. Some data imply that a mutant allele (B2) of the tumor necrosis factor β gene protects against encephalopathy in patients with paracetamol-induced acute liver failure [18,108].

35.3.8.2 Antiemetics

Ondansetron is a serotonin (5HT3) receptor antagonist used for the prevention and treatment of postoperative nausea and vomiting. Ultrarapid metabolizers of CYP2D6 have a high incidence of ondansetron failure, caused by their rapid metabolism of ondansetron and low overall drug exposure [19,109].

35.4 CONCLUSION

Even though anesthesia was at the forefront of the pharmacogenetic discoveries, applied pharmacogenetics in anesthesia is still in its infancy. Nevertheless, the range of anesthetic drugs along with the fact that the majority of subjects undergoing elective anesthesia do not have comorbidities and that those who do are generally at high risk and are exposed to multiple pharmacological agents—all of these factors indicate that pharmacogenomics and personalized medicine are the way forward in tailoring interventions to individual needs as a way to minimize adverse events [110].

36.1 OVERVIEW

Tuberculosis (TB) remains a serious infectious disease around the world [1]. It causes ill health among millions of people each year and ranks as the second leading cause of death from an infectious disease worldwide, after the human immunodeficiency virus (HIV) [2]. This is despite the availability of treatment that will cure most TB cases.

The World Health Organization (WHO) declared TB a global public health emergency in 1993. Starting in the mid-1990s, efforts to improve TB care and control intensified at national and international levels. WHO developed the Directly Observed Treatment Short-Course (DOTS) strategy, a five-component package comprising political commitment, diagnosis using sputum smear microscopy, a regular supply of first-line anti-TB drugs, short-course chemotherapy, and a standard system for recording and reporting the number of cases detected.

36.2 TB ETIOLOGY AND NATURAL HISTORY

Tuberculosis is caused by the bacillus *Mycobacterium tuberculosis* (Figure 36.1) [3]. It typically affects the lungs (pulmonary TB) but can affect other sites as well (extrapulmonary TB). The disease is spread in the air when people who are sick with pulmonary TB expel bacteria, for example by coughing. In general, a relatively small proportion of people infected with *Mycobacterium tuberculosis* will develop TB disease; however, the probability of developing TB is much higher among people infected with HIV. TB is also more common among men than women and affects mostly adults in economically productive age groups.

The natural history of TB is influenced by several factors, the course being determined by the balance between host immunity and virulence of the TB bacillus. This understanding facilitates identification of areas where interventional strategies can be identified for TB control [4–6].

36.3 BURDEN OF TB

The burden of disease caused by TB can be measured in terms of incidence (defined as the number of new and relapse cases arising in a given time period, usually one year), prevalence (defined as the number of cases at a given point in time), and mortality (defined as the number of deaths in a given time period, usually one year).

There has been major progress in reducing TB cases and deaths in the past two decades, with incidence having fallen globally for several years and declining at a rate of 2.2% between 2010 and 2011. Globally, the TB mortality rate has fallen by 41% since 1990 and the world is on track to reach the global target of a 50% reduction by 2015. Despite this encouraging progress, the global burden of TB remains enormous. There were an estimated 8.7 million cases of TB in 2011 (13% coinfected with HIV). There were also 1.4 million deaths from it (990,000 among HIV-negative individuals and 430,000 among HIV-positive individuals) (Figure 36.2) [7]. These deaths included 0.5 million among women, making TB one of the top killers of women worldwide [2].

Geographically, the burden of TB is highest in Asia and Africa. India and China combined have almost 40% of the world's TB cases; the Southeast Asian and Western Pacific regions, of which India and China are a part, account for 60%. The African region has approximately one-quarter of the world's cases, as well as the highest rates of cases and deaths relative to population. Globally, 3.7% of new and 20% of previously treated cases are estimated to have multidrug-resistant TB (MDR-TB). India, China, the Russian Federation, and South Africa have almost 60% of the world's cases. The highest proportions of TB patients with MDR-TB are in Eastern Europe and Central Asia. Almost 80% of TB cases among people living with HIV reside in Africa. There were an estimated 0.5 million cases and 64,000 deaths among children in 2011 [2].

36.3.1 Incidence and Prevalence

In 2011, there were an estimated 8.7 million incident cases of TB (range 8.3–9.0 million) globally, equivalent to 125 cases per 100,000 population. Most of these cases occurred in Asia (59%) and Africa (26%); smaller proportions of cases occurred in the Eastern Mediterranean region (7.7%), the European region (4.3%), and the Americas (3%). Of the 8.7 million incident cases, an estimated 0.5 million were children and 2.9 million (range 2.6–3.2 million) were women [2].

FIGURE 36.2 **TB incidence and HIV prevalence in new cases of TB.** (a) Estimated tuberculosis incidence (2010); data are from a WHO report. The 22 countries with the highest burden of tuberculosis—which account for 80% of cases worldwide—are labeled. (b) Estimated HIV prevalence in new cases of tuberculosis (2010). *Source: Reproduced with permission from Raviglione et al.* [7].

The five countries with the largest number of incident cases in 2011 were India (2.0–2.5 million), China (0.9–1.1 million), South Africa (0.4–0.6 million), Indonesia (0.4–0.5 million), and Pakistan (0.3–0.5 million). India and China alone accounted for 26% and 12% of global cases, respectively. Of the 8.7 million incident cases in 2011, 1.0–1.2 million (12–14%) were among people with HIV, with a best estimate of 1.1 million (13%). The proportion of TB cases coinfected with HIV was highest in countries in the African region (39%) which accounted for 79% of TB cases among people living with HIV worldwide [2].

Globally, incidence rates were relatively stable from 1990 up to around 2001 and then started to fall. Between 2010 and 2011, the rate of decline was 2.2%. The rate of decline between 2010 and 2011 was 0.5% in the Eastern Mediterranean region, 2.0% in the Southeast Asia region, 2.3% in the Western Pacific region, 3.1% in the African region, 3.8% in the Americas, and 8.5% in the European region. Incidence rates have been falling since the mid-1990s in the Eastern Mediterranean region and since around 2000 in Southeast Asia; they peaked at the end of the 1990s in the European region and around 2002 in Africa; they have been falling since 1990 in the Americas and the Western Pacific region [2].

There were an estimated 12 million prevalent TB cases (range 10 million–13 million) in 2011, equivalent to 170 cases per 100,000 population. Prevalence rates have fallen by 36% globally since 1990, and they are declining regionally. America halved its 1990 TB prevalence level by around 2005, and the Western Pacific region is close to doing so [2].

36.3.2 Mortality

The number of TB deaths worldwide fell just below 1 million among HIV-negative individuals in 2011. The number of TB deaths per 100,000 population in this group, plus the estimated number of TB deaths among HIV-positive individuals, equates to a best estimate of 20 deaths per 100,000 population in 2011. Globally, mortality rates (excluding deaths among HIV-positive individuals) have fallen by 41% since 1990. The current forecast suggests that a 50% reduction by 2015 compared with a baseline of 1990 will be achieved.

36.4 BURDEN OF TB AMONG CHILDREN

For many years, prevention, diagnosis, and treatment of TB in children have been relatively neglected. The greatest attention has been given to the detection and treatment of infectious cases, most of which occur in adults. To help address the burden of TB in children (defined as those aged <15 years) and monitor progress, robust data are necessary. WHO report (2012) on global TB care and control has included, for the first time estimates of the burden of TB among children, with best estimates of 490,000 cases and 64,000 deaths per year.

36.4.1 Incidence, Mortality, and Prevalence

There is no easy-to-use, accurate diagnostic test for TB in children. Most children have paucibacillary TB, which is harder to diagnose with sputum smear microscopy and culture. Many children, especially younger ones, are also not able to expectorate sputum. Diagnosis is usually made via a combination of clinical (as opposed to laboratory) criteria and a nonspecific test for tuberculous infection, but there is no universally applied diagnostic algorithm.

The definitive diagnosis of extrapulmonary TB requires specialized services that are usually available only in referral hospitals and thus not often accessible to those in need. Besides diagnostic challenges, children diagnosed with TB are not always reported to national surveillance systems because of the lack of linkages among individual pediatricians, pediatric hospitals, and national TB programs; also, data from national surveys including children are limited.

TB incidence among children was estimated at 490,000 (range 470,000–510,000) in 2011, which is equivalent to about 6% of the total number of 8.7 million incident cases [2]. The total number of deaths from TB among HIV-negative children was estimated at 64,000 (range 58,000–71,000) in 2011, which is equivalent to 6% of the 990,000 TB deaths among HIV-negative TB cases in 2011 [2]. Besides the direct impact of TB on children themselves, parental TB deaths have created large numbers of orphans. In 2009, there were almost 10 million children who were orphans as a consequence of losing at least one parent to TB.

Data on the prevalence of TB in children are limited to a few nationwide surveys conducted before 2001. Examples include a survey in India in 1956 and surveys in China in 1980, 1990, and 2000. A 2007 survey in the Philippines included children aged 10–14 years. These surveys consistently found a low burden of bacteriologically confirmed TB in children compared with adults [2].

36.5 TB DIAGNOSIS

36.5.1 Active Disease and Latent TB Infection

Sputum smear microscopy, the primary method for diagnosis of pulmonary TB, is a simple, rapid, and inexpensive technique that is highly specific in areas with very high prevalence [8]. Its limitations include low sensitivity and diagnosis of extrapulmonary TB, pediatric TB, and patients coinfected with HIV [9]. Although fluorescent microscopy has improved the sensitivity of sputum smear microscopy, it involves major cost constraints [10]. These may be circumvented by the use of light-emitting diodes (LEDs), which are relatively cheaper [11].

Rapid culture-based methods for TB diagnosis include rapid automated liquid culture, thin-layer agar culture, phage-based culture, and microscopic observation drug susceptibility assay (MODS) [12]. However, while performance indicators on these techniques might be better, turnaround times are longer. There are also requirements in terms of investment in infrastructure and equipment [13]. Nucleic acid amplification tests (NAATs) attempt to provide accurate and rapid TB diagnosis using a technology that provides improved sensitivity and specificity functions as compared to sputum smear microscopy.

The Xpert MTB/RIF assay, which is based on molecular detection, enables simultaneous detection of *M. tuberculosis* and rifampicin resistance. It has been endorsed by WHO and is recommended as an initial diagnostic test for smear-negative patients and those at high risk for rifampicin (RMP) resistance. Although the development of the Xpert MTB/RIF assay is undoubtedly a landmark event, clinical and programmatic effects and cost-effectiveness remain to be defined [14]. A schematic of current TB diagnostic methods is shown in Figure 36.3 [14].

Diagnosis of latent TB infection (LTBI) is considered important as a tool for assessing the burden of TB for epidemiological purposes. Because LTBI contributes significantly to the pool of active TB cases later on, its early recognition is assuming importance in high-risk groups where there is a potential for treatment for this condition [15]. The tuberculin skin test (TST) and interferon-gamma release assays (IGRAs) are two diagnostic tests for the detection of LTBI [16]; both have advantages and limitations. In high-burden TB countries, WHO recommends that neither IGRAs nor TST be used to diagnose active TB and that IGRAs not be used to diagnose LTBI [17,18].

36.5.2 Extrapulmonary TB (EPTB)

The diagnostic yield of conventional AFB smear and mycobacterial culture varies with extrapulmonary fluid/specimen type [19,20]. A battery of diagnostic tests, including culture (and DST where feasible), enhances diagnostic yield in EPTB. PCR-based methods, adenosine deaminase, and interferon gamma are also used in EPTB diagnosis. There is

a need to systematically evaluate and establish the utility of newer tests such as GeneXpert in early diagnosis to increase diagnostic yield.

36.5.3 Diagnostic Methods: Serodiagnostic Tests, and Imaging Studies

A broad range of serodiagnostic tests with a varying degree of reliability, repeatability, and concordance have been marketed for TB diagnosis. Since no commercial serological assay consistently results in an accurate diagnosis. WHO recently recommended that they not be used for the diagnosis of pulmonary or extrapulmonary TB [21].

Imaging modalities, such as conventional X-ray, ultrasonography, computed tomography (CT), magnetic resonance imaging (MRI), and positron emission tomography CT (PET-CT) have been used to localize the disease, assess the extent of organ involvement, and evaluate treatment response. The chest X-ray is the mainstay of pulmonary TB imaging. However, it can be normal in HIV-infected patients with active TB disease as well as in some patients with miliary TB [22].

36.6 CHEMOTHERAPY FOR TB

The foundations of chemotherapy are (1) the prevention of the emergence of drug-resistant *M. tuberculosis*; (2) the bactericidal activity of drugs; and (3) the principles of intermittent drug dosage and mycobacteria lag phase.

Chemotherapy for TB became possible only after the discovery of streptomycin in 1944. The introduction of isoniazid (INH) as a drug in the combination regimen for TB treatment formed the basis of primary chemotherapy in the 1950s and 1960s. During that time, the standard regimen comprised streptomycin, INH, and PAS for a few months, followed by the latter two drugs for 18 months. Following the discovery of rifampicin in 1965, short-course chemotherapy for TB was introduced in the 1970s [23]. Figure 36.4 is a schematic representation of anti-TB drug development [24].

The aims of drug treatment of TB are

- To cure patients by the shortest duration of drug administration, preferably with minimum interference with their activities of daily living
- To prevent death from TB or late effects
- To prevent relapse
- To reduce transmission to the community

Figure 36.5 [24] shows the mechanism of action of anti-TB drugs currently being developed for treating TB. An important research priority is development of new drugs, given that no new drug has emerged since the discovery of RMP. The global pipeline for new anti-TB drugs is shown in Figure 36.6 [25].

36.6.1 Scientific Basis for Short-Course Chemotherapy

M. tuberculosis, the causative bacterium of TB, is slow-growing and can enter a phase of dormancy. A patient with TB can basically harbor four populations of organisms. The first is the actively growing extracellular organisms, which are present in abundance in aerated cavities. The second is slow intermittently growing organisms in an unstable part of the lesion. The third includes organisms surviving in a low environmental pH, which can occur in inflammatory lesions or in phagolysosomes or macrophages. The fourth is completely dormant organisms surviving under anaerobic conditions. The major actions of anti-TB drugs [26] are as follows:

- Bactericidal action, defined as the ability to rapidly kill actively growing bacilli
- Sterilizing action, defined as the capacity to kill semi-dormant organisms
- Prevention of resistance

INH is the most potent bactericidal drug followed by RMP. RMP and pyrazinamide (PZA) are capable of sterilizing tuberculous lesions and preventing disease relapse. Resistance to an anti-TB drug is due to spontaneous chromosomal mutation at a frequency of 10^{-6}–10^{-8} bacterial replications [27]. As mutations resulting in drug resistance are unlinked, the probability of resistance to all three drugs used simultaneously becomes 10^{-18}–10^{-20} [28]. Thus, the chance of drug resistance is practically nil when three or more effective drugs are used in combination. Among the first-line drugs, INH and RMP are the most effective in preventing resistance [26]; streptomycin (Sm), ethambutol (EMB), and PZA are less effective.

Drug-resistant TB usually results from poor patient adherence and other causes of failure to implement TB control programs. Poor treatment adherence can be multifaceted and complex, involving the interplay of individual patient characteristics and societal and economic factors.

Although the main aim in designing drug regimens has been prevention of drug resistance, more recently, increasing attention has been paid to methods of improving of

healthcare delivery and patient compliance. This can be accomplished by fully supervised drug administration.

36.6.2 Treatment of Smear-Positive TB

In the past few decades, a number of effective drug regimens have been found, largely through clinical trials for treating patients with newly diagnosed smear-positive pulmonary TB [29–32]. Most regimens are given for six months, this currently being the shortest duration of treatment required. A four-drug regimen (for two months) followed by two drugs (for four months) is advisable. Thus, the modern six-month short-course regimen comprises RMP, INH, PZA, and EMB for two months (intensive phase) followed by RMP and INH for four months (continuation phase), either daily or intermittently. For individual cases with extensive disease or cavitation on chest Xray and slow sputum bacteriological conversion to negative, the intensive phase may be prolonged beyond two months.

36.6.3 MDR and XDR TB

Drug resistance is a widespread phenomenon. MDR TB is defined as resistance to INH and RMP, the two key first-line anti-TB drugs. Extensively drug-resistant (XDR TB) is defined as resistance not only to RMP and INH but also to any fluoroquinolone and a second-line injectable drug [33]. Recent global epidemiological data on M/XDR-TB are shown in Figure 36.7 [34]. Although DOTS is highly effective in the management of drug-susceptible TB, it is not sufficient for controlling established MDR TB. Treatment success rates for patients with MDR TB are much lower compared with those for patients with drug- susceptible disease—namely 56–80% versus ≥90% [35–37]. On the basis of available data, WHO has recommended a three-part response to the global threat of MDR TB [37,38]—the widespread implementation of DOTS as the cornerstone of good TB control, improved drug susceptibility testing and surveillance, and rapid expansion of second-line drug therapy. This new initiative, known as DOTS-Plus [36] is currently coordinated by WHO in partnership with many agencies and institutions worldwide. The most important determinant in formulating a drug regimen for MDR TB is the patient's current drug susceptibility pattern *in vitro* [32], but most countries use standardized regimens.

A patient with MDR TB should receive a regimen comprising at least four to five second-line drugs for the initial months and three to four drugs subsequently. One regimen recommended by WHO consists of treatment with EMB, ethionamide/prothionamide, ofloxacin/ciprofloxacin, PZA, and aminoglycoside for 3 months, with the first four drugs being administered for at least a further 18 months [38,39].

36.7 RISK FACTORS: GENETICS, HIV, DIABETES, AND SMOKING

Several genetic, social, environmental, and biological determinants of health have been intuitively recognized by clinicians as risk factors for TB. Some of these are discussed in the following sections.

Certain key issues should be considered when evaluating genetic susceptibility to TB disease. Susceptibility does not follow a Mendelian pattern and is polygenic and multifactorial. The presence of two different genomes (of the TB bacillus and the host) and their interaction can influence the disease [40]. Several reports have associated certain genes with TB risk

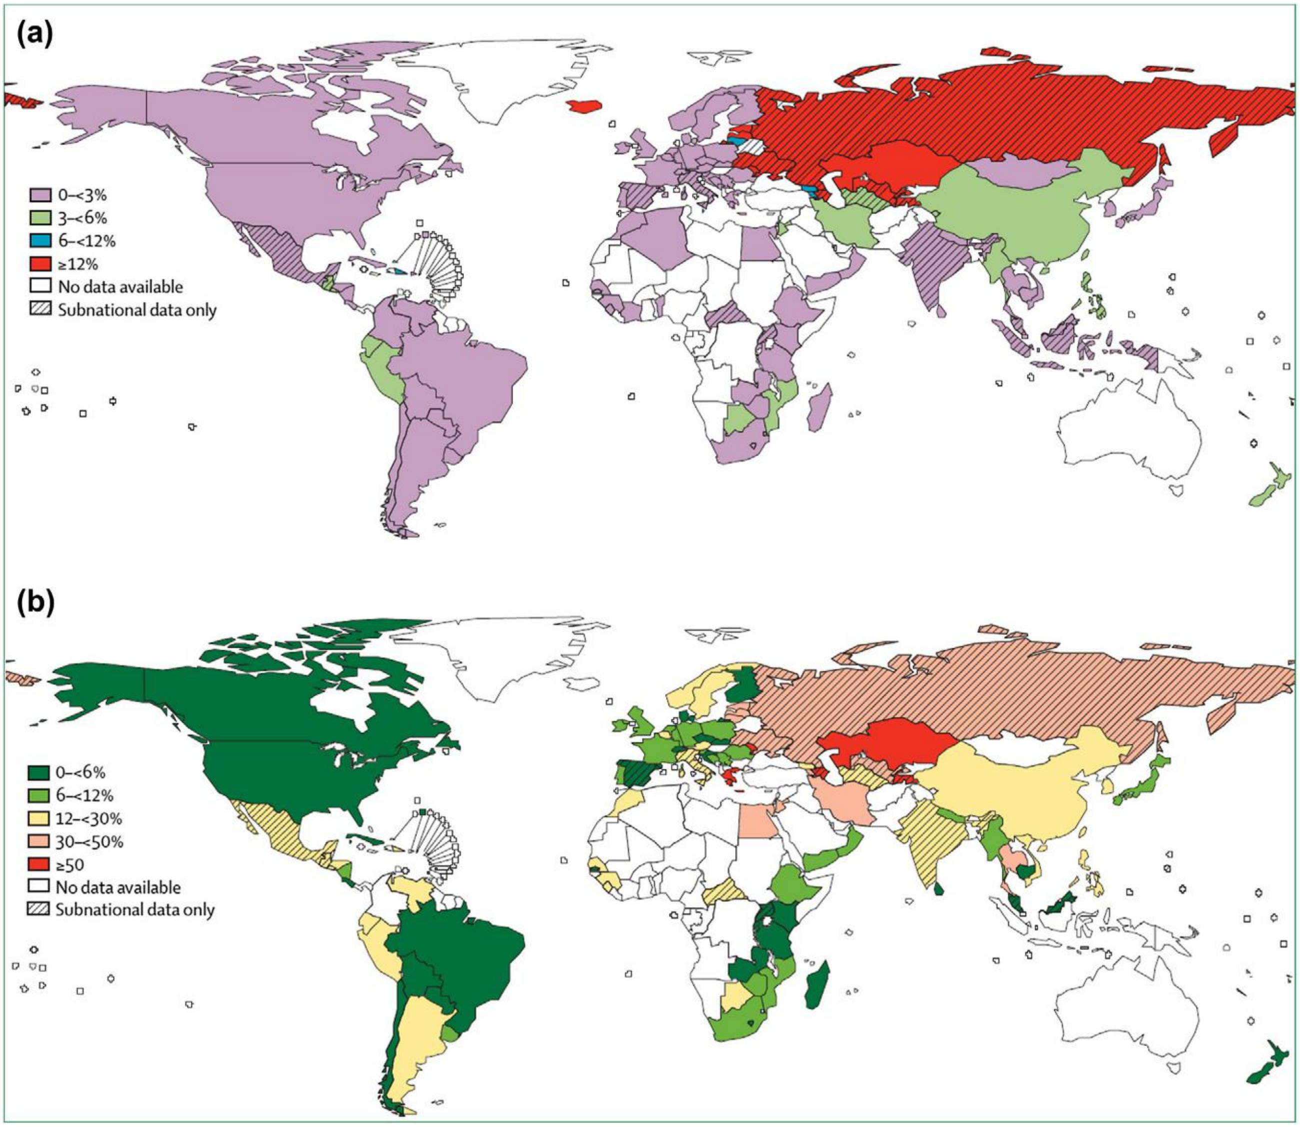

FIGURE 36.7 **Proportion of multidrug-resistant diseases.** Data shown are for (A) new cases and (B) previously treated cases of tuberculosis. *Source: Based on Global Drug Resistance Surveillance Project data. Australia, Democratic Republic of the Congo, Fiji, Guam, New Caledonia, Solomon Islands, and Qatar reported data for combined new and previously treated cases. (including natural resistance–associated macrophage protein 1, interferon γ, nitric oxide synthase 2A, mannan-binding lectin, vitamin D receptor, and some Toll-like receptors) [41,42].

HIV infection and AIDS stand out as the most significant among all risk factors for TB and have consistently and significantly altered the incidence rate over the last three decades [43–46]. The impact of HIV/AIDS has been most profound on HIV prevalence in Sub-Saharan Africa, where a dramatic increase in TB notification rates has been documented concurrent with increasing HIV prevalence. Among persons living with HIV, TB can develop at any stage of infection and there is strong evidence that a declining CD4+ T-lymphocyte count and a high viral load are risk factors for disease. Treatment with highly active antiretroviral therapy (HAART) reduces risk [43].

Even though, several institutional outbreaks of MDR-TB among HIV-infected patients drew attention to the problem two decades ago [47–49], according to available evidence, HIV infection per se does not appear to be a risk factor for MDR-TB.

The lethal interaction between diabetes mellitus (DM) and TB is being increasingly recognized the world over [50,51]. Epidemiological modeling data suggest that, in India, 14.8% of all pulmonary TB cases and 20% of sputum smear–positive cases are attributable to DM [51], suggesting that DM substantially contributes to the burden of TB, especially sputum smear–positive pulmonary TB in India.

Data from recent systematic reviews on tobacco smoking and TB suggest that tobacco smokers have about a 3-fold higher risk of TB than do nonsmokers, even after adjustment for other factors [52,53].

36.8 TB IN CHILDREN

Tuberculosis in childhood is the consequence of droplet infection with *Mycobacterium tuberculosis* spread by aerosol formation from sputum expectorated mostly by adults with pulmonary TB. Because of the broad base of the population pyramid in developing communities, considerably more young children are infected and become diseased than is the case in a developed community. Also, because more severe forms of disease tend to occur in younger children, morbidity and mortality resulting from childhood TB are proportionately higher in the developing world.

36.8.1 Development and Natural History

Children in close household contact with an adult, often a parent, grandparent, or other adult family member, with "open," or sputum smear–positive, TB, experience considerably higher morbidity and mortality than do those in contact with adults whose sputum is positive on culture only [54]. However, only a minority of children develop disease following infection. The risk of disease varies in different communities, from approximately 10–30% and is concentrated in the 3–12 months following infection [55]. Risk is further influenced by the age of the child. The lifetime risk of developing disease after infection is 43% in infants, 24% between 1 and 5 years age, and 15% in adolescents, compared to immunocompetent adults, who have a lifetime risk of 5–10% [56]. This risk, as well as morbidity and mortality, is the highest in very young children. Young children are particularly susceptible to disseminated forms of TB such as miliary TB and tuberculous meningitis.

The natural history of TB in childhood is well documented from close observations made by experienced pediatricians in the pre-chemotherapy era [57]. Following infection, *M. tuberculosis* spreads from the primary focus and is soon found in the regional lymph nodes. Further lymphohematogenous spread distributes the organism throughout the body. Small foci of viable organisms are established in vulnerable sites, such as the meninges, the bone ends, the apices of the lungs (Simon foci), and the kidneys. This period of dissemination ends 6–8 weeks after infection, at which point the tuberculin test becomes positive, a nondescript "fever of initiation" may be experienced [58], and the primary focus and primary complex enlarge and may become visible on chest X-rays. A period of great danger for the development of disease follows; most disease will manifest itself in children in the next 3–24 months.

36.8.2 Diagnosis and Treatment

In only a minority of cases of childhood respiratory TB will a culture of *M. tuberculosis*, usually from an early morning gastric aspirate, be obtained. In most instances, a clinical diagnosis is made by drawing on the result of tuberculin testing, clinical features, a history of close contact with an adult with pulmonary TB, and chest X-ray. In developed countries, most cases of childhood TB are identified following contact tracing [59].

Induced sputum or early morning gastric aspirates are the most appropriate specimens in young children, but other specimens such as nasopharyngeal swabs or biopsy of lymph nodes or other tissues should not be ignored. Chest X-rays plays a major role in the diagnosis of childhood TB and the radiological features of childhood TB are well known.

The principle governing the treatment of pulmonary TB in children is similar to that followed in adults, which is a six-month short course regimen comprising of INH, RMP, EMB and PZA for two months (intensive phase) followed by INH and RMP for four months (continuation phase) [60]. The response to treatment of childhood respiratory TB is best judged by clinical features, in particular, weight gain. Abnormalities on chest X-ray are slow to respond, and mediastinal adenopathy may remain visible for up to 24 months, even following successful chemotherapy.

36.8.2.1 Drug-Resistant TB

Because of the relatively low mycobacterial burden in childhood TB, which is only intermittently metabolically active or dormant, acquired drug resistance in young childhood is very unusual. Depending on the incidence of drug resistance in a particular community, primary drug resistance in childhood is more common. INH-resistant and multidrug-resistant (MDR) *M. tuberculosis* strains had once been postulated to be less infectious and less likely to cause disease than their drug-susceptible counterparts, but studies have shown them to be just as likely to cause infection and disease [61].

Clinical and chest X-ray features are similar in children with drug-resistant and drug-susceptible TB, and so they do not help to identify resistant cases. Treatment of MDR TB cases in children need careful consideration of drug susceptibility patterns in the index case or, if available, the child's *M. tuberculosis* strain; the extent of the disease; and the possible toxicity of the anti-TB drugs considered (although toxicity is often less common in children). In general, a regimen of at least four anti-TB drugs to which the isolate is susceptible is employed. A fluoroquinolone and an injectable agent are most important for MDR cases; PZA, a sterilizing agent, may be continued because of the difficulty of performing a drug susceptibility test against this agent. Optimal duration of treatment is unknown, but 9–12 months after the last positive culture seems to be sufficient, depending on the severity of the disease. WHO recommends a standardized regimen for MDR TB that is followed in most developing countries. Clinical and chest X-ray follow-up after treatment completion is recommended.

36.9 PHARMACOGENOMICS OF TB

The science of pharmacogenomics—that is, defining the genetic determinants of drug effects—has evolved over the past 50 years. It aims to identify the inherited basis for interindividual differences in drug response and translate this into molecular diagnostics that can be used to individualize drug therapy. Individuals respond differently to drugs, and sometimes the effects are unpredictable. Differences in DNA sequences that alter the expression or function of drug-targeted proteins can contribute significantly to response variation in individuals.

The idea that genes control some drug responses was suggested in the 1950s because of the link between race or ethnicity and aberrant drug responses [62]. Subsequently, genes responsible for several inherited differences in drug metabolism and disposition were isolated, characterized, and linked to differences in drug effects [62]. Polymorphisms in genes encoding drug transporters and targets were also identified and shown to alter drug response [63,64].

It is well recognized that different patients respond in different ways to the same dose of a medication. These differences are often greater among members of a population than they are in the same person at different times [65]. The existence of large population differences with small intrapatient variability is consistent with inheritance as a determinant of drug response; it is estimated that genetics can account for 20–95% of variability in drug disposition and effects [66].

Although many nongenetic factors influence the effects of medications, including age, organ function, concomitant therapy, drug interactions, and nature of disease, there are now several examples of interindividual differences in drug response that are due to sequence variants in genes encoding drug-metabolizing enzymes, drug transporters, or drug targets [63]. Unlike other factors influencing drug response, inherited determinants generally remain stable throughout a lifetime [67].

More than 1.4 million single-nucleotide polymorphisms (SNPs) were identified in the initial sequencing of the human genome [67], with over 60,000 of them in the coding region of genes. Most drug effects are determined by the interplay of several gene products that influence the pharmacokinetics and pharmacodynamics of medications, including inherited differences in drug targets (e.g., receptors) and drug disposition (e.g., metabolizing enzymes and transporters).

36.9.1 Genetic Control of Drug Action

An individual's genetic endowment, phenotypically in protein structure, concentration, and configuration, may alter drug action in multiple ways. A drug entering the body comes into contact with numerous enzymes and other proteins. Nearly all drugs undergo enzymatically controlled transformations during their passage through the liver and other organs. Theoretically, genetic mutations that alter the quality of any of these proteins can lead to a recognizable disturbance in drug–cell interactions. For instance, variations in enzyme components of drug metabolism and conjugation may retard drug inactivation and consequent excretion, resulting in toxic concentrations after small doses. They may modify the site of enzymatic attack on the drug molecule, producing different metabolites with different properties.

Alternatively, genetic mutations may increase the activity or inducibility of drug-metabolizing enzymes and prevent the drug from reaching effective concentrations in plasma or tissues. Structural differences in serum proteins can presumably change binding affinities and alter the ratios of bound to free drug. Similarly, aberrant products at the site of a drug's action in organs, tissues, or cells may confer increased or decreased responsiveness to usual therapeutic drug concentrations.

Pharmacogenetic conditions may exist that result from the action of a single mutant gene. This leads to discontinuous variation in the measure of drug action or metabolism, and the population can be divided into two or more groups (with continuous variation in each) suggesting single-gene polymorphism. However, the variations most frequently observed have a Gaussian distribution resulting from polygenic and /or environmental factors or influences.

36.10 PHARMACOGENOMICS AND TB

Pharmacogenomics is the study of genetically determined, molecular bases of drug therapy outcomes. Outcomes can be broadly divided into areas of efficacy and toxicity.

TB is treated with a combination regimen that includes first-line drugs, INH, RMP, PZA, and EMB. Genetic factors are widely reported to play a significant role in modulating INH metabolism and drug/metabolite concentrations; this has a varying impact on treatment outcomes in terms of both efficacy and adverse events [68–71]. There are few reports that suggest gene polymorphisms as affecting RMP metabolism [72,73] and causing aminoglycoside-induced ototoxicity [74].

36.10.1 Isoniazid

Since its introduction in 1952, isoniazid (isonicotinyl hydrazine; INH) continues to be the most widely used chemotherapeutic agent for the treatment of TB [23]. It is highly efficacious and quite specific in its action against tubercle bacilli; also it has minimal toxicity and is less expensive, making it an important first-line anti-TB drug.

36.10.1.1 Metabolism

The pharmacology of INH has been extensively investigated [75]. Evidence from several studies [75,76] confirms that acetylation is the most important pathway for the metabolism of INH, and that difference in the rates of acetylation are determined by the INH acetylator status of individuals. INH is metabolized by acetylation, which takes place mainly in the liver and gut mucosa. This conjugation reaction is catalyzed by N-acetyl transferase (NAT2), during which an acetyl group from acetyl coenzyme A is transferred to the acceptor amine, thereby forming an amide. INH acetylation results in the formation of acetyl INH, which is conjugated with pyruvic acid and α ketoglutaric acid to form hydrazones; acetyl INH is hydrolyzed to monoacetyl hydrazine and isonicotinic acid. Monoacetyl hydrazine undergoes acetylation to form diacetyl hydrazine; isonicotinic acid is conjugated with glycine to form isonicotinyl glycine. A summary of INH metabolism is shown in Figure 36.8 [77].

36.10.1.2 Acetylator Genotypes and Phenotypes

Human acetylation rate is genetically determined; this is due to the polymorphic enzyme NAT, which is responsible for the metabolism of INH to acetyl INH. This enzyme activity is expressed at highly variable levels. Several studies over the years have concluded that human subjects show broad variations in their capacity to acetylate or inactivate INH to acetyl INH, the metabolites being devoid of anti-TB activity. Studies on TB patients treated for many months with INH-containing regimens have demonstrated that INH metabolism is noninducible.

Evidence has been obtained showing that rapid acetylators metabolize INH more rapidly than do slow acetylators; similar conclusions have been drawn from *in vitro* studies using liver biopsies from previously phenotyped individuals. Thus, the rate of INH acetylation varies from individual to individual because of differences in concentrations of the cytosolic NAT2 enzyme in liver and gut mucosa.

The difference in rapid and slow acetylators is due to the difference in the quantity rather than the quality of the enzyme, rapid acetylators having four to five times the quantity of the enzyme as the slow acetylators do. Variability in *NAT2* expression can therefore affect therapeutic response to drugs. Individuals with reduced *NAT2* expression may have different drug levels than those with normal expression. Consequently, they may need a different dosage schedule of drugs that are metabolized by *NAT2*.

INH acetylator status can be determined using phenotypic or genotypic methods. Humans can be phenotypically divided into "slow acetylators" and "rapid acetylators" and genotypically into three genotypes: homozygous slow (SS), heterozygous fast (FS), and homozygous fast (FF). The SS genotypes are those who have several mutations in the *NAT2* gene (*NAT2*5A*, *NAT2*5B* and *NAT2*6A*) [78]. They are at greater risk of drug-induced adverse reactions due to reduced drug elimination. The FS genotypes are those with one active and one inactive *NAT2* allele (heterozygous). They might require lower than average drug dosages for favorable therapeutic response. The FF genotypes are those in which the *NAT2*4* allele codes for a completely active enzyme. The polymorphic metabolism of INH is genetically determined in a simple Mendelian fashion, and the frequencies of the genes controlling slow or rapid INH metabolism vary among racial populations. The acetylator gene frequency for slow allele ranges from 10% in the Mongoloid race like the Eskimos, Japanese, and Chinese to 90% in Middle Eastern races, 60% in the Negroid, Caucasian, and south Indian populations, and 72% in the United States. Figure 36.9 shows the variation in plasma INH concentrations in the three genotypes of *NAT2* gene [79].

A study was undertaken by Kinzig-Schippers and others of 18 healthy Caucasians to assess individual INH exposure based on the *NAT2* genotype to predict personalized therapeutic dose [80]. They observed that *NAT2* genotypes accounted for 88% variability in apparent INH clearance, while INH preparation and body weight accounted for 2% and 3% of variations, respectively [80]. The researchers found a linear relationship between INH clearance and the number of high-activity *NAT2* alleles. The recommended standard daily dose of INH in adults is 5 mg/kg, but this can be roughly adjusted to 2.5 mg, 5.0 mg, and 7.5 mg/kg for subjects with, respectively, none (slow acetylators), one (intermediate acetylators), and two (rapid acetylators) alleles to achieve similar INH exposure. In another study, Parkin and colleagues reported differences in INH disposition among subjects with different *NAT2* genotypes, slow acetylators having four-fold to six-fold higher serum INH concentrations [81]. Based on this study, an individualized INH dosing regimen was suggested. Similarly, Kita and coworkers compared urinary INH excretion between healthy volunteers and patients, and found that subjects with a higher number of active *NAT2* alleles had higher levels of INH acetylation [82].

36.10.1.3 Isoniazid Acetylator Status and Treatment Efficacy

Limited information is available on the association between INH blood concentrations and efficacy and toxicity. Donald and others undertook a study to examine the influence of the human *NAT2* genotype on early INH bactericidal activity in 97 patients with sputum smear–positive pulmonary TB. Significant differences were found in the mean EBA activity of INH between slow and rapid acetylators and slow and intermediate acetylators. In this way, it was confirmed that *NAT2* genotypes exert a significant effect on INH EBA over a range of doses [83]. Thus, possible that low plasma INH levels in rapid acetylators are one of the causes of occasional therapeutic failure or relapse [84]. In contrast, higher levels in slow acetylators may predispose to toxicity. For these reasons, *NAT2* genotyping prior to INH administration may be clinically useful for predicting pharmacokinetic variability and for possible adjustment of INH dosing regimen.

In the 1950s and 1960s, Studies to understand the relationship between INH acetylator status and treatment outcome in patients with pulmonary TB receiving treatment with INH alone or in combination with p-amino salicylic acid were undertaken at the Tuberculosis Chemotherapy Centre in Chennai, India. Comparison of response to TB treatment between slow and rapid INH inactivators suggested an association between treatment response and rate of INH inactivation; there was a difference in the rate of conversion to bacteriological negativity between slow and rapid inactivators [85].

Under trial conditions, INH acetylator status had little prognostic significance during daily, twice-weekly, or thrice-weekly TB treatment [75]. However, under field conditions or in cases of drug irregularity, INH acetylator status may assume importance and may have an appreciable effect on outcomes among patients on twice- and thrice-weekly regimens [86]. Controlled clinical trials using once-weekly INH-containing regimens found that response to treatment was better in slow acetylators compared to rapid acetylators—the differences in cure rate were in the order of 20–35% ($p < 0.001$) [87]. To understand this inferior response of rapid acetylators, studies of serial serum INH concentrations in slow and rapid acetylators were undertaken. The peak concentration attained in slow acetylators was slightly higher than that in rapid acetylators; however, the fall-off was fast in rapid acetylators but more gradual in slow acetylators. Coverage, defined as the number of hours a bacteriostatic concentration of INH (0.2 μg/ml) is maintained in blood, was significantly greater in slow acetylators. Exposure, defined as the area under the time-concentration curve (AUC) was also significantly greater. Significant differences in coverage and exposure between slow and rapid acetylators suggest that, among rapid acetylators, failure of once-weekly INH regimens results from suboptimal coverage and exposure [88].

FIGURE 36.9 **PK variation due to genetic variation in acetylation status.** Classic pharmacogenetic traits: inherited variation in N-acetylation. (a) Plasma concentrations of the antituberculosis agent isoniazid in 267 subjects 6 hours after an oral dose. The bimodal distribution results from polymorphisms in the gene encoding N-acetyltransferase-2 (NAT2), which catalyzes the metabolism of isoniazid. (b) NAT2 acetylation, measured as a ratio of the caffeine metabolites 5-acetylamino-6-formylamino-3-methyluracil (AFMU) and 1-methylxanthine (1X), in 795 unrelated German subjects. The antimode log AFMU/1X was −0.3 (10 – 0.3 = 0.5). 45.3% of the subjects were phenotypically rapid acetylators and 54.7% were phenotypically slow acetylators. NAT2 genotypes showed that 444 (55.8%) were slow/slow, 312 (39.2%) were rapid/slow, and 39 (4.9%) were rapid/rapid. Therefore, 5.7% of subjects were genotype–phenotype discordant. *Source: Reproduced with permission from Weinshilboum and Wang* [79].

A study by Weiner and others reported on the disadvantages that rapid acetylators have because of the development of rifamycin monoresistance in HIV-infected individuals receiving once-weekly intermittent therapy. This study showed poor treatment outcomes to be associated with INH acetylator status in patients on a once-weekly regimen [84].

The INH acetylator phenomenon may have important clinical implications in certain settings, such as during TB treatment in HIV-infected individuals, and in patients with chronic renal failure. A study undertaken by our group to understand the influence of HIV infection on the pharmacokinetics of anti-TB drugs showed that differences in INH peak concentration and exposure between HIV-infected and HIV-uninfected TB patients were more significant in rapid than in slow acetylators. Thus, among HIV-infected TB patients, where bioavailability of anti-TB drugs has been shown to be suboptimal, rapid acetylators are at a further disadvantage [89].

Determination of INH acetylator status may be particularly important in TB patients with chronic renal failure. The pharmacokinetics of INH was compared between patients with chronic renal failure and healthy volunteers. While plasma INH concentrations were similar in both groups, peak INH concentrations, exposure, and half-life were significantly higher in slow acetylators with renal failure than in healthy subjects ($p < 0.01$). This study suggested that it is necessary to reduce the dose of INH in slow acetylators to minimize adverse events [90].

In a study that examined the impact of INH dose and *NAT2* genotype and phenotype on the pharmacokinetics and pharmacodynamics of INH in adult pulmonary TB patients, it was observed that fast INH acetylators receiving a daily 6 mg/kg dose had exposure similar to that of slow acetylators who received a 3 mg/kg dose daily. It was suggested that reducing the dose below 6 mg/kg would be disadvantageous for fast acetylators; however, 3 mg/kg was sufficient for slow acetylators to achieve optimal INH exposure [91].

Wilkins and others designed a study to characterize the population pharmacokinetics of INH in South African pulmonary TB patients. A model based on data from 235 patients receiving oral doses of INH was developed to understand the pharmacokinetic variability. This study observed that the existing treatment guidelines might cause suboptimal exposure in rapid INH acetylators [92].

36.10.1.4 Isoniazid Acetylator Status in Pediatric TB

The pharmacokinetic study of Jeena and coworkers of children with TB suggested that INH doses may have to be individualized based on age, acetylator status, and disease process [93]. Other studies have also shown that decreased INH exposure was likely to impact TB treatment outcomes in children who were rapid acetylators compared to those who were slow acetylators [94–96]. Schaaf and others suggested that, in view of the enhanced rate of INH metabolism in young children, those below five years of age receive at least a 10 mg/kg dose to ensure that faster acetylators are exposed to adequate serum INH concentrations [95]. We undertook a pharmacokinetic study of anti-TB drugs in 84 children with TB. It was observed that INH acetylator status (AOR 4.2; 95% CI 1.1–15.4; $p = 0.033$) significantly impacted TB treatment outcome [96].

36.10.1.5 Isoniazid-Induced Hepatotoxicity

Isoniazid is quite nontoxic in conventional doses, with hepatotoxicity the most common and serious adverse reaction to occur during treatment. The incidence of hepatotoxicity during anti-TB treatment is reported to vary 2–28% [97]. This toxicity has been related to the slow clearance of acetyl hydrazine, a toxic metabolite of INH in affected patients who were identified as slow acetylators [68].

Hepatotoxicity is a major toxic effect of INH. This has caused concern, because INH is widely used in preventive therapy programs, apart from its use in TB treatment.

36.10.1.6 Mechanism of INH-Induced hepatotoxicity

INH-induced hepatotoxicity is considered to be idiosyncratic [98]. It is not the result of hypersensitivity or an allergic reaction [75,99] and is most probably caused by toxic metabolites. Although the predominant pathway of INH metabolism is acetylation by the hepatic enzyme NAT2, a small part of INH is directly hydrolyzed into isonicotinic acid and hydrazine; this pathway is of greater quantitative significance in slow than in rapid acetylators [100].

Most previous research focused on the hypothesis that acetyl hydrazine is the toxic metabolite of INH [99]. More recent studies, however, suggest that hydrazine, not INH or acetyl INH, is most likely to be the cause of INH-induced hepatotoxicity [100,101]. In early studies, it was suggested that fast acetylators are more susceptible to developing liver injury [99,102]. Again, however, more recent studies show that slow acetylators develop drug-induced liver injury more often and more severely when compared with fast acetylators [103,104]. In slow acetylators, more INH is left for direct hydrolysis into hydrazine; also, the "accumulated" acetyl hydrazine can be converted into hydrazine.

Mitchell and colleagues proposed that the incidence of hepatotoxicity due to INH may be greater in rapid than in slow acetylators because rapid acetylators produce monoacetyl hydrazine from INH faster than do slow acetylators; monoacetyl hydrazine is subsequently converted by the cytochrome P450-dependent hepatic microsomal enzyme system into a potent acylating agent that may cause hepatic necrosis [102]. However, this hypothesis was questioned because of the fact that formation of monoacetyl hydrazine was similar in the two phenotypes, its more rapid formation being offset by its more rapid elimination via diacetyl hydrazine in rapid acetylators [105].

RMP is a potent inducer of the hepatic microsomal enzyme system in the liver and intestine, thereby increasing the metabolism of many other compounds [106]. The combined use of INH and RMP has been associated with an increased risk of hepatotoxicity. Raghupati Sarma and others investigated the effect of daily RMP administration on the direct conversion of INH to isonicotinic acid and hydrazine by INH hydrolase in six slow and eight rapid acetylators [107]. They observed that the proportion of INH metabolized in slow acetylators through the direct pathway was 3% when INH alone was given compared to 6% during concomitant RMP administration. In rapid acetylators, the proportions were considerably less (<1% and 2.5%, respectively), suggesting that INH hydrolase was induced by RMP. In the direct pathway, INH is converted to isonicotinic acid and hydrazine. Thus, hydrazine, a known hepatotoxic agent in animals formed from INH, [108], was responsible for INH hepatotoxic action. The direct pathway of INH metabolism induced by RMP was shown to be more pronounced in slow than in rapid acetylators.

Most anti-TB drugs are liposoluble, and their elimination requires biotransformation into more water-soluble compounds. This is mostly performed by phase I and phase II biotransformation enzymes. In the phase I reaction, oxidation or demethylation occurs, usually performed by cytochrome P450 (CYP450) enzymes. The compound is still not very water soluble and requires further metabolism. Phase I reactions often produce toxic intermediates. In a typical phase II reaction, a large water-soluble compound is attached by glucuronidation or sulphation, resulting in nontoxic metabolites that can be easily eliminated. A third metabolic step for detoxification involves glutathione, which can covalently bind to toxic compounds by the enzyme glutathione S-transferase [109].

Human genetic studies have shown that cytochrome P450 2E1 (CYP2E1) is involved in anti-TB drug–induced liver toxicity [110,111]. The CYP2E1 cl/cl genotype is associated with a higher CYP2E1 activity and may lead to a higher production of hepatotoxins. Rat studies showed that isoniazid and hydrazine induce CYP2E1 activity [112,113]. INH has an inhibiting effect on CYP1A2, 2A6, 2C19, and 3A4 activity [114]. CYP1A2 is suggested to be involved in hydrazine detoxification [112,113]. INH can induce its own toxicity, possibly by the induction or inhibition of these enzymes. Thus, INH-induced hepatotoxicity is the interplay of acetylation by NAT2, oxidation by cytochrome P450 oxidase (CYP2EI), and detoxification by glutathione S-transferase (GST).

36.10.1.7 Genetic Susceptibility to Drug-Induced Liver Injury

Kim and others adopted a candidate gene approach to identify genetic susceptibility to anti-TB drug–induced hepatitis, by studying the association of genetic polymorphisms in phase I and II drug-metabolizing enzymes with anti-TB drug–induced hepatitis [115]. In 67 cases and 159 controls, the researchers compared genotype distributions of tagging SNPs in promoters, exons, and haplotypes in seven drug-metabolizing enzyme genes (*CYP2C9*, *CYP2C19*, *CYP2D6*, *CYP2E1*, *NAT2*, *UGT1A1*, and *UGT1A3*). They observed that among four tagging SNPs of *NAT2*, −9796T > A in promoter and R197Q, were significantly associated ($p = 0.0016$ and $p = 0.0007$, respectively). *NAT2* haplotype 2 (A-A-A-G), carrying the A allele of −9796T > A and the A allele of R197Q, showed significant association ($p = 0.0004$). However, there was no significant association between genotypes of other enzyme-metabolizing genes and anti-TB drug–induced hepatitis. The constructs containing −9796A of *NAT2* showed significant lower luciferase activity ($p < 0.01$), suggesting decreased *NAT2* expression. The variant alleles and haplotype 2 showed significantly higher peak serum INH levels, a lower acetyl INH:INH ratio, and lower INH clearance, compared with wild types.

Kim and colleagues suggested that genetic variants in the promoter and exons of *NAT2* increase the risk of anti-TB drug–induced hepatitis by modifying acetylation phenotypes and/or gene *NAT2*expression, and that there is no essential role for genetic mutation of the other metabolizing enzymes in the development of this adverse reaction [115]. Further, their study showed that there were no significant differences in the levels of RMP, PZA, and EMB according to *NAT2* genotype.

Yimer and others [116] reported on the susceptibility of coinfected Ethiopian patients to drug-induced liver injury (DILI) when receiving efavirenz-based antiretroviral therapy (ART) for HIV in the face of RMP-based anti-TB therapy. The overall incidence of liver injury in this population was 30%, with more than half being severe cases. Yimer and colleagues' findings in a prospective case-control study indicated that patients with higher efavirenz plasma levels were at higher risk for DILI, with genetic predictors that included having the slow acetylator *NAT2* genotype and the *ABCB1* 3435TT genotype. Hence, it was suggested that pharmacogenetic testing be employed before initiation of ART and anti-TB therapies in order to identify the patients at risk.

36.10.1.8 NAT2 Polymorphisms

One study reported a 28-fold higher risk of INH-induced hepatotoxicity in slow compared to rapid acetylators in Japanese and Taiwanese populations [104]. Another study, of a Korean population, observed that *NAT2* slow acetylators had a 3–8-fold increase in this risk ($p = 0.005$). The latter study suggested that *NAT2* genotyping might serve as a useful tool to predict anti-TB drug–induced hepatotoxicity [117]. Slow *NAT2* acetylator status as a risk factor was observed in a study conducted in Tunisian patients with TB; it was concluded that diplotypes, *NAT2*53/5B*, *NAT2*6A/6A*, 481T/T, and 590A/A may serve as useful biomarkers predicting this condition [118]. A retrospective study of 102 Japanese TB patients showed that the occurrence of side effects was greater in slow acetylators than in rapid/intermediate acetylators [119]. A recent meta-analysis by Wang and coworkers of 14 studies, comprising 474 cases and 1446 controls, showed a significant association between *NAT2* slow acetylators and anti-TB-drug–induced liver toxicity risk [70]. The OR for *NAT2* slow acetylators compared with rapid acetylators was 4.7 (95% CI 3.3–6.7; $p < 0.001$). Subgroup analysis indicated that both Asian and non-Asian slow acetylators develop liver damage more frequently. On comparing *NAT2* intermediate acetylators and rapid acetylators, the OR was 1.3 (95% CI 0.93–1.71; $p < 0.14$). Another subgroup analysis for different treatment regimens showed that the combined ORs for INH + RMP, INH + RMP + PZA + EMB and INH were, respectively, 34.3 (95% CI 10.4–113.0; $p < 0.001$), 4.1 (95% CI 2.8–6.0; $p < 0.001$), and 2.4 (95% CI 0.52–10.73; $p < 0.27$) on comparing *NAT2* slow and rapid acetylators [70].

Contrary to these findings, a case-control study undertaken in TB patients of Caucasian origin did not find any association between increased risk of anti-TB drug–induced liver injury and the presence of slow *NAT2* polymorphisms [120]. Moreover, genotyping studies in an Indian population [121] and in a heterogenous population consisting of Hispanics, Africans, Caucasians, South Americans, and Asians [111] reported a lack of association between INH-induced hepatotoxicity and *NAT2* acetylator status.

36.10.1.9 CYP2E1 Polymorphisms

CYP2E1 is an enzyme of the hepatic microsomal enzyme system. It brings about conversion of acetyl hydrazine to hepatotoxins—namely, acetyl diazene, ketene, acetylonium ion, and the like [122]. It has been proposed that INH or its hydrazine metabolite may induce *CYP2E1* activity in rat; this activity is driven by blood INH levels [122]. On the other hand, INH may also inhibit *CYP2E1* activity, this being more prominent in individuals with the *CYP2E1* variant genotype [110]. Two point mutations in *CYP2E1*'s 5′ flanking region (PstI, RsaI sites) were found to be associated with higher transcription and increased enzyme activity [123]. Individuals with *c1* allele exhibited higher transcriptional activity, protein level, and enzymatic activity than those with the *c2* allele.

The DraI polymorphism has been reported to be located in intron 6 of *CYP2E1*, which has been shown to be linked with other polymorphic sites in the exonic region [77]. Further, the *c1/c1* genotype significantly increased the risk of anti-TB drug–induced hepatotoxicity when combined with the slow acetylator *NAT2* genotype. This was attributed to the fact that, in slow acetylators, less acetyl hydrazine is detoxified by NAT2-catalyzed acetylation and thus more acetyl hydrazine is oxidized by *CYP2E1* into toxic intermediates [68].

For a Chinese population, Lee et al. [124] reviewed 140 cases of patients treated for TB and found that slow acetylators defined by *NAT2* genotypes had a higher risk of anti-TB–induced liver injury as opposed to fast acetylators. They also concluded that *CYPE1* was associated with the severity of this condition. A study from Taiwan showed that the common **1A/*IA* genotype of *CYP2E1* enhanced the odds of INH-induced liver toxicity by 2.5 times in adult TB patients [110]. Further, a combination of the **1A/*1A* genotype and *NAT2* slow acetylation status increased these odds (OR 7.43; 95% CI 2.4–22.8) compared with the presence of any one polymorphism. Another study in Indian pediatric patients observed that the risk of liver toxicity was enhanced by the variant *CYP2E1*6* allele and the **IA*6*ID* haplotype at *CYP2E1* (OR 11.0; 95% CI 1.02–11.0 and OR: 4.6; 95% CI 1.3–16.3, respectively) [125]. The common **IA* allele at *CYP2E1* that increases liver enzyme levels was observed in a heterogenous group of Asians, Africans, Caucasians, South Americans, Hispanics, and Africans [120]. However, a study of a Korean population did not find any such association [117].

Teixeira and others [126] studied *NAT2*, *CYP2E1*, and *GST* gene polymorphisms in 167 patients undergoing TB treatment. The slow acetylators had a higher incidence of hepatitis than the moderate or rapid acetylators, as related to polymorphisms in those specific genetic loci. An and others [127] also looked at *NAT2*, as well as the P450 *CYP2E1* mentioned previously. Their results also revealed that subjects with *NAT2* alleles had an increased susceptibility to liver injury from anti-TB medication—specifically, those who had the slow acetylator type *NAT2*. They also found the *CYP2E1* genotype to be significantly involved with susceptibility to hepatotoxicity unless it was combined with the slow *NAT2* acetylator.

Another study by An and others [128] evaluated 101 patients who experienced anti-TB drug–induced liver injury and revealed that those with the 282 T/T, 590A/A, 857 G/A, or *857A/A* genotypes were more likely to develop it. Variant diplotypes *NAT2*5B/5B*, and *NAT2-6A/6A* were found by Ben Mahmoud and coworkers [118], in their study of 14 patients with anti-TB drug–induced hepatotoxicity, to be more frequent and that, overall, slow acetylator *NAT2* alleles were more susceptible to hepatotoxicity from these drugs.

Not all investigators have found such consistent observations. For example, Tang et al. [129] evaluated 4304 patients who had undergone anti-TB therapy and found no statistically significant positive association with the *CYP2E1* or *GSTM1* and *GSTT1* genetic polymorphisms.

36.10.1.10 GSTM1, GSTT1 Polymorphisms

The GSTs are a group of enzymes that are involved in the detoxification of carcinogens, toxic chemicals, and medications [130]. They bring about the conjugation of glutathione and the substrate for solubilization and elimination from the body. The GST enzymes are coded by at least five distinct loci. Of these, *GSTM1* and *GSTT1* are reported to be associated with hepatotoxicity [131]. GSTs are reported to play a key role in INH metabolism. Glutathione serves as an intracellular scavenger of free radicals by conjugating with toxic INH metabolites. Inadequate GST activity due to homozygous deletion at the *GSTM1* and *GSTT1* loci can influence susceptibility to INH-induced liver toxicity.

The risk of INH-induced hepatotoxicity has been shown to be increased (OR 2.13; 95%CI 1.25-3.10) in Indian patients with the *GSTM1* homozygous mutation [121]. Also, while Taiwanese patients with *GSTM1* homozygous deletion had twice the risk of this condition, such risk did not occur in those with the *GSTT1* homozygous deletion [117,131]. Similar studies with reasonable sample sizes should be carried out in different ethnic populations. Identifying patients with the *GSTM1* homozygous deletion may help in preventing DILI and better management of it when it occurs.

36.10.1.11 UDP Polymorphisms

Chang and coworkers [132] examined the association of genetic variations of UDP glucuronosyl transferase (A) (UGT1A1) and anti-TB drug–induced hepatotoxicity. In their series of 17 patients, UGT1A1*28 compounds were related to increased DILI risk.

36.10.1.12 TNF-Alpha Polymorphisms

Tumor necrosis factor (TNF) -alpha plays an important role in immune responses [133]. Kim et al. [134] studied its impact on hepatotoxicity. Seventy seven patients with anti-TB drug–induced live injury in their study were found to have a higher frequency of the genotype TNF-alpha-308 G/A compared to patients on the same drug regimen who did not develop hepatotoxicity.

36.10.1.13 Manganese Superoxide Dismutase

It is known that hepatic damage can be caused by reactive oxygen species (ROS) that are formed from various reactions. Manganese superoxide dismutase (MnSOD) brings about a decrease in ROS load in mitochondria. A study from Taiwan showed that genotypes with the variant C allele (the T > C polymorphism at codon 47; alanine > valine) enhanced the risk of anti-TB drug–induced liver toxicity [131]. This is probably because, along with the variant amino acid, valine, at codon 47, it augmented the formation of toxic hydrogen peroxide, which can lead to DILI.

36.10.1.14 Human Leucocyte Antigen Alleles

The lack of HLADQA1*0102 and the existence of the DQB1*0201 alleles have been reported to have an independent association with enhanced risk of anti-TB–induced hepatotoxicity in Indian patients [135].

36.10.2 Rifampicin

Rifampicin (RMP) is an important first-line drug used to treat TB. It has demonstrated concentration-dependent activity against *M. tuberculosis* under *in vitro* and *in vivo* conditions [136]. Marked intersubject variations in RMP levels are reported to occur, but the basis for variation has not been well characterized. Weiner and colleagues undertook a pharmacokinetic study to explore why huge inter-individual variations in RMP levels are seen in patients receiving standard treatment dosages [72].

Organic anion transporter peptides (OATPs) play an important role in the transport and disposition of drugs in the human system. RMP is a substrate of these drug transporters, which include p-glycoprotein and OATP1B1. Nuclear receptors—namely, pregnane X receptor (PXR) and constitutive androstane receptor (CAR)—transcriptionally regulate drug transporters. The pharmacokinetics of RMP was compared between TB patients and healthy subjects, between regions (African and non-African), and between races (black and all others).

The relationship between RMP pharmacokinetics and polymorphisms of drug influx and efflux transporter genes—anion-transporting polypeptides (*SLCO1B1*-463C > A and 521T > C and *SLCO1B3*) and p-glycoprotein (*ABCB1*)—was also studied [72]. The findings from a study of 72 adult pulmonary TB patients from North America, Africa, and Spain showed that polymorphisms in the *SLCO1B1* gene had a significant influence on RMP exposure: 36% lower among SLCO1B1 463 CA genotypes than among CC genotypes (29.8 versus 46.7 μg.h/ml; $p = 0.001$) [72]. Further, *SLCO1B1* gene polymorphisms related to reduced RMP exposure were more pronounced in black subjects. This study was the first to report an association between RMP exposure and *SLCO1B1* 463 C>A gene polymorphism. Marked interindividual RMP exposure variations were probably due to this polymorphism.

Chigutsa and others undertook a study of South African TB patients to examine the impact of *ABCB1*, *SLCO1B1*, *PXR*, and *CAR* polymorphisms on RMP pharmacokinetics [73]. Patients heterozygous and homozygous for the variant allele of *SLCO1B1* rs4149032 polymorphism, showed decreases in RMP bioavailability of 20% and 28%, respectively. This polymorphism explained 21% of the between-subject variability in drug clearances. Simulations revealed that an increased RMP dose of approximately 30% in patients harboring the polymorphism resulted in plasma RMP levels similar to those with the wild-type allele, with a typical peak concentration above the recommended minimum of 8 μg/ml. The other polymorphisms—*ABCB1*, *PXR*, and *CAR*—however, did not have any significant impact on RMP pharmacokinetics. This study suggested that an increase in RMP dose is desirable for *SLCOB1B1* carriers. More studies in different populations are required to understand the role of *SLCOB1B1* polymorphisms in influencing RMP plasma concentrations and their role in influencing TB treatment outcomes.

36.10.3 Aminoglycosides

Aminoglycosides (e.g., streptomycin, kanamycin, and amikacin) are used in TB treatment. Ototoxicity is an adverse event that may result from the use of aminoglycosides. Mutations in mitochondrial DNA (mt DNA) have been found to be associated with both aminoglycoside-induced and nonsyndromic deafness. The A1555G mutation has also been found in a number of families and patients with sporadic aminoglycoside-induced severe or profound hearing loss [74,137]. It lies in the conserved decoding region of small ribosomal RNA, which is important for aminoglycosides action [138].

In fact, the new C1494-1555G pair in 12S rRNA created by the A1555G mutation facilitates the binding of aminoglycosides to mitochondrial 12S rRNA [139]. Functional studies demonstrated a decrease in the growth rate of lymphoblastoid cells derived from symptomatic and asymptomatic members of the Arab-Israel pedigree in the presence of a high concentration of neomycin or paromomycin [140]. In addition, a C insertion or deletion at position 961 of the 12S rRNA gene has been shown to be associated only with aminoglycoside-induced deafness [141]. These data strongly indicate that the human mitochondrial 12S rRNA, particularly that carrying the A1555G mutation, is the main ototoxic target for aminoglycoside antibiotics. Mutations at positions 1555 and 961 in the 12S rRNA gene account for only a small portion of patients with aminoglycoside-induced hearing impairment.

Zhao and others undertook a molecular characterization study in a Chinese family with aminoglycoside-induced and nonsyndromic hearing loss to understand the association between aminoglycoside-induced ototoxicity and mitochondrial mutations. It was observed that a C>T transition at position 1494 in the mitochondrial 12S rRNA gene was responsible in individuals genetically predisposed to ototoxicity [74]. This mutation is localized at the A site of the mitochondrial 12S rRNA [138,142], which has been implicated to be associated with aminoglycoside ototoxicity [139]. It is likely that the deafness phenotype linked to the C>T 1494 12S rRNA gene polymorphism can be induced or made worse by aminoglycosides.

36.10.4 Predicting Drug–Induced Liver Injury

Considerable research continues to be directed toward identifying genetic and other risk factors for drugs causing idiosyncratic drug-induced liver injury [143]. Among the most commonly reported drugs causing severe drug-induced liver are microbial agents such as INH and other anti-TB drugs. Being able to predict individuals who break down with injury remains a major research focus. Classic clinical predictors were studied by Singla and others [144], who evaluated 175 cases of anti-TB drug–induced liver injury and found that subjects above 35 years of age and with poor nutritional status were independent risk factors.

36.11 CONCLUSION

Although genetic polymorphisms are known to impact drug effects, individualized drug therapy is seldom used in clinical practice. The cornerstone of TB management is a six-month course of INH, RMP, PZA, and EMB. Compliance is crucial for curing TB. Adverse events often negatively affect compliance, and this can impact treatment outcome. As for anti-TB drugs, genetic factors are known to influence INH metabolism and disposition; this alters INH levels in different patients to varying degrees and puts some of them at greater risk for liver toxicity. Determining INH acetylator status will aid clinicians in identifying patients at higher DILI risk. Close monitoring of these patients might prove useful in reducing the occurrence of adverse drug effects and enhancing treatment success. In the long run, it will probably decrease healthcare costs.

Pharmacogenomic studies have the potential to achieve this by translating genome variability into improved therapeutics. Importantly large clinical trials will be needed to prospectively evaluate the merits of genotyping and of adjusting TB drug dose during treatment. These studies must link pharmacogenetic data with TB treatment outcomes.

The US Food and Drug Administration now requires genetic testing prior to treatment with abacavir and carbamazepine (in patients of Han Chinese or Thai origin) and with a few other drugs for cancer therapy [145]. This shows that pharmacogenetics is becoming more common in clinical practice. New developments in genotyping technologies, including next-generation sequencing and epigenetics will move the field of pharmacogenetics forward. However, one has to keep in mind the cost-effectiveness and feasibility of integrating pharmacogenomics in routine practice. It is important to establish the benefits of genetic testing and individualized treatment before it becomes a routine exercise.

37.1 OVERVIEW

The human genome contains about 3 billion nucleotides, which are the building blocks of DNA. Although it is mostly conserved in the population, variation in the nucleotide sequence between individuals may lead to differences in gene expression or function. During the past decade, spectacular progress in technology and bioinformatics has profoundly changed the way human genetic research can be performed. Building on the success of the Human Genome Project, in which the 3 billion nucleotides constituting our genome were first decoded [1], the international research community has continued working together to catalog the genomic variation present at the population level through the HapMap project [2]. This effort has not only resulted in a wealth of new information about human diversity, but has also represented a key step in the development of genome-wide association studies (GWASs). In a GWAS, scientists search for statistical associations between variants present in the genome and any phenotype of interest, typically disease susceptibility, but more recently drug response and toxicity, hoping to identify changes that can help personalize patient care and lead to a better understanding of underlying pathophysiological mechanisms.

The most common form of genetic variation in the human genome is the single-nucleotide polymorphism (SNP). There are more than 10 million common SNPs in any given population, where a "common SNP" has a minor allele frequency of ≥5%. The HapMap project defined patterns of linkage disequilibrium (LD) between SNPs. LD describes the tendency of neighboring variants to be inherited together as part of genomic blocks called haplotypes (Figure 37.1). This allows SNPs to be identified that "tag" haplotype blocks and indirectly represent multiple other SNPs (tag SNPs). The SNPs genotyped on a GWAS chip are selected to represent haplotypes across the entire genome, covering common variants for all genes, and they contain information about almost all common variants present in human populations. The genome-wide genotyping chips used in GWASs contain hundreds of thousands—now up to 5 million—tag SNPs.

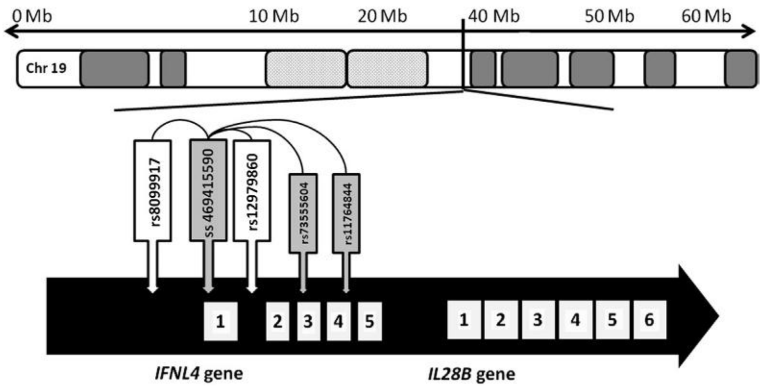

FIGURE 37.1 **GWAS use of tag SNPs to identify loci associated with a phenotype of interest.** rs12979860 and rs8099917 were the two SNPs identified in the original discovery studies that tag a haplotype in the region of the *IL28B* gene on chromosome 19. Recent data suggest that they may in fact tag the newly identified *IFNL4* gene, which is upstream of *IL28B* [44]. ss469415590 is in strong linkage disequilibrium with rs12979860. Two additional nonsynonymous variants in *IFNL4* have subsequently been identified: rs73555604 (p.Cys17Tyr), and rs11764844 (p.Pro70Ser), which may modify risk in carriers of the unfavorable ss469415590[ΔG] [44].

It is this ability of tag SNPs to indirectly represent non-genotyped SNPs that makes the technology truly genome-wide and particularly attractive for non-a-priori discovery genetic studies. This is the scientific approach that was used to identify the association between genetic variation in the *IL28B* gene region and peginterferon-α (pegIFN) and ribavirin (RBV) treatment response in patients chronically infected with the hepatitis C virus (HCV), as well as spontaneous clearance of acute HCV infection.

37.2 *IL28B* POLYMORPHISM AND HCV OUTCOMES

37.2.1 Genotype 1 HCV Treatment Outcome

Four genome-wide association studies published in late 2009 and early 2010 independently identified a strong association between genetic variation in the region of the *IL28B* gene and pegIFN and RBV treatment response in patients chronically infected with genotype 1 HCV (HCV-1).

The first genome-wide analysis of common genetic variants associated with HCV-1 outcome interrogated 1604 patients from the IDEAL study. This was a large phase 4 comparative effectiveness study of the two commercially available pegIFN preparations (pegIFNα-2b versus pegIFNα-2a) in North American patients chronically infected with HCV-1 [3]. A further 67 patients were enrolled from a second randomized clinical trial that evaluated the efficacy of pegIFNα-2b plus RBV in Caucasians versus African Americans [4]. Samples were genotyped using the Illumina Human610-Quad BeadChip (Illumina, San Diego, CA). The primary analysis for treatment outcome compared sustained virological response (SVR) to true biological nonresponse in 1137 patients of European American (n = 971), African American (n = 191), or Hispanic (n = 75) ancestry. Biological nonresponse was defined as no SVR despite adherence ≥80%. Seven SNPs on chromosome 19 in the region of the *IL28B* gene, coding for IFN-λ-3, met the threshold for Bonferroni-corrected genome-wide significance [3].

The top discovery SNP was rs12979860, located 3 kb upstream of the *IL28B* gene and having a p-value for association of 1.06×10^{-25} in European Americans ($p = 1.37 \times 10^{-28}$ combined across the three ethnic populations). This is a bi-allelic polymorphism with three possible genotypes (C/C, C/T, and T/T). In this adherent cohort, the good-response C/C *IL28B* variant was associated with a 2-fold increase in SVR rate in all ethnic groups. Although the heterozygote C/T variant was associated with a small increase in SVR rate compared to the T/T variant, the difference was not clinically meaningful. Six other SNPs exceeded the statistical threshold for genome-wide significance, including the polymorphism rs8099917. All displayed different degrees of LD with rs12979860, and their effects were largely explained by this polymorphism. None of these seven associated SNPs were obviously functional.

A number of other important observations were made in this cohort. The *IL28B* polymorphism was associated with early viral decline on treatment, with higher rates of viral clearance at week 2, week 4, and week 12 in patients with the good-response *IL28B* genotype (Figure 37.2) [5]. This has since been shown to be a dominant effect on phase 1 kinetics, with clear differences in viral load reduction as early as 24 hours following the first injection of pegIFN [6]. The favorable C/C genotype was more common in European Americans compared to African Americans, and it was estimated that this difference in genotype frequency was responsible for more than half of the discrepancy in treatment response rates between the two populations.

FIGURE 37.2 Data from Caucasian patients treated with pegIFN and RBV in the IDEAL pharmacogenomics cohort (intent-to-treat analysis) [5]. (a) Virological response rates according to *IL28B* genotype (rs12979860). This genotype is a *pretreatment* predictor of on-treatment virological milestones, including RVR and cEVR, as well as SVR. (b) SVR rates according to on-treatment response and *IL28B* genotype. RVR and cEVR remain important *on-treatment* predictors of IFN treatment outcomes. The *IL28B* genotype frequency for each responder group is shown in the pie chart. RVR4—rapid virological response, undetectable HCV RNA at week 4; cEVR—complete early virological response, undetectable serum HCV RNA at week 12; pEVR—partial EVR, >2 log reduction in serum HCV RNA from baseline to week 12 but persistent viraemia. *Non-RVR4—cEVR + pEVR + NR.

In fact, the frequency of the protective allele is now recognized to be highly divergent between ethnic groups, with Asians > Caucasians (Northwestern Europe > North America) > Hispanics > Africans [7,8] (Figure 37.3). This is generally consistent with the pegIFN and RBV response rates that have been observed in different populations [4,9].

The *IL28B* polymorphism was also implicated in spontaneous clearance of HCV infection. The C allele frequency in the study population was lower than in healthy controls, suggesting selection away from the protective allele. Finally, a genome-wide analysis of pretreatment viral load set point identified rs12979860 as the only common variant associated with HCV viral load, with the good-response genotype associated with a higher viral load [7]. This apparently paradoxical association may be explained by patterns of intrahepatic IFN-stimulated gene (ISG) expression, to be discussed.

A second GWAS conducted in HCV-1-infected patients of European ancestry (Australian/Western Europe) also identified an important role for the *IL28B* gene region in determining HCV treatment response [10]. Investigators tested for polymorphisms associated with SVR in a clinic population. Adherence to therapy was not specifically defined. A 2-stage approach was taken (discovery, $n = 293$/replication, $n = 555$). The discovery GWAS was performed using the Illumina CNV 370-Quad BeadChip or the Illumina Infinium HumanHapMap300. A total of 172 SNPs were taken forward for replication, selected on the basis of a p-value for association $<10^{-5}$, or $p < 10^{-3}$, and immune-regulatory/antiviral function. The polymorphism rs8099917 exceeded the threshold for genome-wide significance in the analysis of the combined cohort (OR 1.98 [1.57–2.52], $p = 9.25 \times 10^{-9}$). rs12979860 was not included on the genotyping chip and was not tested.

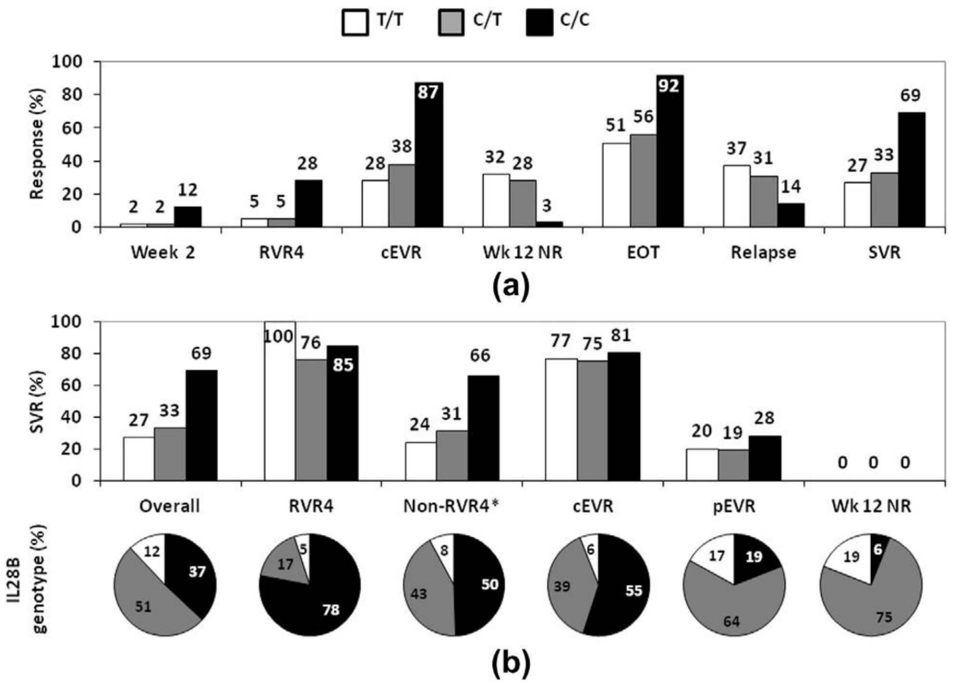

FIGURE 37.3 World map of rs12979860 allele frequency. *Source: From Thomas et al.* [8].

Japanese investigators conducted a third GWAS in an HCV-1B population [11]. The 2-stage design included a discovery cohort of 154 Japanese patients and an ethnically matched replication cohort of 172 patients. The Affymetrix SNP 6.0 genome-wide SNP typing array (Affymetrix, Santa Clara, CA) was used. The analysis tested for variants associated with null virological response (NVR) (defined as serum HCV RNA reduction <2log$_{10}$ IU/mL at week 12 of therapy and detectable HCV RNA at week 24). Adherence >80% during the first 12 weeks of treatment was required for inclusion. Two SNPs in the *IL28B* gene region were strongly associated with NVR, rs8099917, and rs12980275 (combined $p = 2.68 \times 10^{-32}$, OR 27.1 [14.6–50.3] and $p = 2.84 \times 10^{-27}$, OR 17.7 [10.0–31.3], respectively). Again, the tag SNP rs12979860 was not genotyped. The large ORs observed can be explained by the extreme phenotype—virtually no patients homozygous for the good-response allele qualified for NVR (also noted in the IDEAL cohort, where <5% of patients with the good-response genotype were NVR) [7,11]. In a secondary analysis, the SNPs rs8099917 and rs12980275 were confirmed to be associated with SVR versus no SVR.

Finally, the results of a fourth GWAS, by Rauch and colleagues, came from the Swiss Hepatitis C and HIV Cohort Studies. Although the primary aim of this study was to analyze genetic predictors of spontaneous clearance (see Section 37.2.2), the control cohort of patients with persistent HCV infection included 465 individuals for whom pegIFN and RBV treatment response data were available. All patients were ≥80% adherent to therapy. Patients were infected with HCV-1/4 (n = 188/34) or HCV-2/3 (n = 60/162). Genotyping was performed using the Illumina Human1M-Duo, HumanHap550, or Human610W-Quad BeadChips. *IL28B* genotype was significantly associated with treatment response (rs8099917, $p = 3.11 \times 10^{-8}$).

Multiple retrospective candidate gene studies have since replicated the observation that a polymorphism within a common haplotype in the region of the *IL28B* gene is a key predictor of treatment response in genotype 1 HCV [12–21].

37.2.2 Spontaneous HCV Clearance

The *IL28B* polymorphism is strongly associated with spontaneous clearance of acute HCV infection. Thomas and colleagues evaluated *IL28B* genotype (rs12979860) frequency in a large cohort of individuals with either spontaneous clearance of HCV (n = 388) or persistent HCV infection (n = 620). The frequency of the good-response C/C genotype was strongly associated with spontaneous clearance in both white and black patients (OR = 3.0 [2.2–4.0], $p = 3 \times 10^{-13}$). The effect of the locus on spontaneous clearance was similar between patients of European and African ancestry, and was not altered by HBV or HIV coinfection. A genome-wide association study of spontaneous HCV clearance subsequently provided independent validation of this association (rs8099917, OR = 2.3 [1.7–3.1], $p = 6.1 \times 10^{-9}$). *IL28B* variants were the only common variants associated with natural clearance [22]. The association between *IL28B* genotype and spontaneous clearance has now been confirmed in multiple replication cohorts [23–25].

37.2.3 *IL28B* Polymorphism and Other Clinical Phenotypes

Studies have investigated the association between the *IL28B* polymorphism and a number of other clinical and laboratory phenotypes, including liver histology, necro-inflammatory activity, fibrosis, and steatosis, as well as serum lipid levels.

Further exploration of the IDEAL pharmacogenomics cohort identified *IL28B* polymorphism to be associated at the genome-wide level with serum ALT level as well as necro-inflammatory activity on liver biopsy, where the good-response variant was associated with a higher-level serum ALT as well as higher-grade activity [26]. No other common variants were associated with either ALT level or hepatic necro-inflammation. There was no significant association between the *IL28B* genotype and METAVIR fibrosis stage in the same cohort [27]. Similarly, there was no significant association noted between *IL28B* genotype and fibrosis stage in a second cross-sectional study of 496 Japanese patients [28]. No relationship between *IL28B* genotype and fibrosis progression rate over time was noted in an Italian study of 297 patients in longitudinal follow-up [29]. However, A second study from Japan reported a positive correlation between the good-response variant and both histological activity and liver fibrosis stage (F2-4) [30]. The good-response *IL28B* genotype (rs12979860) was also associated with more prevalent cirrhosis, as defined by Fibroscan >15.5 kPa, in a Spanish cohort of patients with HCV-HIV coinfection [31]. In other series, the poor-response *IL28B* genotypes was linked to advanced liver fibrosis [32,33], although this may reflect selection bias for patients who have failed antiviral therapy.

As can be seen, the existing data, mostly cross-sectional, that link *IL28B* genotype to liver fibrosis stage are conflicting. There is a need for more prospective studies that test for genetic associations with fibrosis progression rate.

Chronic infection with HCV has been associated with low serum lipid levels and hepatic steatosis, both of which correct after viral eradication. The *IL28B* polymorphism was recently associated with both dyslipidemia and hepatic steatosis in the setting of HCV-1 infection. Serum total cholesterol (TC), low-density lipoprotein (LDL), and apolipoprotein B levels have been reported to be significantly lower in patients with the poor-response *IL28B* genotypes [34,35]. Interestingly, this relationship is no longer present following viral eradication [36]. The poor response *IL28B* genotypes have also been associated with greater degrees of hepatic steatosis in HCV [35,37]. This might suggest a common mechanism linking *IL28B*, lipid metabolism, and hepatic steatosis. The researchers hypothesized that these associations might be explained by levels of intrahepatic ISG expression (see later), consistent with the known effect of exogenous IFN to reduce serum LDL levels [38].

37.2.4 Mechanistic Studies and *IFN-lambda-4*

The mechanism by which *IL28B* variants influence IFN responsiveness was not identified by the discovery GWASs. The studies generated a number of key questions, among them: What is the causal variant, and how does this mediate the downstream immunological phenotype?

Initial attempts to identify a causal variant focused on pure genetic approaches, using association statistics in the discovery studies. They were largely unsuccessful because of the high linkage disequilibrium in the region [7,39]. Putative causal variants were identified by fine mapping/resequencing. These included a nonsynonymous coding variant in exon 2 of *IL28B* (rs8103142), a variant near the translation initiation codon (rs28416813, G>C), two promoter SNPs (rs4803219, C>T; rs28416813, C>G) and two 3′-UTR SNPs (rs4803217, C>A; rs581930, C>T). All are in very high LD with the top discovery tag SNPs [7,39]. Functional studies of the most likely candidate, rs8103142, have not confirmed any differential role in *IL28B* innate immune stimulation or antiviral efficacy [40]. Differential expression of *IL28B* has not been demonstrated in stimulated hepatocytes, infected hepatocytes [40–43], stimulated immune cells, or immune cells of individuals infected with HCV [43].

Very recently, it has been proposed that the GWAS discovery polymorphisms may in fact tag a new gene, *interferon-lambda-4* (*IFNL4*) [44]. A dinucleotide polymorphism (ss469415590, ΔG/TT) has been identified upstream of *IL28B* that creates (ΔG) or disrupts (TT) an open reading frame in *IFNL4*. Individuals who carry the ΔG allele can generate the IFNL4 protein. IFNL4 is not produced by individuals who are homozygous for the TT allele because of a frameshift in exon 1 caused by the insertion variant. ss469415590 is in strong linkage disequilibrium (LD) with the previously identified tag SNPs in individuals of European or Asian ancestry—rs12979860 is actually located within intron 1 of *IFNL4* (Figure 37.1) [44].

In contrast, linkage disequilibrium is only moderate in individuals of African ancestry [44]. This weaker LD has been exploited to show that, in African American individuals, ss469415590 appears to be more closely associated with IFN responsiveness as well as with spontaneous clearance of HCV, than is rs12979860 [44,45]. The ΔG *IFNL4* allele was more closely associated with outcome than the poor-response T allele of rs12979860. The data are consistent with a critical role for IFNL4 in regulating exogenous IFN response, with the simple hypothesis that ss469415590 determines the expression of IFNL4, and that IFNL4 negatively regulates type 1 IFN signaling.

Rarely is biology simple, however. Haplotype analysis has shown that, although the ss469415590 TT allele is present on a unique favorable haplotype, the unfavorable ΔG allele occurs on a number of haplotypes, including two that were previously reported to be neutral in Europeans despite carrying the unfavorable rs12979860 T allele [46,47]. If ss469415590 alone explains IFN responsiveness, all haplotypes carrying the ΔG allele should have equal risk. The genetics may therefore be more complicated.

Two nonsynonymous variants in *IFNL4* have subsequently been identified—rs73555604 (p.Cys17Tyr) and rs11764844 (p.Pro70Ser)—that may mitigate the effect of the IFNL4 protein [44]. Discordant haplotypes were noted to include minor alleles of either variant [44]. This requires further investigation. Although the data are compelling, we refer to the *IL28B* polymorphism rather than the *IFNL4* polymorphism in the rest of the chapter, given that the existing literature has been generated using *IL28B* genotyping.

IL28B and IFNL4 are both members of the type 3 IFN family [48], also known as the IFN-lambda family (including IL29 (IFNL1), IL28A (IFNL-2) and *IL28B* (IFNL3), and IFNL4). Expression of type 3 IFNs is triggered by most stimuli that induce type 1 IFN, and both cytokine families activate similar downstream signaling pathways to induce ISGs. Type 3 IFNs inhibit viral replication *in vitro* and *in vivo*, and recombinant IL29 is currently in phase 2/3 clinical development for the treatment of both HCV and HBV [49]. A key point of distinction from the type 1 IFN axis is that IFNL1–3 signal via the unique type 3 IFN receptor. In contrast to the ubiquitous type 1 IFN receptor, the distribution of the type 3 IFN receptor appears to be tissue-dependent; it is expressed at a high level in liver and epithelial cells but at a low level in hemopoietic cells and in the central nervous system. Type 3 IFN inhibits HCV replication in cell culture models [16,17] as well as *in vivo* [18]. Recent data suggest that type 3 IFN may be the dominant IFN produced by the liver in response to HCV infection [19,20].

IFNL4 is the newest member of the type 3 IFN family. Although it is more similar to the members of the IFN-lambda family (IL28A, IL28B, and IL29, or IFNL1–3) than is any other protein, it shares only 29% amino acid identity and is therefore very different [44]. In primary human hepatocytes, IFNL4 is transiently transcribed and translated following stimulation with poly (I:C), an analog of viral double-stranded RNA. Expression of IFNL4 in HepG2 cells leads to induction of ISGs via the Janus kinase-signal transducers and activators of the transcription (JAK-STAT) pathway. Somewhat surprisingly, treatment of cells with recombinant IFNL4 does not stimulate the JAK-STAT pathway, suggesting that this pathway is activated by cytoplasmic expression intracellularly. This makes it distinct from the other members of the type 3 IFN family, which signal via the external type 3 IFN receptor. Again, further functional studies are required in this very novel and fertile area.

Regardless of the exact genetic mechanism, it is likely that intrahepatic ISG expression is central to the biology involved. The favorable *IL28B* genotype has been associated with low-level ISG expression in the liver [40–42], consistent with the historical observation that low levels of liver ISG expression predict for rapid IFN treatment response [50]. Conversely, unfavorable *IL28B* genotypes are associated with higher-level intrahepatic ISG expression and poor responsiveness to exogenous pegIFN therapy. Low-level intrahepatic ISG expression might also explain the observation that the favorable *IL28B* variant is associated with a higher viral load set point [7]. Differential expression of intrahepatic ISGs may now be explained by the presence, or absence, of IFNL4 expression; this needs to be confirmed *in vivo*. The *IL28B* genotype has also been associated with NK cell activity [26] as well as with peripheral blood mononuclear cell markers of innate immunity [43]. Further investigation of the relationship between the *IFNL4*/*IL28B* genotype, hepatic ISG expression, and immunological phenotype is therefore required.

We are only just starting to understand the biological mechanism for the *IL28B* association. The innate immune system is implicated by the strong association with phase 1 kinetics, the intrahepatic ISG data, and, as discussed later, the observed association between donor liver IL28B genotype and IFN response in the post–liver transplant setting. Detailed *ex vivo* and *in vitro* experiments will be required, opening up a new field of *IL28B* immunovirology.

37.3 *ITPA* POLYMORPHISMS AND RIBAVIRIN-INDUCED HEMOLYTIC ANEMIA

Two functional polymorphisms in the *ITPA* gene on chromosome 20 have more recently been associated with ribavirin-induced hemolytic anemia in a separate GWAS performed using the IDEAL pharmacogenetics cohort [51]. Several tag SNPs on chromosome 20 were associated with quantitative reduction in hemoglobin (Hb) at week 4 of treatment. The top discovery SNP was rs6051702 (patients of European American ancestry, p-value = 1.1×10^{-45}) [51]. The *ITPA* polymorphism was also associated with Hb reduction >3 g/dL and Hb level <10 g/dL at week 4.

The genetic locus identified contains the *ITPA* gene, coding for the enzyme inosine triphosphatase (ITPase). Functional *ITPA* polymorphisms were previously identified that result in reduced ITPase activity [52–55] and accumulation of inosine triphosphate (ITP) in red blood cells, including rs1127354 and rs7270101. Rs1127354 is a missense variant in exon 2 of the *ITPA* gene (P32T); rs7270101 is a splicing-altering variant located in the second intron (IVS2). Neither were included on the genotyping chip, but they were noted to be in LD with rs6051702 using data from HapMap, where the low-activity variants were associated with the protective rs6051702 C allele. The cohort was then genotyped for the two functional variants. The two variants cosegregated with the top association variant, each was independently associated with anemia, and the two were shown to entirely explain the discovery association signal [51]. The p-value for association of a combined low-activity *ITPA* allele made up of either functional variant was $p = 2.23 \times 10^{-91}$. On the basis of this combined allele, 14% of the study population ($n = 186$) were predicted to have severe ITPase deficiency (<30% ITPase activity). None dropped Hb to a level <10 g/dL at week 4; only 4% experienced Hb reduction >3 g/dL (compared respectively to 12% and 56% of patients with wild-type activity) [51]. The association between *ITPA* polymorphism and treatment-induced anemia has since been replicated in a number of independent cohorts [15,56–59]. The association is independent of HCV genotype [57].

ITPase is the enzyme responsible for the hydrolysis of the inosine triphosphate (ITP) protein. ITPase deficiency was originally described as a benign red cell enzymopathy. Functional variants result in reduced ITPase activity and lead to accumulation of ITP in erythrocytes. A mechanism for the protective effect of the *ITPA* genotype was recently proposed. RBV depletes erythrocyte guanosine triphosphate (GTP), leading to ATP depletion, oxidative stress, and hemolysis. ITP is able to substitute for GTP in the biosynthesis of ATP, thereby protecting against RBV-hemolysis [60].

More recently the *ITPA* polymorphism was also associated with pegIFN-induced thrombocytopenia, with the effect in the opposite direction (low-activity variants predict for more severe thrombocytopenia) [59,61]. In fact, this an indirect genetic association, where normal ITPase activity is associated with more severe hemolytic anemia, driving a reactive thrombocytosis that manifests as a relative amelioration of pegIFN-related thrombocytopenia. Therefore, in patients with ITPase deficiency who are protected from RBV-hemolysis, more severe thrombocytopenia is observed. Genome-wide analysis for predictors of pegIFN-related leukopenias in the IDEAL cohort did not identify any significant associations [61].

37.4 GENETIC DETERMINANTS OF LIVER FIBROSIS PROGRESSION

The discovery that *IL28B*/*ITPA* variants act as predictors of HCV treatment outcomes has generated much hope that genome-wide screening might lead to similar insights into the understanding of liver fibrosis progression.

The identification of factors associated with disease progression in chronic hepatitis C has been a major focus in the field over the last two decades. Indeed, the availability of a treatment with limited efficacy and poor tolerability (e.g., pegIFN and RBV) called for the identification of patients who either required treatment immediately or could be safely deferred until the arrival of more effective and/or better tolerated regimens. Much emphasis has been put on the important role of exogenous factors such as alcohol consumption, HIV coinfection, or metabolic diseases (e.g., diabetes, insulin resistance) on the rate of fibrosis progression [62]. However, these factors are estimated to contribute no more than 30% of the individual variability observed in rates of fibrosis progression.

This finding indirectly supports a role for host genetics in determining fibrosis progression in chronic hepatitis C. Although progression rate is a difficult phenotype to accurately define—given the limitations of histological stage as a gold standard reference and the difficulties involved in the precise characterization of disease duration, as well as important confounders such as alcohol consumption—this observation indirectly supports a role for host genetics in determining prognosis.

Most early studies used a relatively straightforward candidate gene approach, in which cohorts were analyzed for the allele frequency of SNPs affecting plausible genes according to the presence or absence of advanced liver fibrosis. Unfortunately, the candidate gene literature has been generally limited by small cohort size and the absence of independent replication, making it difficult to draw firm conclusions. The data are therefore difficult to evaluate. Candidate genes identified include *matrix metalloproteinases (MMP-1/3/9)* and *monocyte chemotactic protein 1 (MCP-1)* [63,64].

The CCA haplotype in the vitamin D receptor gene was identified as a risk marker for fibrosis progression in a third study that used a more stringent definition for fibrosis progression: evaluation of paired biopsies from the same patient performed after a congruous period of time in the absence of effective anti-HCV treatments [65]. However, the most promising genetic variant to emerge from candidate gene studies is a SNP in the gene known as *patatin-like phospholipase-3 (PNPLA3)*. *PNPLA3* encodes a 481–amino acid protein of unknown function that belongs to the patatin-like phospholipase family. Patatin, the progenitor of this family, has nonspecific lipid acyl hydrolase activity. A nonsynonymous polymorphism at position 148 (rs738409 C>G) encodes an isoleucine-to-methionine substitution, which has been shown to be the strongest genetic determinant of human steatosis in GWASs of nonalcoholic fatty liver disease (NAFLD) [66,67]. The G allele of rs738409 SNP was subsequently associated with the presence of histologically determined liver steatosis, cirrhosis, and accelerated fibrosis progression in patients with chronic hepatitis C infection [68,69].

More comprehensive genetic studies are now starting to emerge. In a gene-centric disease association study of 24,832 putative functional SNPs, Huang and colleagues identified a 7-SNP variant signature that was associated with the risk of advanced fibrosis in chronic HCV infection as well as with estimated fibrosis progression rate [70]. By analyzing SNPs in seven genes (*adaptor-related protein complex 3 S2*, *aquaporin 2*, *antizyme inhibitor 1*, *degenerative spermatocyte homolog 1 lipid desaturase*, *syntaxin binding protein 5-like*, *toll-like receptor 4* (*TLR4*), and *transient receptor potential cation channel M5*), the researchers created the Cirrhosis Risk Score (CRS) to estimate the risk of developing cirrhosis at the individual patient level. Three cut-offs for CRS were proposed: <0.5 low risk, 0.5–0.7 moderate risk, and >0.7 high risk. The high-risk CRS cut-off was able to correctly identify 82% of HCV patients progressing to cirrhosis as well as 90% of those with mild fibrosis at the initial liver biopsy who showed fibrosis progression at a second liver biopsy. The CRS has been independently validated in small longitudinal cohorts for predicting patients with and without progression [71,72]; it has also been validated in the setting of post–liver transplant HCV recurrence [73]. However, mechanistic data linking these SNPs to pathways of liver fibrogenesis are limited, although TLR4 has been identified as an important mediator. Further validation in large prospective cohorts is required before the CRS can be recommended as a clinical tool.

A more traditional genome-wide approach was recently used to investigate fibrosis progression. Patin and colleagues conducted a GWAS using 1161 well-characterized HCV-infected patients of European descent who had liver biopsy prior to treatment [74]. Fibrosis progression was defined categorically by METAVIR stage, as well as continuously by progression rate (stage ÷ estimated duration of infection). The researchers tested for associations with 780,650 SNPs; the top discovery SNPs (p-values $<5\times10^{-5}$) were then validated in an independent replication cohort of 962 patients. Two SNPs were significantly associated with fibrosis progression, one located in *RNF7* ($p=8\times9\times10^{-9}$) and another linked to *MERTK* ($p=2\times1\times10^{-9}$) [104]. Both are plausibly related to fibrogenesis. *RNF7* acts as an antioxidant, protecting against apoptosis, and *MERTK* is involved in phagocytosis of apoptotic cells by macrophages. However, mechanistic data are not yet available.

In conclusion, liver fibrosis progression remains an important clinical issue, and genetic predictors could prove helpful in prioritizing patients for lifestyle modification or therapeutic intervention. Although the data support a role for host genetic background as a modifier of the natural course of HCV infection, clinical utility has yet to be translated. More important, the advent of more highly effective DAA therapies in the near future is likely to lessen the impact of future studies on this topic, as universal treatment of HCV patients is likely to be recommended.

37.5 CLINICAL TRANSLATION

The *IL28B* polymorphism strongly predicts for the clinical outcome of pegIFN and RBV-based treatment of genotype 1 HCV infection. However, the combination of pegIFN and RBV is no longer the standard of care in many parts of the world. In 2011, the first direct-acting antivirals (DAAs) were approved for the treatment of HCV-1. Telaprevir and boceprevir are HCV NS3 protease inhibitors that increase SVR rates almost 2-fold [75–78]. The year 2011 also saw proof of concept that HCV could be cured using IFN-free regimens. DAA therapy clearly attenuates the association between IL28B genotype and HCV treatment response, but emerging data suggest that IL28B genotype will remain relevant to emerging treatment paradigms, including IFN-free therapy. This is an extremely dynamic area, but in the global context it is still germane to discuss the clinical utility of *IL28B* genotyping for pretreatment counseling in the context of pegIFN and RBV, as well as for the rapidly evolving DAA therapies for HCV.

37.5.1 Peginterferon and Ribavirin Therapy for Genotype 1 HCV

37.5.1.1 IL28B Genotyping

Most of the clinical studies that validated the association between IL28B genotype and pegIFN and RBV treatment response have tested one of two SNPs—either rs12979860 or rs8099917. As stated, these two polymorphisms tag a common haplotype [7] and are in strong linkage disequilibrium (LD) in Caucasians and Asians. In most patients the genotypes will be concordant. Therefore, they provide very similar information for clinicians; both predict for treatment response/nonresponse with reasonable, but not perfect, accuracy. The exception is patients of African ancestry, where rs12979860 and rs8099917 are in weaker LD, and rs12979860 is more closely associated with IFN outcome [7]. Although data have been presented showing that the accuracy of prediction of clinical outcomes may be increased by testing both SNPs [47], this requires validation in different ethnic populations, and in practice the clinical utility is uncertain. The recent identification of the *IFNL4* dinucleotide polymorphism (ss469415590) as a proposed causal variant suggests that this will be the most appropriate SNP to genotype in all populations in the future [44].

37.5.1.2 IL28B Genotype and Peginterferon/Ribavirin Therapy in HCV-1

Intent-to-treat analysis of the IDEAL pharmacogenomics cohort showed that amongst Caucasians HCV-1 patients treated with pegIFN and RBV, the rate of SVR was 69% in patients carrying the good-response *IL28B* variant versus 33% and 27% in the setting of poor response variants [5] (Figure 37.2). In regions where DAAs are anticipated, this information may be useful for informing the decision to treat immediately, or to wait for the availability of direct-acting agents (DAA) for HCV-1 [5]. Patients carrying the poor response *IL28B* genotypes have a low SVR rate with the current standard-of-care and are most suitable for deferral. The negative predictive power of *IL28B* genotype is only ~70% however [5], and it should therefore not be used alone to exclude patients from treatment, particularly in cirrhotic patients from regions where the availability of DAA-therapy is likely to be delayed. *IL28B* genotyping is now available as a commercial diagnostic or as a research test in most developed countries.

37.5.1.3 IL28B Genotyping versus On-Treatment Kinetics for Predicting SVR

IL28B genotyping and rapid virological response (RVR) are complementary, and both are associated with IFN sensitivity and viral kinetics. IL28B genotype is the strongest *baseline* predictor of virological response to treatment and has the advantage of identifying patients who are IFN responsive *before* treatment initiation. It profoundly influences phase 1 viral kinetics such that the good-response variant is associated with greater rates of RVR, complete early virological response (cEVR), and SVR. The positive predictive value (PPV) for SVR of the good-response *IL28B* genotype was 69% in the intent-to-treat analysis of Caucasian members of the IDEAL pharmacogenetics cohort [5].

In contrast, RVR is an on-treatment measure of IFN responsiveness. It selects a smaller number of patients, but its PPV is higher. In the same intent-to-treat analysis, the overall rate of RVR in the Caucasian group was 14%, but 84% of these patients attained SVR [5]. Once RVR has been achieved, *IL28B* genotype is no longer predictive of treatment outcome, and rates of SVR are high in all patients (SVR in Caucasians: rs12979860 C/C = 85%; C/T = 76%; T/T = 100%; p = NS [5]). Note that in the IDEAL study, >75% of these RVR patients carried the C/C good-response variant. Importantly, in non-RVR patients, homozygosity for the good-response variant is still associated with a 2-fold increase in SVR rate (SVR in Caucasian non-RVR patients: C/C = 66%; C/T = 31%; T/T = 24%; $p < 0.001$) [5] (Figure 37.2).

37.5.1.4 IL28B Polymorphism and Short-Treatment Duration

There is now considerable data supporting a treatment duration of 24 weeks as sufficient for noncirrhotic RVR patients with a baseline HCV RNA level <400,000–800,000 IU/mL [79]. Therefore, patients can already be treated for 24 weeks in the setting of RVR and low baseline viral load. A key issue is whether it is possible to shorten treatment in *all* good-response *IL28B* patients, including those with non-RVR or high baseline viral load. This is of interest given the high SVR rates observed in non-RVR patients in the IDEAL pharmacogenomics cohort [5].

No prospective data have compared the efficacy of 24 versus 48 weeks of pegIFN and RBV therapy for good-response *IL28B* patients. It is unlikely that studies will be performed to address this issue given the development of DAAs. However, recent data from a large retrospective series in Taiwan showed that short-duration therapy (24 weeks) is sufficient only for patients who carry the good-response *IL28B* genotype, who have a low baseline viral load, and who achieve an RVR (SVR rates 95 versus 99% with 24 versus 48 weeks) [80]. Among patients carrying the good-response *IL28B* genotype, SVR rates were significantly lower with 24 versus 48 weeks total treatment duration in the following setting: RVR plus high baseline viral load (SVR 70% versus 97%), non-RVR plus (26% versus 60%) [80].

37.5.1.5 IL28B Genotyping and PegIFN Therapy in Other Settings

*Non-genotype 1 HCV

Peginterferon and ribavirin remains the standard-of-care treatment of non-genotype 1 HCV. There is emerging evidence concerning the role of *IL28B* genotype in predicting non-genotype 1 HCV treatment response. The data for genotype 2/3 (HCV-2/3) are mixed. Compared to HCV-1, HCV-2/3 are more responsive to IFN-based therapy, requiring only a 24-week duration and achieving SVR rates >70% [79]. Rauch and colleagues included 222 adherent patients with genotype 2/3 HCV in their treatment response subanalysis. *IL28B* polymorphism was not significantly associated with treatment outcome (OR = 1.6 [0.8–3.3], p = 0.18) [22].

In contrast, *IL28B* polymorphism was associated with overall SVR in a cohort of Italian patients treated with variable-duration pegIFN and RBV for genotype 2/3 HCV [81], although the absolute effect size was attenuated compared to genotype 1 HCV (rs12979860, C/C: SVR = 82%% versus C/T = 75% versus T/T = 58%; $p < 0.01$). *IL28B* genotype was most relevant for predicting SVR in patients who failed to attain a week 4 RVR (39% of the overall cohort). In this non-RVR group the respective SVR rates were C/C = 78% versus C/T = 58% versus T/T = 32%; $p < 0.001$. An association between *IL28B* genotype, early virological kinetics, and RVR (but not necessarily SVR) was subsequently demonstrated by multiple replication studies [13,14,16,82–85]. This may reflect inadequate power to differentiate statistically significant differences where SVR rates are generally high.

Systematic differences between study populations—patient ethnicity, *IL28B* genotype frequency, ratio of genotype 2:3 HCV, as well as treatment regimen (short-duration, variable RBV dosing)—complicate comparisons of the multiple datasets. Larger prospective studies will therefore be necessary to define the role of *IL28B* genotyping in these patients. Most importantly, the relevance of *IL28B* genotype to non-RVR HCV2/3 requires validation. The data suggest that 24 weeks of treatment may be sufficient for C/C non-RVR patients, whereas T/T patients might benefit from extending to 48 weeks (note that the EASL guidelines recently recommended extending therapy to 48 weeks for non-RVR HCV-2/3 patients [79]). This warrants prospective evaluation. For now *IL28B* genotyping should remain a research tool in patients infected with genotype 2/3 HCV.

There are fewer data for other HCV genotypes. The standard treatment for genotype 4 HCV (HCV-4) is 48 weeks of pegIFN and RBV. Treatment response rates are similar to those observed for HCV-1. A number of small datasets suggest that in patients with HCV-4 infection, the predictive power of *IL28B* polymorphism is similar to that for genotype 1 HCV [22,86]. More detailed confirmatory studies of the relevance of *IL28B* genotype to HCV-4 infection, particularly in the Egyptian population, are required. The relevance to genotype 6 HCV is less clear. There is only one description of a small cohort of 24 patients of Chinese ancestry, in which 23 of 24 patients carried the good-response genotype for rs12979860 and all 23 attained an SVR. One patient carried a poor-response genotype and relapsed after 48 weeks of treatment [31].

HCV-HIV Coinfection

The association of *IL28B* genotype and HCV infection outcome does not seem to be affected by HIV coinfection. *IL28B* polymorphism is a strong predictor of pegIFN and RBV treatment response in coinfected patients with genotype HCV-1/4, with effect sizes that are similar to those in monoinfection [25,86–91]. *IL28B* genotyping may therefore be useful in planning the timing of antiviral therapy in genotype 1/4 HCV, with the caveat that there are as yet limited data on the use of DAAs in HIV coinfected patients and availability may be delayed. In genotype HCV-2/3 coinfection, the association between *IL28B* and IFN response is attenuated, as with HCV-2/3 mono-infection [86]. The association between *IL28B* polymorphism and spontaneous HCV clearance is not attenuated by HIV coinfection, where rates of clearance are not significantly different from those seen in HCV monoinfected individuals [8,22]. *IL28B* polymorphisms have been shown not to influence the natural history of HIV infection itself [92–95].

Post-Transplantation HCV

Recurrent HCV post–liver transplantation is universal and typically aggressive, leading to progressive fibrosis and risk of graft failure. Its eradication is associated with improved clinical outcomes [96–98]. Unfortunately, treatment with pegIFN and RBV is more complicated than in the nontransplant setting, with lower overall safety and efficacy [99]. DAA therapy has yet to be evaluated in the post-transplant setting, where drug–drug interactions are challenging [100], and is therefore likely to be some years away. For all of these reasons, it would be clinically useful to be able to more accurately identify those patients most likely to respond to IFN-based therapy.

A number of small retrospective studies have now evaluated the relationship between recipient and donor liver *IL28B* genotype and IFN treatment response for recurrent HCV post–liver transplantation [33,101–104]. The data indicate that both recipient and donor liver good-response *IL28B* genotypes are associated with an increased rate of SVR and that this benefit is additive. In a Japanese study, 41 patients were classified on the basis of recipient/donor *IL28B* genotype (good response (+) versus poor response (−)) [101]. SVR rates according to *IL28B* genotype pairs were: −/− 0% versus +/− 10% versus +/+ 56% ($p<0.01$). In a retrospective study of 65 consecutive patients from the Mayo clinic, SVR rates were: −/− 16% versus +/− 47% versus +/+ 86% ($p<0.01$) [33]. The data suggest that *IL28B* genotyping might be used to prioritize patients for treatment with pegIFN and RBV. Given the poor prognosis of post-transplant HCV, the data also suggest a theoretical benefit for preferential organ allocation according to *IL28B* genotype, notwithstanding the considerable logistic challenges this would present.

Acute HCV Infection

Good-response *IL28B* patients are more likely to clear HCV infection spontaneously [22–25]. Very recently, the same observation was made using the novel *IFNL4* polymorphism [45]. Good-response patients are also more likely to present with jaundice at the time of infection [23,24], which is consistent with the historical observation that jaundiced patients are more likely to clear HCV. Jaundice is not completely explained by *IL28B* genotype, however. In an analysis of 136 women from the German Anti-D cohort, an interaction was observed between *IL28B* genotype, jaundice, and spontaneous clearance [23]. In patients with the good-response *IL28B* genotype, jaundice was more common (33% versus 16%, $p=0.03$), but the rate of clearance was high even in the absence of jaundice (61% versus 56%, $p=0.98$). In contrast, in patients with the poor-response *IL28B* genotypes jaundice was less common, but it was predictive of clearance (43% versus 14%, $p=0.019$) [23]. Therefore, patients who carry the poor response *IL28B* variant, and who do not present with jaundice, are unlikely to spontaneously clear the infection.

The current recommendation for acute HCV infection management is treatment after a period of observation to allow for spontaneous clearance—typically 8–12 weeks from the onset of symptoms [79,105]. Treatment of acute HCV with pegIFN monotherapy is associated with cure rates that are considerably higher than for chronic hepatitis C. SVR rates >80–90% have been reported [79]. Not surprisingly given these response rates, no significant association between *IL28B* genotype and treatment outcome has been observed in this setting [24,25]. Patients carrying the poor-response *IL28B* variants appear to gain a particular advantage with treatment in the acute setting. The data on this have implications for management with pegIFN therapy. An observation period is very reasonable in patients carrying the good-response *IL28B* genotype, where the spontaneous clearance rate is >50% [8,22,23] and, in the event of persistent high SVR rates, is expected with combined pegIFN/RBV therapy. In contrast, patients carrying poor-response *IL28B* genotypes are unlikely to naturally clear infection, particularly if anicteric [23]. These patients might be considered for immediate therapy to maximize the likelihood of SVR.

37.5.2 Direct-Acting Antiviral Therapy for Genotype 1 HCV

37.5.2.1 *IL28B* Genotype and First-Generation Protease Inhibitors

The standard-of-care treatment for genotype 1 HCV is now the combination of an HCV-NS3 protease inhibitor (PI) and pegIFN/RBV. There are currently two PIs on the market, telaprevir (TVR) and boceprevir (BOC). Retrospective analyses of the association between *IL28B* genotype and treatment outcome in phase 3 TVR/BOC registration programs have shown that *IL28B* genotype remains relevant to treatment response in treatment-naïve patients [106,107]. However, the strength of the association is attenuated when compared to pegIFN and RBV response, because TVR/BOC significantly increase SVR rates in patients who carry the poor-response *IL28B* genotype [106,107]). The increment in SVR rate in good-response *IL28B* genotype patients was lower in these retrospective analyses (Table 37.1). In treatment-naïve patients, the SVR rate was no different in the BOC arms from that of controls among good-response *IL28B* patients (Table 37.1) [107]. A small increment in SVR in good-response *IL28B* patients due to TVR was observed (Table 37.1).

Importantly, the good-response *IL28B* genotype strongly predicted eligibility for short-duration (24–28 week) therapy in both studies (BOC: 89% versus 52% in CC versus non-CC patients, rs12979860 [108]; TVR: 78% versus 54% [109]). This shows that, for most good-response *IL28B* patients, TVR/BOC allows short-duration therapy. In poor-response *IL28B* patients, TVR/BOC regimens increase SVR rates and allow short-duration therapy in a subset. Even shorter therapy appears to be possible in good-response patients—it was recently shown that 12 weeks total duration of TVR-based triple therapy is associated with very high SVR rates [110].

IL28B genotyping is less useful for predicting the outcome of TVR/BOC therapy in patients who previously failed to respond to pegIFN/RBV dual therapy [106,107]. Here, the treatment history defines IFN responsiveness (relapse versus partial response versus nonresponse). *IL28B* genotyping no longer predicts for SVR once patients have been classified on this basis (Figure 37.3), but it may still have a role in real-world populations where previous IFN response is less well defined.

37.5.2.2 *IL28B* Genotype and Next-Generation DAA Response

The treatment of HCV is rapidly evolving. Data suggest that treatment-naïve patients who carry the good-response *IL28B* genotype are easier to cure with regimens that involve a single DAA combined with a pegIFN/RBV backbone, including next-wave NS3 protease inhibitors (e.g., simeprevir), NS5B inhibitors (e.g., sofosbuvir), and NS5A inhibitors (e.g., daclatasvir) [111–118]. The strength of association here is weaker than for pegIFN/RBV alone, however, and appears to negatively correlate with DAA antiviral potency. Indeed, as SVR rates reach very high levels, the clinical significance of small but statistically real differences in response according to *IL28B* genotype becomes less and less meaningful. The highest SVR rate observed to date for a triple therapy regimen in a phase 3 study was that reported for the 12-week regimen of sofosbuvir plus pegIFN/RBV [119]. The overall SVR rate was 89% in genotype 1 HCV patients, with SVR rates of 98% versus 87% according to *IL28B* genotype (rs12979860 CC versus non-CC, $p<0.05$) [119].

Quadruple therapy regimens with combination DAAs plus pegIFN/RBV are in phase 2 development. Early data show very high SVR rates in small cohorts [113], including null-responder cohorts, indicating that *IL28B* genotype may be less relevant in this setting. Thus, it is reasonable to expect little, if any, relationship between *IL28B* genotype and of IFN-free outcomes. One scenario in which both *IL28B* genotype and IFN remain relevant to future HCV therapy is if distinct treatment paradigms emerge for patients who are good versus poor IFN responders. Patients carrying the *IL28B* good-response genotype might be treated with dual DAA plus pegIFN/RBV for very short duration (e.g., 6–8 weeks) [120]. In contrast, poor-response *IL28B* genotype patients might require therapy of a longer duration or be prioritized for IFN-free therapy.

Interferon-free therapy for HCV-1 is likely to be approved in the next 3–5 years. Data suggest that the good-response *IL28B* genotype may represent an “easy-to-cure” characteristic for certain IFN-free regimens as well. The INFORM-1 study was the first to demonstrate that IFN-free therapy can have a potent antiviral effect. Patients were treated with a combination of mericitabine (a NS5B nucleotide inhibitor, NI) and danoprevir (a PI) for 14 days before follow-on PR therapy to 48 weeks. Analysis of the

TABLE 37.1 Retrospective Analyses of the Association Between *IL28B* Genotype and Treatment Response

Outcome		Treatment Regimen	*IL28B* Genotype (rs12979860)					
			C/C		C/T		T/T

		PR control	0/0	0	1/18	6	1/15	7

[a] *Patients were eligible for short-duration therapy if HCV RNA was undetectable at week 8 and week 24.* [b] *Patients were eligible for short-duration therapy if they achieved an extended rapid virological response (eRVR), defined by undetectable HCV RNA at weeks 4 and 12 of treatment.*

Note: The information here is from the phase 3 registration studies of boceprevir (BOC) and telaprevir (TVR) in both treatment-naïve [76,77] and treatment-experienced patients [75,78].

on-treatment viral kinetics in 15 patients during the two weeks of oral therapy revealed a significant difference in phase II viral kinetics according to *IL28B* genotype [121], suggesting that *IL28B* genotype influences the rate of clearance of infected hepatocytes during IFN-free therapy. This might be consistent with the association between *IL28B* genotype and spontaneous HCV clearance.

SOUND-C2 was the first large study of IFN-free therapy [122]. It evaluated the combination of faldaprevir (PI), deleobuvir (NNI) ± RBV (Figure 37.1). Interim results demonstrated a clear difference in SVR12 according to *IL28B* genotype (58–84% among patients with *IL28B* CC versus 33–64% of those with non-CC genotypes). The difference was more marked in patients infected with genotype 1a HCV versus genotype 1b. The low SVR rates observed in HCV-1a non-C/C patients resulted from a virological breakthrough in most patients, suggesting that *IL28B* genotype influences RAV emergence. It should be noted that this area is rapidly developing. Multiple IFN-free regimens that involve DAAs with high potency and a lower genetic barrier to resistance are now in phase 3 development. It is expected that response rates with "optimized" DAA combinations will be higher still and, again, will overcome most of the clinical impact of *IL28B* genotype.

A recent study on the combination of sofosbuvir plus daclatasvir reported SVR4 of 100% in 44 HCV-1 treatment-naïve patients with or without ribavirin [123]. Such optimized regimens are very expensive, however, and may not be necessary for all patients. *IL28B* genotype may continue to be useful in identifying patients for whom such regimens are most appropriate as first-line therapy.

In summary, it seems that it will be possible to overcome the effect of *IL28B* polymorphism in most patients with a combination of drugs with high potency and high genetic barriers to resistance (e.g., sofosbuvir + daclatasvir) ± pegIFN/RBV. Even so, it may be that *IL28B* genotype will be used to individualize treatment strategies such that patients who carry the good-response *IL28B* genotype may be eligible for shorter, simpler, or cheaper regimens and that, conversely, "poor-response" patients may require longer therapy with multiple DAAs. Such individualized treatment algorithms have yet to be explored in detail [110,120].

IL28B Genotype and Pharmaco-Economics

Antiviral therapy for HCV is expensive. The pricing schedule for telaprevir in North America in 2011 was $US49,200 for 12 weeks of treatment; for boceprevir, it was $US1100 per week (24–44 weeks). This comes on top of the cost for pegIFN and RBV. With finite healthcare budgets, it is important to ask whether prioritizing certain patients for these new agents is justified. *IL28B* genotyping is an obvious tool for use in this situation. Indeed, in the phase 3 registration study of the PI boceprevir, although triple therapy allowed shortening of total treatment duration in most patients, overall SVR rates did not increase relative to pegIFN and RBV among good-response *IL28B* patients [107]. One strategy would therefore be to treat all good-response *IL28B* genotypes with pegIFN and RBV alone, reserving DAAs for the minority of nonresponders [28,124,125]. Poor-response *IL28B* genotype patients might be prioritized for first-line access—a policy that has been adopted in a number of regions. In any case, formal economic modeling should be performed on a region-by-region basis, taking into consideration *IL28B* genotype, other baseline predictors of SVR such as fibrosis stage, and on-treatment milestones such as week 4 virological response.

37.5.3 Clinical Translation of *ITPA* Genotyping

ITPA genotype is strongly associated with ribavirin-induced anemia; predicted ITPase deficiency identifies approximately 25% of patients to be protected at week 4 [51]. Studies have confirmed protection throughout the 24–48-week course of pegIFN/RBV treatment [56,57]. Although patients with ITPase deficiency are less likely to require RBV dose reduction [50,51], *ITPA* variants are not associated with SVR [51,56,57]. Therefore, routine *ITPA* genotyping cannot at this time be recommended prior to pegIFN/RBV therapy. Particular patient groups exist in which *ITPA* genotype may be relevant to clinical decision-making. These include patients at high risk for anemia, such as thalassemic patients, or patients on renal replacement therapy. *ITPA* genotyping may also be relevant to patients who poorly tolerate anemia, such as those with coronary artery disease. Prospective evaluation will be important.

Both telaprevir- and boceprevir-based therapies are associated with more profound anemia compared to pegIFN and RBV alone [109,126]. The mechanism remains unclear, but is additive with RBV and appears to involve bone marrow suppression rather than hemolysis. *ITPA* genotype is associated with the risk of anemia during TVR therapy [127]. It is also associated with anemia, as well as the need for both RBV dose reduction and erythropoietin support, during BOC therapy [83]. *ITPA* genotype has not been shown to be causally associated with telaprevir/boceprevir anemia, however, and it appears to reflect the RBV effect alone. Effect size is small—it is moderate only for both regimens—and ITPA genotyping is not routinely recommended. Nevertheless, knowledge of *ITPA* genotype might be useful for clinicians when planning DAA therapy, especially in regions where access to erythropoietin (EPO) support is restricted or in subgroups at higher risk for anemia (e.g., older patients).

37.5.4 Genomics and Drug Development

Current strategies for the clinical development of DAAs involve combination with pegIFN and RBV to restrict the development of antiviral resistance. Given the population frequency of the good-response *IL28B* variant, and its association with rapid viral decline, it is possible for small early-phase efficacy trials to be confounded by imbalance for *IL28B* genotype across treatment arms. For this reason, treatment arms should be stratified by *IL28B* genotype [128]. This approach has largely been adopted by the pharmaceutical industry [129].

Beyond stratification, pharmacogenetic analyses have the potential to redefine drug development. Analysis for genetic predictors of treatment efficacy as well as treatment toxicity will be important as a means of enhancing efficacy and minimizing toxicity. Future drug development may be targeted accordingly—for example, where a genetic marker for toxicity is identified in early-phase studies, drug candidates may advance into later-phase studies that, rather than halt development entirely, enroll only individuals with low-risk variants. Telaprevir rash is an obvious case where identification of a genetic susceptibility marker might have proved useful during the development phase; however, telaprevir still warrants investigation in the post-regulatory period. Most studies of novel anti-HCV drugs now include an optional pharmacogenomics substudy. This approach has potential application in all fields of therapeutic development.

37.6 CONCLUSION

The discoveries of the associations of *IL28B* and *ITPA* polymorphisms with HCV outcomes are two of the most definitive successes of the GWAS era [130,131]—personalized medicine is now a reality for chronic HCV patients. Nevertheless, such important discoveries should not obscure the intrinsic limitations of GWASs: for one, the stringent statistical significance threshold that must be used to correct for multiple testing severely limits the power to uncover variants that have low to moderate effect size. For another, by using tagging SNPs, GWASs only interrogate common genetic variants and are for the most part uninformative about the bulk of rarer DNA changes that can have a dramatic impact at the individual level, as seen in many Mendelian disorders. It must also be remembered that GWASs identify loci, not genes, and the identification of pathogenic changes (causal variants/mechanism) on an associated haplotype can be complicated. In fact, it is not unreasonable to argue that GWASs thus far represent only a temporary stop on the road toward more comprehensive HCV host genomic studies: next-generation sequencing technology is now widely available and permits cost-effective sequencing of whole human exomes, genomes, or transcriptomes.

Detailed characterization of individual DNA/RNA profiles, in combination with systems approaches for statistical analysis, has the potential to shed new light on the complex interplay between HCV and the host cell, and to provide novel therapeutic targets. Computational issues need to be addressed, and novel statistical methods will be required to make the best use of the unprecedented wealth of genomic information that is being generated. Still, the promise is, finally, a fully comprehensive representation of all human genetic variation. These are exciting times, indeed, for human genomic research, including the host genetics of HCV disease.

DISCLOSURES

A.J.T is a coinventor of patents related to the *IL28B* and *ITPA* discoveries. He has also served on advisory committees or review panels (Merck, Janssen, Roche, Gilead, Glaxo-Smith-Kline, Abbvie, Bristol-Myers Squibb, Springbank), has held speaking or teaching roles (Merck, Roche, Bristol-Myers Squibb, Janssen, Gilead), and has received grant/research support (Merck, Roche, Gilead).

P.J.C. has held speaking or teaching roles (Janssen).

A.A. has served on advisory boards or review panels (Roche, Janssen), has held speaking or teaching roles (Roche, Janssen, Merck, Bayer), and has received grant/research support (Roche, Gilead).

ABBREVIATIONS

IL	interleukin
ITP	inosine triphosphate
ITPA	inosine triphosphatase
HCV	hepatitis C virus
GWAS	genome-wide association study
pegIFN	pegylated interferon-α, RBV, ribavirin
SNP	single-nucleotide polymorphism
LD	linkage disequilibrium
OR	odds ratio
HIV	human immunodeficiency virus
ISG	interferon-stimulated gene
Hb	hemoglobin
RVR	rapid virological response
CEVR	complete early virological response
SVR	sustained virological response
PPV	positive predictive value
DAA	direct-acting antiviral therapy
TVR	telaprevir
BOC	boceprevir
PI	protease inhibitor
NI	nucleotide inhibitor
NNI	nonnucleos(t)ide inhibitor
IFNL	*interferon-lambda*

38.1 OVERVIEW OF ANTIFUNGAL THERAPY

In 1939 the war against fungal diseases began in earnest with the discovery of griseofulvin, a metabolite of *Penicillium griseofulvum* [1]. It was the first truly effective antifungal agent and remains the sole licensed orally active drug for childhood dermatophyte infections. Griseofulvin inhibits fungal mitosis and, while it has good activity against dermatophyte fungi, it has no other clinically useful antifungal activity. The shared eukaryotic origin of fungal and human cells had presented a problem for rational drug development since the common metabolic pathways and cellular organelles increase the risk of dose-limiting toxicity (see Figure 38.1). Previous attempts at therapy, using potassium iodide and the sulphonamides, therefore had limited efficacy.

A decade later, the first of the polyene drugs, nystatin, was discovered, followed in 1955 by amphotericin. Amphotericin B is synthesized by an aerobic actinomycete, *Streptomyces nodosus*. The drug was discovered during a survey of soil samples carried out by a pharmaceutical company looking for antibiotic-producing *Streptomyces* strains. The strain producing amphotericin B was first recovered from the Orinoco River valley in Venezuela. These drugs established the modern era in antifungal therapy and remain widely used today. In addition to the polyenes, two other drug classes dominate systemic antifungal therapy: the triazoles and the echinocandins. Other drugs, such as flucytosine and terbinafine have a role in specific diseases or superficial infections, respectively. A general overview of the spectrum of activity of the currently used antifungal drugs is shown in Table 38.1.

38.1.1 Polyenes

The polyene antifungals that are in current clinical use are nystatin, natamycin, and amphotericin B. They are fungicidal, and their mode of action is disruption of the fungal cell membrane by binding to ergosterol, the main sterol in the membrane. This results in pore formation and leakage of cellular cations and anions, leading to fungal cell death [2].

Although the presence of ergosterol in the fungal cell membrane confers some selectivity to the action of polyenes, there are notable toxicities associated with their systemic use. Nystatin and natamycin are currently only used topically and, although initial studies with a liposomal formulation of nystatin (Nyotran) demonstrated good efficacy, they were halted due to infusion-related toxicity. Amphotericin B is used systemically, but as it is

Yeasts Unicellular organisms, which usually reproduce by budding	**Dimorphic fungi** Exist as either yeast or mold forms and the change in form is usually related to temperature	**Molds** Multicellular organisms, with hyphae, and they often produce specific spore-producing structures
Microscopic appearance (x 400 magnification) 	Microscopic and cultural appearance depends on temperature: usually mold at 27ºC and yeast or yeast-like at 37ºC	Microscopic appearance (x 400 magnification) Culture appearance 		Culture appearance Examples *Candida* *Cryptococcus* *Malassezia* *Trichosporon*	**Examples** *Histoplasma* *Coccidioides* *Blastomyces* *Paracoccidioides*	**Examples** *Aspergillus* *Fusarium* *Scedosporium* Mucoraceous molds Dermatophytes

FIGURE 38.2 Different fungal morphologies with culture and microscopic appearance.

not absorbed orally, it must be administered intravenously (IV). It has a broad spectrum of activity against yeasts and molds (see Figure 38.2) and has been widely used over several decades to treat a range of diseases, including invasive aspergillosis, cryptococcosis, candidosis, the endemic mycoses, and leishmaniasis [2].

In vivo amphotericin B is largely protein bound, with high concentrations in the liver and spleen, and lower concentrations in the lung and kidney. It is eliminated via the urine (21%) and bile (43%), but there is little metabolic breakdown and most of the drug is excreted unchanged over a period of several weeks. The half-life is initially 10–24 hours but after prolonged use may be as long as 15 days [3].

Toxicity associated with amphotericin B includes infusion-related nausea, vomiting, and rigors; chronic toxicity is primarily renal [4]. This toxicity may lead to discontinuation of therapy; in response, lipid formulations were developed and are characterized by reduced toxicity [5]. There are two such formulations currently available in the United Kingdom: Ambisome, which uses liposomes to package the amphotericin, and Abelcet, which uses amphotericin in lipid complexes. These lipid preparations of amphotericin B are also only very slowly eliminated, with only 9% excreted at the end of 7 days [6]. Despite the significantly increased cost, the improved tolerability associated with lipid formulations of amphotericin B has led to a major shift away from the use of amphotericin B deoxycholate except in some resource-poor settings [7].

Drug interactions associated with amphotericin B generally reflect its nephrotoxicity, being most pronounced when concomitant medications undergo renal excretion. Amphotericin B enhances renal toxicity of ciclosporin, aminoglycosides, and some cytotoxic agents such as cisplatin, and it requires vigilant monitoring of renal function if coadministered [2]. Lipid formulations of amphotericin B require no dose adjustment for renal insufficiency and generally none for hepatic insufficiency, although specific recommendations vary with different lipid forms.

38.1.2 Triazoles

The first description of antifungal properties in azole compounds was in 1944 when researchers studying biotin deficiency in animals noted that benzimidazole, which is structurally similar to biotin, had activity against yeasts [8]. This finding was not followed up at the time, but later groups routinely screened other azoles for antifungal activity. Early agents to be developed in the group, including clotrimazole, ketoconazole, and miconazole, are generally now confined to topical use because of unfavorable safety profiles.

Further refinements and chemical modification of these compounds resulted in the triazole group, which is characterized by a five-member azole ring. Triazoles such as fluconazole, itraconazole, voriconazole, and posaconazole are widely used for prophylaxis and treatment of invasive fungal disease (IFD) [9]. The azoles share a common mode of action: inhibition of the fungal cytochrome P450 enzyme (CYP450) lanosterol 14-α-demethylase, which facilitates conversion of lanosterol to ergosterol, a component of the fungal, but not the human, cell membrane. Disruption of ergosterol biosynthesis causes damage to the fungal cell membrane, accumulation of methylsterols, and either cell lysis leading to fungal cell death or inhibition of fungal cell growth, depending on the azole and fungal species [9].

All classes of azoles are substrates and inhibitors of CYP450 enzymes, but the extent to which they are metabolized by or inhibit the various CYP isoforms varies between drugs [10–12]. Individual triazoles exhibit different properties, spectra of activity, and therapeutic indications, and these are discussed next. Their pharmacokinetic properties are summarized in Table 38.2.

38.1.2.1 Fluconazole

The first triazole antifungal to be marketed appeared in 1990. This was fluconazole, a fluorinated bistriazole (i.e., with two triazole rings). Available in capsule and oral solution, and as an intravenous preparation, it has activity against *Cryptococcus*, most *Candida* species (except *C. krusei* and sometimes reduced activity against *C. glabrata*), and some dimorphic fungi. It is generally considered to be fungistatic. Because of its hydrophilic properties, it has excellent oral bioavailability (85–90%) and its absorption is unaffected by gastric pH [9,13]. As fluconazole is largely excreted via the kidneys, dose adjustment is required in patients with reduced creatinine clearance, and it should be used with caution in patients with hepatic insufficiency, although the data are limited. Fluconazole has a favorable safety profile and minimal toxicity, although hepatotoxicity and prolongation of the QT interval in ECG have been noted [3].

Fluconazole is a substrate of CYP3A4 and inhibits CYP 2C9, 2C19, and, to a lesser extent, CYP3A4, an effect that may only occur at doses >200 mg/d [10]. It is also a substrate of P-glycoprotein (P-gp), but not an inhibitor [14]. Drug interactions mediated via the CYP450 enzymes are numerous and include those with alfentanil, ciclosporin A, and midazolam mediated via interactions with CYP3A4; those with amitriptyline, fluvastatin, and phenytoin are mediated via inhibition of CYP2C9 [15].

38.1.2.2 Itraconazole

Itraconazole is a lipophilic triazole, available as capsules, oral solution, and, in some countries, a concentrate for parenteral administration. It has a broad spectrum of activity,

TABLE 38.2 Pharmacokinetic Properties of Triazole Antifungals

	Fluconazole	Itraconazole (Solution)	Voriconazole	Posaconazole
Oral bioavailability (%)	>90 (no food effect)	~50 (fasting)	96 (Fasting)	8–48 (with food)
Protein binding (%)	12	>99	58	98–99
Tissue distribution (%) (as a percentage of serum concentration if known)	Eye: 28–75; CSF: 50–90; bronchial secretions and saliva: 90–100	High: lung, spleen, kidney, liver; moderate: bronchial secretions; very low: eye, CSF, saliva	High: lung, spleen, kidney, liver; moderate: brain, eye, CSF: 22–100	Moderate: bronchial secretions/sputum; low: CSF
Metabolism	<20% metabolized; minor hepatic (CYP3A4)	Extensive hepatic (CYP3A4); many metabolites (including microbiologically active hydroxy-itraconazole)	Oxidative hepatic (mainly CYP2C19; less CYP3A4 and CYP2C9); inactive metabolites	Minimal metabolism; oxidation, glucuronidation (CYP3A4)
Half-life (hour)	25–30	24	6	25
Adult dosing regimen	Varies depending on indication	Varies depending on indication	Maintenance dose of 200 mg twice daily (for patients > 40 kg)	400 mg twice daily or 200 mg 4 times daily
Route of elimination	80% unchanged in urine	3% as metabolites (3–18% unchanged) in urine; 54% as metabolites in feces	80% as metabolites in urine; 20% as metabolites in feces	14% as metabolites in urine; 66% unchanged in feces

Source: Data from Several Sources. See [3,13,32,94–96,125].

including *Candida, Aspergillus,* dimorphic fungi, and some melanized fungi, but not *Fusarium, Scedosporium*, or the mucoraceous molds [16]. Its activity may be either fungistatic or fungicidal depending on the fungal species [17]. Oral bioavailability of itraconazole varies with formulation. Absorption of the capsules is dependent on gastric pH, with increased absorption at acidic pH, while the solution is best absorbed during fasting [9]. Itraconazole has nonlinear pharmacokinetics and because of variable absorption, drug concentrations show significant variability in individuals [18].

In patients with renal insufficiency, use of the IV formulation is not recommended if creatinine clearance is less than 30 ml/min, as the cyclodextrin vehicle is cleared by glomerular filtration. In hepatic insufficiency, there is an increase in the elimination half-life and dose modification may be required [18].

Adverse events associated with itraconazole use include nausea and vomiting (particularly for the oral solution), hepatotoxicity, rash, and headache [18]. There is some evidence that the occurrence of these toxicities correlates with the itraconazole concentration in serum.

Itraconazole is a substrate and potent inhibitor of CYP 3A4, with many metabolites also showing potent CYP3A4 inhibitory activity [19]. It is also an inhibitor of CYP 2C9 and P-gp [15]. These interactions form the basis for many drug interactions seen with itraconazole. Interactions mediated via CYP3A4 include those with fluticasone, lovastatin, phenytoin, rifampin, terfenadine, triazolam, and vincristine; those mediated via P-gp include vincristine, cimetidine, and digoxin [15].

38.1.2.3 Voriconazole

Voriconazole is a second-generation triazole based chemically on fluconazole but with a much broader spectrum of activity. It is active against *Candida* (including most of the fluconazole-resistant species), *Cryptococcus*, and many species of *Aspergillus*; it has some activity against *Fusarium* [16]. Voriconazole activity may be either fungicidal or fungistatic depending on the fungal species [17]. It is the treatment of choice for invasive aspergillosis and is used to treat infections due to *Scedosporium* or *Fusarium*. Formulations of voriconazole include tablets, an oral suspension and an IV solution.

The suspension has good oral bioavailability, especially during fasting, but this is reduced in the presence of high-fat meals [20]. The pharmacokinetics of voriconazole are nonlinear in adults, meaning that relatively small changes in dosing can result in unpredictable changes in drug exposure—being either much larger or smaller than expected.

Voriconazole is extensively metabolized by the CYP 450 enzymes—mainly CYP2C19 but also CYP2C9 and CYP3A4 [21]. It is eliminated as inactive metabolites predominantly via urine (80%), with about 20% excreted in the feces [22].

The vehicle used for IV voriconazole (sulphobutylether beta cyclodextrin sodium, or SBECD) is cleared by the kidneys and hence can accumulate in mild–moderate renal dysfunction; in these patients, the oral formulation is preferable. In mild–moderate hepatic insufficiency, the standard loading dose should be used and then half the maintenance dose, but there are no data for use in severe hepatic insufficiency.

Toxicity associated with voriconazole includes visual disturbances, rash, and hepatotoxicity. Visual disturbances often decrease with continued use and may manifest as photophobia, color changes, blurred vision, or flashes of light; they seem to correlate with high drug concentrations [23]. Cutaneous adverse events are often associated with sun exposure and usually resolve after discontinuation of the drug, although an increased risk of squamous cell carcinoma has been reported with voriconazole use in solid-organ transplant recipients [24]. Hepatotoxicity includes elevated bilirubin, alkaline phosphatase, and transaminases, and correlates with drug concentrations [25].

Voriconazole is both a substrate and an inhibitor for CYP2C19, 2C9, and 3A4, and is also an inhibitor of 2B6 [26]. These properties underpin its multiple interactions with drugs such as sirolimus, alfentanil, cyclosporine, diclofenac, methadone, efavirenz, and midazolam [15].

38.1.2.4 Posaconazole

Posaconazole is the latest triazole to come to market. It was developed from itraconazole and is available only as an oral suspension, although a new tablet formulation is currently under development [27]. Posaconazole has the broadest spectrum of activity *in vitro* of all the azoles, with good activity against *Candida, Cryptococcus, Aspergillus*, many dimorphic or melanized fungi, and several of the mucoraceous molds [16]. It is fungicidal against *Aspergillus, Cryptococcus*, and *Candida* [28]. Oral bioavailability is very dependent on gastric pH, with absorption maximized in the presence of fatty foods [29]. As with itraconazole, absorption is improved by concomitant administration of acidic drinks, but it is saturated at a dose of 800 mg/d and improved by dividing the dose. Drug concentrations achieved in serum vary between patient groups and are known to be reduced in the presence of mucositis and diarrhea, or with the use of proton pump inhibitors (PPIs) or H_2 antagonists [30].

Most of the metabolism of posaconazole is by glucuronidation, with only a limited amount via oxidative CYP450-mediated transformation [31]. Posaconazole has a long half-life and is mainly eliminated unchanged in the feces (66%), with some excreted via the urine, mainly as metabolites (14%) [32]. It can be used in renal insufficiency with no dose modification, and limited data suggest that it should be used with caution in hepatic insufficiency. Toxicity associated with posaconazole use is generally mild, with headache, gastrointestinal upset and rash reported, although at the moment there are no data to suggest that these are related to the drug's concentration. Although posaconazole is minimally metabolized by the CYP450 system, it is an inhibitor of CYP3A4 and P-gp, resulting in some drug interactions, notably with rifabutin, phenytoin, efavirenz, and fosamprenavir [15].

38.1.3 Echinocandins

The echinocandin antifungals, the first new class of antifungals for 15 years, are synthetically modified lipopeptides with three currently licensed: caspofungin, micafungin, and anidulafungin. The lead compound for anidulafungin was discovered in 1974, and all three drugs are derived from fermentation products of fungi [33]. Echinocandins are noncompetitive inhibitors of β-1-3-glucan synthase, an enzyme critical to the synthesis of β-1-3-glucan, which is a major component of the fungal cell wall. The absence of β-1-3-glucan from the cell wall causes loss of rigidity and integrity with resultant lysis. Echinocandins target the *FKS1* gene, which encodes a component of the β-1-3-glucan synthase. Since mammalian cells do not possess a cell wall or β-1-3-glucan synthase, the action of echinocandins is specific to fungi, probably explaining their excellent safety profile. Parenteral administration is obligatory, as their large lipophilic molecular structures have very low oral bioavailability (<10%) [34]. The three echinocandins all have a similar spectrum of activity, a reflection of their mode of action, and they are active against *Candida* and *Aspergillus,* but not against *Cryptococcus* and mucoraceous molds which have less β-1-3-glucan in their cell walls [33,34]. The echinocandins are fungicidal for *Candida* and fungistatic for *Aspergillus* [34]. The pharmacokinetic properties of the echinocandins are summarized in Table 38.3.

Use of the echinocandins is generally well tolerated, although histamine release, some liver toxicity, and headache have all been reported. Caspofungin use is relatively commonly associated with fever and local irritation at the site of administration, while rashes can occur infrequently with all three drugs [35].

The echinocandins are poor substrates for the CYP450 enzymes, are not substrates for P-glycoprotein, and have few drug interactions. Caspofungin is an inhibitor of CYP3A4

TABLE 38.3 Pharmacokinetic Properties of the Echinocandins

	Caspofungin	Anidulafungin	Micafungin
Route of administration	Intravenous only	Intravenous only	Intravenous only
Protein binding (%)	96	>99	99.8
Metabolism	Hydrolysis and N-acetylation	>90% degradation in blood; no hepatic metabolism	>90% degradation; hepatic metabolism; limited role for CYP450
Tissue distribution	High: kidney, liver; moderate: lung, spleen; low: brain, eye	High: lung, liver Moderate: spleen, kidney Low: brain, eye, CSF	High: lung, kidney, liver; low: eye
Half-life for β phase (hour)	11	36–52	11–17
Adult dosing regimen	70 mg loading, then 50 mg if <80 kg or 70 mg if >80 kg	200 mg loading dose, then 100 mg/day	100 mg/day (if >40 kg) or 2 mg/kg/day if <40 kg for invasive candidosis
Route of elimination	41% urine, 35% feces—mostly as metabolites in both	Urine <10%, >90% feces—mainly as metabolites in both	<1% urine; ~70% feces
Dose adjustment in renal insufficiency	None	None	None
Dose adjustment in hepatic insufficiency	Mild: none Moderate: 70 mg loading dose then 35 mg daily Severe: use with caution	Mild–severe: none	Mild–moderate: none Severe: not recommended

Source: Data from Bellman [3], Johnson and Mohr [33], and Wagner et al. [34].

[36]. While ciclosporin A and tacrolimus do interact with it, there is no requirement for dose adjustment although liver function and tacrolimus levels respectively should be closely monitored.

Coadministration of powerful hepatic enzyme inducers (e.g., rifampicin, efavirenz, phenytoin, carbamazepine) require an increase in the daily dose of caspofungin to 70 mg/d [35]. The mechanism of this is unknown, but it is perhaps surprising given that caspofungin is not metabolized by the CYP enzymes. It may be a nonspecific effect or could perhaps be due to induction of the N-acetyltransferases that are involved to some extent in caspofungin metabolism.

Micafungin administration with sirolimus or nifedipine may increase exposure to those drugs and so dosage adjustments may be required if toxicity occurs. Anidulafungin has as yet no known clinically relevant drug interactions [33].

38.1.4 Flucytosine

Flucytosine is a fluorinated pyrimidine that was originally developed as an agent to treat leukemia. It has two modes of action: inhibition of protein synthesis and inhibition of DNA synthesis. The drug penetrates the fungal cell wall via cytosine permease and, once in the cell, is deaminated to form 5-fluorouracil. This is incorporated into fungal RNA instead of uracil and hence disrupts protein synthesis. DNA synthesis inhibition occurs via conversion of 5-fluorouracil to 5-fluorodeoxyuridylic acid, a noncompetitive inhibitor of thymidylate synthase [37]. Flucytosine has fungistatic activity against *Candida* and *Cryptococcus*, and its main current indication is for the treatment of cryptococcal meningitis, in combination with amphotericin B, with which it shows synergy, [38] or the azoles [37]. Flucytosine is available in oral and IV preparations, although the oral preparation is not available in all countries.

Flucytosine has good oral bioavailability, penetrates well into body fluids because of its low protein binding, and achieves good concentrations in cerebrospinal fluid, bone, spleen, liver, heart, and lung. It is mainly eliminated via the kidneys, with almost all of the dose eliminated by glomerular filtration, mainly as unchanged drug. The half-life in patients with normal renal function is 3–4 hours, but can be up to 85 hours in patients with severe renal failure. Renal insufficiency necessitates dose alterations, as does renal replacement therapy, which removes a significant proportion of the drug [37,38]; however, there are no recommendations for use in hepatic insufficiency.

Use of flucytosine is associated with gastrointestinal, hepatic, and hematological toxicities. These side effects may reflect the conversion of flucytosine to 5-fluorouracil [39] and correlate with the levels of flucytosine in serum, with levels above 100 mg/L associated with leukopenia and thrombocytopenia. Hematological toxicity is more common in patients with advanced HIV infection [38]. Therapeutic drug monitoring is required to ensure appropriate dosing and to prevent toxicity.

A particular problem when flucytosine is used as a single agent is the rapid development of resistance [40], so combined use with amphotericin B (or its lipid formulations) is now recommended. Flucytosine has limited drug interactions, but is contraindicated with antiviral nucleoside drugs such as ganciclovir. It may interact with phenytoin and cytarabine, although the evidence for the latter is sparse [38].

38.1.5 Terbinafine

Terbinafine is a member of the allylamine group of antifungals. It inhibits ergosterol biosynthesis by inhibiting squalene epoxidase, a catalyst of the conversion of squalene to squalene epoxide. This resulting accumulation of squalene within the fungal cell and depletion of ergosterol in the fungal cell membrane causes cell death [41]. Terbinafine is highly selective for fungal squalene epoxidase and has no effect on human sterol synthesis [42]. It has *in vitro* activity against a wide range of organisms, including dermatophytes, several melanized molds, *Aspergillus*, *Cryptococcus*, and several dimorphic fungi, although it is mainly used to treat dermatophytosis [43]. It is available as oral and topical preparations.

Terbinafine has good oral bioavailability (70–80%), and absorption is not affected by food. All allylamines are highly lipophilic and hence terbinafine achieves high concentrations in the stratum corneum, sebum, and nail. It is extensively metabolized in the liver, and 15 metabolites have been identified which are subsequently excreted in urine (80%) and feces (20%) [44]. At least 7 CYP enzymes are involved in terbinafine metabolism, of which 1A2, 2C9, and 3A4 are the most important [45]. Elimination takes place slowly, with an initial half-life of 22 hours and another at 90 hours, probably reflecting slow release from adipose tissue [44]. Use of terbinafine is not recommended in patients with active or chronic liver disease or with creatinine clearance <50 ml/min. It has been associated with gastrointestinal effects, skin eruptions, alteration or loss of taste, and hepatobiliary disturbances [46].

Initially, it was thought that terbinafine did not have any inhibitory effect on the CYP enzymes [47], but it is now known to be a potent competitive inhibitor of CYP2D6, although it has been suggested that one of its metabolites, rather than the parent drug, causes this [48]. Because CYP2D6 constitutes only 1.5% of the total liver CYP, there are minimal interactions via this route, except with venlafaxine [49] and amitriptyline [50]. Cimetidine decreases clearance of terbinafine, while fluconazole coadministration causes increased exposure to terbinafine via inhibition of CYP2C9 and 3A4.

38.2 PUBLIC HEALTH IMPACT OF FUNGAL DISEASES

The public health impact of fungal diseases is significant. The impact of superficial versus systemic disease is important for different reasons. Superficial fungal infections are extremely common: various studies estimated that 20–40% of adults in developed countries have some form of fungal foot disease [51], there is an increasing incidence of tinea capitis in children [52], and superficial candidosis is the most commonly seen manifestation of candidiosis [53]. From a public health viewpoint, superficial infections are important because those caused by dermatophytes are infectious and are readily transmitted via communal facilities, such as sports centers or within the family home. While skin infections are not associated with any significant morbidity, the breaches in skin integrity they cause may become a portal of entry for other organisms that may cause more serious infections such as cellulitis. Dermatophytosis may result in alopecia or permanent scarring from scalp infections and difficulty walking in elderly patients with grossly thickened or clawed toenails due to fungal nail infection.

Additionally, because of the sheer numbers of patients affected, the potential cost of medical consultations, diagnosis, and treatment for fungal foot disease alone is huge. Figures from the *Prescription Cost Analysis for England* for 2012 show that prescription costs for terbinafine and griseofulvin, the main drugs used to treat dermatophytosis, totaled £3.8 and £1.2 million, respectively, highlighting the significant cost of treatment alone (www.hscic.gov.uk/catalogue/PUB10610).

For IFD, the public health impact is also significant, despite the small numbers of people affected. Patients in whom systemic diseases are likely to develop are those who are immunocompromised, either because of underlying disease (e.g., leukemia, AIDS) or because of treatments for their disease (e.g., cytotoxic agents, immunosuppressives, organ or haematopoietic stem cell transplantation (HSCT)). Multiple studies in many countries have shown that the incidence of IFD is increasing, partly because more patients are surviving their underlying diseases and partly because more aggressive treatments are being used, resulting in many profoundly immunosuppressed, at-risk individuals [54].

Systemic diseases are relatively infrequent when compared to the prevalence in the community of superficial fungal infections. However, the cost associated with each episode of IFD is disproportionately high. This is because IFDs are associated with increased length of hospital stay and prolonged courses of antifungal drugs. A recent American study estimated that a patient with a systemic fungal infection stays in the hospital an extra 7 days and costs an extra $29,000 compared to a patient with the same underlying disease but no fungal infection [55]. Overall, this represents an additional cost of $1.89 billion, demonstrating that the cost associated with IFD has a significant public health impact.

The recent emergence of *Aspergillus fumigatus* with resistance to the azoles has been documented. Although there is a low level of resistance in many countries throughout Europe, the levels in Holland and the United Kingdom are higher. In Holland, the widespread use of azole-based compounds in agriculture has been implicated as the cause [56], but in the United Kingdom most of the resistance has occurred in patients treated with azoles, usually for months or years, for chronic aspergillosis [57]. The development of resistance to an important class of drugs, which often confers cross-resistance between members of the class, is of concern and may impact our ability to treat these infections in the future.

38.3 THE NEED FOR PHARMACOGENOMICS AND STRATIFIED MEDICINE

Treatment of fungal disease has been increasingly successful over the last 10–20 years, partly due to the advent of better antifungal drugs with broader spectra and less toxicity; and partly due to improvements in diagnosis of IFD, enabling earlier interventions. However, the morbidity and mortality associated with some fungal diseases is still very high.

Various risk factors predispose to IFD, including malignancy (particularly hematological malignancy), the use of steroids or antimicrobial agents, surgery, burns, uncontrolled diabetes, AIDS, chemotherapy, immunosuppressive agents, and neutropenia. The risk of IFD can be crudely predicted based on the level of patient immunocompromise. Therefore, patients who have undergone allogeneic HSCT have a greater risk of fungal disease than do patients receiving autologous transplants, which partly relates to their degree of immune suppression [58]. However, even within groups known to be particularly "at risk," susceptibility to fungal disease varies.

Approaches to prevention and diagnosis of fungal disease vary among institutions. Some use antifungal prophylaxis in high-risk patients in an attempt to avoid the disease. The triazole antifungals have been widely used in this setting, with fluconazole, itraconazole, and posaconazole all having a licence for this indication in the United Kingdom. Despite not having a licence for prophylaxis, voriconazole has also been used. The disadvantages associated with this approach include the cost of the drugs, the potential for drug interactions and toxicity, and the inability to achieve appropriate therapeutic levels in all patients. This can then require the use of therapeutic drug monitoring to ensure drug concentrations high enough but not toxic, which incurs a further cost [59]. Another disadvantage is that evidence suggests that the use of mold-active prophylaxis reduces the sensitivity of the *Aspergillus* galactomannan (GM) ELISA, which is widely used in the diagnosis of invasive aspergillosis [60]. This may then lead to the use of empiric antifungal therapy because of a lack of confidence in the results of the diagnostic test.

Another approach is the routine screening of patients with PCR and GM ELISA—a so called "enhanced diagnostic" approach. This relies on the high negative predictive value of the tests and, unless other features of fungal disease occur, it enables the patient to remain on prophylaxis rather than receive empiric antifungal therapy. One study showed no difference in morbidity or mortality when empiric therapy was withheld and a reduction in antifungal expenditure of £124,000 using the enhanced diagnostic approach [61].

Diagnosis of superficial fungal disease is relatively simple, with direct microscopy and culture of skin, hair, or nail samples allowing the recovery of the causative agent in most patients. The situation is more challenging in patients with suspected IFDs. Patients are likely to have serious underlying disease, and the development of new signs and/or symptoms, which are often nonspecific, may be difficult to pinpoint. Direct microscopy and culture may be useful if tissue is available, but is often slow and insensitive; the inability to take biopsies and deep tissue samples in patients with coagulopathies further limits the usefulness of this modality. Detection of antibodies to fungi is rarely helpful in patients who are immunocompromised.

The use of fungal antigen detection kits has become increasingly common, and several are available, including cryptococcal antigen, *Aspergillus* GM, *Candida* mannan, and the more general β-D-glucan detection kits. While the sensitivity and specificity of the cryptococcal antigen kit is very high, the corresponding figures for the GM kit vary with patient group. It is highest in the HSCT recipient and lower in solid organ transplant recipients. Other tests such as PCR have been useful for some diseases and in certain laboratories, but the lack of standardization and variable performance means that they are still not used routinely in many centers [62].

Whatever approach is used, it is recognized that the successful outcome of an IFD relies on the early institution of appropriate antifungal therapy and that successful outcomes correlate with early initiation of therapy [63].

Although there are now many efficacious antifungal drugs available, the prevention, diagnosis, and treatment of IFD still presents a major challenge. To date we still do not understand the subtle differences between patients that impact their risk of infection or their response to antifungal drugs. Developments in pharmacogenomics that better enable us to predict how antifungal drugs will behave in a given patient will help us move toward more tailored or personalized management in this area.

38.4 GENETIC VARIABILITY ASSOCIATED WITH ANTIFUNGAL DRUGS

The effect of genetic variability on antifungal drugs may occur at any point during their absorption, distribution, metabolism, or elimination from the body. In addition to genetic variability, there are many other factors that may impact the efficacy of antifungal drugs, including drug interactions and various physiological factors [59,64,65].

38.4.1 Absorption

Antifungal drugs are administered either orally or intravenously, and absorption is affected by many factors but is most variable for drugs that are taken orally. With IV dosing, absorption is assumed to be complete and the total dose reaches the systemic circulation. When the drug is given orally, it must dissolve in the stomach (the extent of which may be affected by gastric pH and the presence and type of food) and may then be subjected to first-pass metabolism in the intestines and liver or transporter-mediated efflux back into the intestinal lumen. These processes are affected by the amount and activity of the drug transporters and metabolizing enzymes at those sites (see Figure 38.3). Biliary excretion at this initial stage may also reduce the net amount of absorption. Because most of the drug is absorbed from the intestines rather than the stomach, any factor that speeds gastric emptying is likely to enhance drug absorption.

Gastric pH is particularly important for the absorption of itraconazole and posaconazole, while it has little effect on the absorption of flucytosine, fluconazole, voriconazole, and terbinafine. Itraconazole and posaconazole are weak bases and hence do not dissolve well in an alkaline environment [66,67]. Gastric pH can vary by up to 10-fold between individuals [68], and men tend to have lower gastric pH than women [69]. Age is now no longer thought to affect pH. Specific patient groups also have alterations in gastric pH due to their disease: those with AIDS have increased gastric pH [70], while critically ill patients show reduced gastric pH [71].

The widespread practice of using PPIs or H_2 antagonists to reduce the risk of gastric ulcers in hospitalized patients [72] will also have a significant impact on gastric pH. Indeed, it has been shown for posaconazole that concomitant PPIs or H_2 antagonists cause a significant reduction in drug exposure in patients [30]; although this is not due to genetic variability, it is an important determinant of drug absorption. For itraconazole capsules (but not oral solution), factors that enhance gastric acidity improve absorption, such as administration with food; whereas factors that decrease gastric acidity (use of PPIs or fasting) reduce absorption [9]. Therefore, patients receiving itraconazole capsules may be affected by variations in gastric pH that

result in serum concentrations of itraconazole that are insufficient to prevent or treat their disease.

The main efflux drug transporters in the intestines are P-gp, breast cancer resistance protein (BCRP), and multidrug resistance protein 2 (MRP2) [73]. These transporters are found at the luminal side of enterocytes and are important in limiting the uptake of drugs that are substrates for them. They are all members of the ATP-binding cassette transporters and use ATP to allow them to pump substrates against the concentration gradient. It was recently shown that there is a large amount of inter-individual variation in the quantity of each transporter in the intestines and liver [74] and this might contribute to the variability in drug absorption between different individuals. BCRP and P-gp are present in smaller amounts in the liver than in the gut, while MRP2 is present in smaller amounts in the gut.

All of these efflux transporters have genetic polymorphisms which result in clinically significant changes in substrate binding. P-gp has multiple genetic variants, caused by single-nucleotide polymorphisms (SNPs) that vary with ethnicity and cause clinically relevant differences in, for example, clearance of ciclosporin [75]. SNPs in BCRP and MRP2 also occur and can affect the extent of substrate binding [73].

Several of the orally administered antifungals are either substrates or inhibitors of these transporters (see Table 38.4). Itraconazole, fluconazole, and posaconazole are all P-gp substrates, with itraconazole having the strongest interaction with it; itraconazole and posaconazole are also P-gp inhibitors. Voriconazole binds to CaMdr1P, the yeast homolog of human P-gp, suggesting theoretically that it may be a substrate in humans as well, but as yet there are no data to support this contention [76]. Itraconazole is an inhibitor of BCRP. Based on the chemical similarity between itraconazole and posaconazole and the presence of a long side chain in posaconazole (which enhances inhibitory capacity), it is likely that it too is an inhibitor of BCRP [77]. There are little data on the interaction of terbinafine with these transporters, but it is unlikely to be an inhibitor of

Fluconazole	3A4 [10]	2C9 [30.3 μM] [12]; 2C19 [12.3 μM] [12]; 3A4 [13.1 μM] [11]; 1A2 [31]	++ [14]	– [11,14]	ND	– [77]	UGT2B7/UGT1A4 substrate [118]; UGT2B7 inhibitor [119]; not OAT-P1B1/OATP1B3 inhibitor [93]
Itraconazole	3A4 +++ [19]	3A4 [0.033 μM] [11]; 2C9 [>10 μM] [12]; 2C19 [>10 μM] [12]; 1A2 [31]	+++ [15]	[2 uM] [14] [5–50 uM] [11]	ND	[<1 uM] [77]	Suggested OATP inhibitor via interaction with fexofenadine [91] but *in vitro* study found no inhibition [92]; not OATP1B1/OATP1B3 inhibitor *in vitro* [93]; multidrug resistance protein 3 inhibitor [89]; not NTCP/BSEP inhibitor; UGT1A4 substrate [118]
Voriconazole	2C19 +++ 3A4 ++ 2C9 ++ [21]	2C9 [8.4 μM] [12], [3.62 μM] [26]; 2C19 [8.7 μM] [12], [5.25 μM] [26]; 3A4 [10.5 μM)] [12] [2.9 μM] [26]; 2B6 [1.7 μM] [26]	Possibly [76]	– [140]	ND	– [77]	UGT1A4 substrate [118]; possible UGT2B inhibitor [130]; FMO enzyme substrate [129]
Posaconazole	– [140]	3A4 [1.3 μM)] [31]; 1A2 –; 2C9 –; 2C19 –; 2A6 –; 2D6 –	++ [78]	++ [78]	ND	Likely to be based on long side chain and structural similarity to itraconazole [77]	UGT1A4 substrate [123]
Caspofungin	– [120]	3A4 + [36]	ND	– [98]	ND	ND	NCTP inhibitor; OAT1B1 substrate/ inhibitor [98].
Micafungin	– [12]	2C9 –; 2C19 –; 3A4 [13.5 μM] [11]	– [11]	– [11]	+ [100]	ND	OATP/NTCP (+)/BSEP (++) substrate [100]
Anidulafungin	– [114]	– [102] Not 1A2, 2B6, 2C9, 2C19, 2D6, or 3A inhibitor [114]	ND	ND	ND	ND	Not OATP inhibitor [102]
Flucytosine	ND	ND	ND	ND	ND	ND	
Terbinafine	1A2 +++ 2C9 +++ 3A4 +++ 2C8 +[45]	2D6 [0.2 μM] [45]; 3A4 – [47]	ND	Unlikely [10]	ND	ND	

[a] *IC_{50} (uM) is shown in brackets where figures are available; these may vary between studies in which different probes have been used in vitro.* [b]*Relevant source in reference list.*

ND—no data available; – no inhibitory effect or not a substrate; + weak inhibitor or weak substrate; ++ moderate inhibitor or moderate substrate; +++ potent inhibitor or major substrate.

P-gp because of the lack of effect when it is coadministered with digoxin, a P-gp-dependent substrate [10].

The presence of SNPs in any of the efflux transporters potentially affects the absorption of orally administered antifungals if they cause altered binding due to those polymorphisms. The only drug for which data are available is posaconazole, where the effect of SNP's in P-gp have been studied [78]. Homozygous expression of the T allele results in significantly less expression of P-gp than does expression of heterozygous or wild-type alleles. Volunteers (28 black and 28 Caucasian) were dosed with 400 mg of posaconazole twice daily after food for 8 days, after which concentrations of posaconazole and expression of SNPs in P-gp were investigated. Overall, 41 SNPs were found in the alleles, with 13 individuals being homozygous for the T allele and 43 being either heterozygous or wild-type. There was no difference in drug exposure for either group, and hence it seems that polymorphisms in P-gp have no effect on posaconazole absorption. However, as this study was performed in healthy volunteers, its applicability to patients is uncertain.

There are currently no other data for the other antifungals, but similar studies are of interest particularly for itraconazole, which is a potent substrate and inhibitor of P-gp.

38.4.2 Distribution

Once the drug has been absorbed after oral administration, it must reach the bloodstream. Drugs that are administered intravenously overcome the issues related to absorption, but they too must move from the bloodstream to the interstitial and intracellular fluid and ultimately to the site or sites of the fungal disease. Blood flow to the various organs is one of the main determinants of tissue delivery, with the well-perfused organs (e.g., liver, kidney, brain) receiving the highest concentrations initially, with the skin, muscles, and fat receiving the drug possibly several hours later. The extent to which the drug partitions between blood and tissue is determined by how much the drug is bound by serum proteins, as only an unbound drug can move across cell membranes. The main proteins that bind drugs in serum are albumin—the major carrier for acidic drugs—and α_1 acid glycoprotein (AAG), which binds basic drugs. Lipoproteins also act as carriers for some drugs.

The concentrations that are achieved for different antifungals at different body sites vary considerably (see Tables 38.2 and 38.3). Some antifungals are highly protein bound (e.g., itraconazole, posaconazole), while others have much lower protein binding (e.g., fluconazole, flucytosine). Itraconazole and posaconazole are mainly bound to albumin, although itraconazole does also bind, to a lesser extent, to AAG. Although much less protein bound, fluconazole preferentially binds to AAG [79]. Amphotericin B is bound by lipoproteins, albumin, and AAG [80,81], while terbinafine is strongly bound to serum proteins and the binding is even across the lipoproteins and albumin [44]. All echinocandins are extensively protein bound, mainly to albumin, but the extent of binding of caspofungin varies between healthy volunteers and patients [34].

Many serum proteins are now known to have genetic variants, with human serum albumin having 67 genetic variants [82] and AAG having 2 [83]. These variants have altered substrate binding and because of the extensive protein binding of many antifungals, this may affect their distribution. If protein binding of the antifungal were reduced, this could allow greater concentrations to move into the cells more quickly; conversely, if the binding were increased, this could reduce the rate at which the drug dissociates and moves into the tissues. At the moment, however, this is entirely speculative and there are no data about how antifungals are affected by serum protein genetic variants.

Drugs are taken into cells by either passive diffusion or active transport. As well as the extent of its protein binding, a drug's ability to cross the cell membrane and hence enter the cell is determined by factors such as its size, degree of ionization, and lipid solubility of its ionized and nonionized forms. Passive diffusion into the cell usually occurs because the drug is soluble in the lipid bilayer and its movement occurs down a concentration gradient. Hydrophilic drugs penetrate cell membranes via the aqueous channels. In contrast, active transport requires the expenditure of energy and usually moves a drug against the concentration gradient, is saturable, and may be subject to competitive inhibition. Uptake transporters include those that transport anionic drugs (organic anionic transporters, or OATs) and organic anionic transporting polypeptides (OATPs), as well as those that transport cationic drugs (organic cationic transporters, or OCTs) and peptide transporters (PEPTs). As with efflux transporters, genetic polymorphism occurs for the uptake transporters resulting in alterations in substrate binding [84].

The distribution of drugs around the body and entry into specific tissues is determined partly by the uptake transporters. Antifungal drugs must be taken up into tissues to reach the site of the fungal disease, and in sufficient concentrations to allow them to either inhibit or kill the fungi. If the concentration achieved locally is not sufficient, then although the fungus may appear to be susceptible to the agent *in vitro*, the drug will not be efficacious *in vivo*, resulting in clinical failure.

Amphotericin B achieves high concentrations in the liver and spleen, and moderate concentrations in the lung and kidney. The data on the involvement of drug transporters in the uptake of this drug into tissues are very limited. Amphotericin B potentiates the effects of various cytotoxic drugs. This may be due either to increased cellular permeability or to P-gp inhibition [85]. P-gp is involved in the efflux of drugs from many types of cancer cells, which causes resistance to cytotoxic agents; however, if amphotericin B inhibits P-gp, this may enhance both the level and the effects of cytotoxic agents in cancer cells. In contrast, it was shown that the coadministration of amphotericin B and ciclosporin in rats caused an induction of multidrug resistance gene 1 (*MDR1*) expression and higher levels of P-gp, suggesting that amphotericin B may induce P-gp rather than inhibit it [86]. Studies *in vitro* showed that amphotericin B has no activity as a P-gp inhibitor. For this reason, the extent to which amphotericin B interacts with P-gp is still not clear, and hence its role in the distribution of this drug is also unknown. There are no other data on which drug transporters amphotericin B interacts with, so few conclusions can be drawn about the likely effect of drug transporter polymorphisms on amphotericin B distribution.

Fluconazole has low protein binding and is hydrophilic; hence, it achieves good tissue penetration with high concentrations in cerebrospinal fluid (CSF), saliva, bronchial secretions, and brain [3]. It is not an inhibitor of OATP1B1 or OATP1B3, which are both involved in uptake into the liver. Fluconazole is probably taken up into cells and tissues by passive diffusion and so is unlikely to be affected by genetic variability in uptake transporters.

Itraconazole is found in the highest concentrations in the liver, spleen, kidney, and lung, and in very low concentrations in the eye and CSF. It is known to be a potent substrate and inhibitor of P-gp, which is likely to affect its tissue distribution. Absorption of itraconazole can be variable, and it may be that as a substrate of P-gp, some of the drug is pumped back into the lumen of the intestine by P-gp and hence reduces absorption. Similarly, P-gp acts within the brain to limit drug uptake into brain tissue. In a mouse model, itraconazole was shown to be effluxed from the brain by P-gp; in knockout mice that lacked P-gp, this efflux mechanism was removed, allowing accumulation of itraconazole within the brain [87]. Similarly, an inhibitor of P-gp allowed improved concentrations of itraconazole in a mouse model by overcoming the efflux due to P-gp [88]. The low concentrations of itraconazole seen in the brain and CSF suggest that this may be a possible mechanism responsible in humans, too. In the presence of genetic variants of P-gp, this has the potential to alter both the uptake of itraconazole from the intestine and its access into the brain. Itraconazole is also a substrate or inhibitor of several other drug transporters, including BCRP and MRP3, but at physiological concentrations it does not inhibit the bile salt extract pump (BSEP) or the hepatic uptake transporter Na+ taurocholate-cotransporting peptide (NTCP) [89]. Polymorphisms in BCRP or MDR3 could therefore also impact itraconazole distribution. Based on its interaction with atorvastatin [90] and fexofenadine [91], it has also been suggested that itraconazole may be an inhibitor of OATP1B1, which is important in uptake into the liver, although *in vitro* data do not support this idea [92,93]. Therefore, because of extensive interactions with drug transporters, there are multiple points at which genetic variability could impact the distribution of itraconazole in the body.

Voriconazole is found at high concentrations in the lung, spleen, liver, and kidney, with moderate concentrations in the brain, eye, and CSF [94,95]. The data on voriconazole's interaction with drug transporters are currently very limited. Voriconazole does not inhibit P-gp or BCRP, and there is only circumstantial evidence that it may be a substrate for P-gp. Its penetration into brain and CSF tends to suggest that it is not a substrate of P-gp or it would be subject to efflux from the brain and CSF, as is seen for itraconazole. As more information emerges about interactions between voriconazole and drug transporters, it may be possible to determine whether there is potential for genetic variants to impact its distribution; at the moment, however, there is no obvious point where this might occur.

Little is known about the tissue distribution of posaconazole except that it does not achieve high concentrations in CSF, although it achieves concentrations above the MIC for most fungi in various compartments of the lung [96]. Posaconazole is a substrate for P-gp and hence P-gp-mediated efflux may explain some of the absorption problems seen with this antifungal and its low CSF concentration. Based on its structural similarity to itraconazole, it is probably an inhibitor of BCRP; if so, its inhibition of BCRP in the intestine might enhance its own uptake. Potentially, polymorphisms in either P-gp or BCRP might affect the distribution of posaconazole; at the moment, however, the evidence for this is limited.

Caspofungin is a large molecule and highly protein bound; nevertheless, it achieves high concentrations in the kidney and liver, moderate concentrations in the lung and spleen, but only low concentrations in the brain and eye. Its profile in plasma is determined by its rate of distribution into tissues rather than by its metabolism or elimination [97]. Uptake into the liver is a two-step process. The first part is a rapid reversible absorption to the cell surface, followed by a second slower phase with transport across the cell membrane [97,98]. OATP1B1 mediates uptake into hepatocytes, with no uptake by OATP1B3. Caspofungin has a relatively low affinity for OATP1B1 and is also a modest inhibitor of this transporter [98]. It also inhibits NTCP, OCT1, and OAT1 at 100 μM, although at physiological concentrations of 1–10 μM, this inhibition may not occur. Caspofungin has no inhibitory activity against P-gp [98].

The importance of OATP1 in the transport of caspofungin into the liver is illustrated by the interaction with rifampin, which inhibits OATP1 and causes a decrease in the trough levels of caspofungin by 14–31% after multiple rifampin doses [99]. The most important drug transporter for caspofungin is OATP1B1, and so it is only OATP1B1's genetic variants that may affect caspofungin distribution. Multiple genetic polymorphisms have been described for OATP1B1, including some that occur with relatively high frequency in several ethnic groups and cause reduced transporter activity. Therefore, if any of these polymorphisms occur in patients who are receiving caspofungin, they may potentially affect the drug's uptake into the liver and hence its distribution.

Micafungin accumulates to high concentrations in the liver, lung, and kidney, and its uptake into the liver is well characterized and involves both passive and active transport. The hepatic uptake transporter NTCP is most important in micafungin uptake, with OATP playing a minimal role. This finding is unusual, as it was previously thought that NTCP was a specific transporter solely for bile salts. P-gp has no involvement in transport of micafungin [100]. NTCP shows genetic variability across different ethnic groups, resulting in reduced activity [101]; thus, individuals expressing variants in this transporter may have altered ability to take micafungin into the liver.

In clinical studies, anidulafungin reached high concentrations in the lung and liver, moderate concentrations in the spleen and kidney, and low concentrations in the brain, CSF, and eye. At concentrations achieved at steady-state (1–3 μM), anidulafungin is not a substrate or inhibitor for OATP-B or OATP-C, although at higher concentrations (10 μM) it causes inhibition of OATP1B3 [102]. The potential for anidulafungin distribution to be affected by genetic polymorphisms therefore appears to be very limited.

Flucytosine has very low protein binding and is very hydrophilic. Because of these two factors, it can achieve good tissue concentrations in CSF, saliva, bronchial secretions, and brain [3]. There are currently no data on the interaction of flucytosine with any of the drug transporters, but because it appears to be taken up by passive diffusion into cells it is unlikely to be affected by genetic uptake transporter variability.

Terbinafine is primarily used for the treatment of superficial fungal infections and so its distribution in other tissues of the body has been little studied. The drug is lipophilic and achieves good concentrations in skin, hair, and nail. It is unlikely to be a P-gp inhibitor because of its lack of interaction with digoxin [10]. However, there are no other data on its interaction with drug transporters. Given this lack of information, it is not currently possible to determine whether polymorphisms in drug transporters may affect terbinafine distribution.

38.4.3 Metabolism

Many drugs are lipophilic, which allows them to transit biological membranes but hinders their removal from the body. These compounds must be metabolized to more hydrophilic molecules for excretion. Drug metabolism reactions are classified either as phase I or phase II. Phase I reactions include oxidation, reduction, and hydrolysis and generally result in inactive drugs. Phase II reactions conjugate the result of phase I reactions with a second molecule and result in metabolites with improved water solubility. Phase I reactions are carried out by superfamilies of related enzymes, including CYP450 enzymes and flavin monooxygenases (FMO).

CYP450 enzymes metabolize a wide range of endogenous and exogenous substrates, including sterols, fatty acids, vitamins, and a multitude of drugs. Substrate specificity for each enzyme is often very broad—for example, CYP3A4 is responsible for metabolizing about 50% of clinically used drugs, including many immunosuppressives, statins, benzodiazepines, and other drugs. This lack of reaction specificity means that if coadministered drugs are metabolized by the same enzyme, there is substantial potential for drug interaction [103].

The expression of different CYP enzymes varies between tissues. The main CYPs expressed within the intestine are CYP3A, accounting for approximately 80% of total protein, and 2C9, which contributes ~14% [104]. In the liver, CYP3A4 contributes 29% of the total protein content; CYP2C (2C8, 2C9, 2C18, and 2C19), 18%; CYP 1A2, 13%; and other CYPs, smaller amounts [105]. CYP3A expression levels vary throughout the length of the intestines, with the highest levels in the duodenum and middle jejunum, declining in the distal jejunum and ileum [106]. As well as this variability in CYP enzyme distribution, enzyme activity can vary significantly between individuals, with up to 20-fold variability in the activity of CYP3A4 [107]. Because of this, the extent of metabolic activity on drugs can be markedly different between individuals and hence the concentrations achieved in the tissues, even though the individuals received the same initial dose.

Compounding this variability in expression and lack of enzyme specificity is the widespread occurrence of genetic variants within the different CYP alleles. Many of the alleles have SNPs that result in reduced, lack of, or occasionally increased metabolic activity. CYP3A4/5 currently has over 40 described allelic variants, 2C9 has more than 60, and 2C19 has more than 30 [108]. The prevalence of these alleles varies with ethnicity, as discussed in Chapter 16. For 2C9, about 80% of the Caucasian population express the wild-type allele (2C9*1A) and about 20% express the allele's genetic variants [109]. CYP2C19 has several variants that result in a "poor metabolizer" phenotype, where individuals are not able to clear CYP2C19 substrates as well as those who have wild-type alleles and are either heterozygous or homozygous for the wild-type 2C19*1A allele. The incidence of 2C19 poor metabolizers is about 2–5% in Caucasians; in Asian populations this may be 15–20% [110]. The prevalence of polymorphic variants of 3A4 alleles is very low (about 1% in Caucasians), but it has been suggested that some of the activity ascribed to 3A4 is actually due to 3A5, which has a polymorphic allele frequency of 90% in Caucasians [111].

The other main group of enzymes involved in phase I metabolism are the FMOs. These are involved in the oxygenation of compounds to make them more polar and hence easier to excrete. There are five isoforms of the enzyme, which vary in tissue distribution and activity, and have genetic variants with altered substrate activity [112].

Phase II reactions are carried out by various enzymes, including the glutathione-S-transferases (GSTs), UDP-glucuronosyltransferases (UGTs), and N-acetyltransferases (NAT). These reactions result in the conjugation of a substrate and usually ablate its activity. As with the phase I enzymes, genetic variants have been described that result in changes in the enzymes' metabolic activity [113].

Some data exist on the effect of genetic polymorphisms on the metabolism of various antifungals. The magnitude of the effect mainly depends on the way in which the drug is metabolized. For drugs that either are not metabolized at all or undergo metabolism independent of the phase I and II enzymes, the potential for genetic variants affecting them is minimal. This includes anidulafungin, amphotericin B, flucytosine, and fluconazole.

Anidulafungin is unusual among antifungal drugs in that it undergoes a slow nonenzymatic degradation mainly in the tissues, with no involvement of either the phase I or phase II enzymes. Initially, an inactive metabolite is formed that is thought to undergo further degradation by plasma peptidases [114]. Therefore, there are no points at which genetic variants in phase I or II enzymes can impact this process. Unlike anidulafungin, flucytosine and amphotericin undergo virtually no metabolism and are almost entirely excreted unchanged [6], although very small quantities of metabolites have been described for flucytosine [115]. Because of this lack of metabolism, there is no way in which genetic polymorphisms can affect this process.

However, evidence from drug interactions suggests that amphotericin B may have various effects on CYP450 enzymes. In animals, amphotericin B caused reduced concentrations of hepatic CYP enzymes, and in patients with HIV a reduction in CYP enzymes was also reported [116]. The mechanism is unclear and may have been hepatocyte damage rather than a specific effect on CYP. In contrast, amphotericin B was found to induce CYP3A2 and consequently first-pass metabolism of ciclosporin, which may contribute to decreased levels when amphotericin B and ciclosporin are coadministered [86]. Nothing is known about its ability to interact with the genetic variants of these CYP enzymes.

Fluconazole is highly water soluble and so circumvents most of the hepatic metabolism needed by the other azoles. It is mainly excreted unchanged in urine, although about 10% is metabolized [117]. Fluconazole is a weak substrate for CYP3A4 [10] and a substrate [118] and inhibitor [119] of UGT2B7, both of which have been shown to have genetic variants with altered enzymic activity. However, as only 10% of fluconazole is metabolized, genetic polymorphisms in CYP3A4 or UGT2B7 are unlikely to affect this process significantly.

Caspofungin is not metabolized by phase I enzymes, but is broken down by peptide hydrolysis and N-acetylation. In the plasma, unchanged caspofungin is found mainly in the first 24 hours, but later M0, a linear peptide, is the main metabolite. In urine, in the initial 24-hours, the parent drug is mainly found, but later the hydrolytic metabolites M1 and M2 are the predominant form [120]. N-acetylation is carried out by NATs and numerous genetic polymorphisms affect their activity [113]. However, there is currently no data on which NAT is involved with caspofungin metabolism, and hence whether genetic variability has any impact on it.

Micafungin is metabolized to an M1 metabolite by arylsulfatase, which is then further metabolized by catechol-O-methyltransferase (COMT) to the M2 metabolite [121]. Micafungin's side chain is also metabolized by CYP3A to produce a third metabolite, but this is only a minor metabolic pathway [122]. COMT is present in cells either as a soluble form in the cytoplasm or as a membrane-bound form in the rough endoplasmic reticulum. The soluble form is mainly expressed in peripheral tissues. Both arylsulfatase and COMT are polymorphic, which affects their enzymic activity [113]. Because both of the enzymes involved in micafungin metabolism have genetic variants with differing metabolic activity, the potential exists for this to affect an individual's ability to metabolize micafungin; as yet there are no data as to whether this occurs.

Several antifungal drugs must undergo extensive metabolism before they can be excreted from the body; for them, the potential for genetic variants of the phase I and II enzymes to impact clearance is highest.

Terbinafine is metabolized to five main metabolites by four main metabolic pathways: N-demethylation, deamination, alkyl side chain oxidation, and dihydrodiol formation [45]. The CYP enzymes responsible for each of the metabolic pathways have been defined: N-demethylation is mediated by 2C9, 2C8, and 1A2; deamination, by 3A4; alkyl side chain oxidation, by 1A2, 2C8, 2C9, and 2C19; and dihydrodiol formation by 2C9 and 1A2. Overall, 2C9, 1A2, and 3A4 are the most important isoforms involved in metabolism. All of the CYP isoforms involved are genetically variable [108] and so polymorphisms could affect the metabolism of terbinafine. However, because metabolic activity is spread over a range of isoforms, the potential impact of each polymorphism is limited. As for most other antifungal drugs, there are currently no data on how terbinafine metabolism is affected by CYP polymorphisms.

Of the newer triazoles, posaconazole has the most limited interaction with the CYP enzymes, as it is not metabolized by this route. Indeed, posaconazole does not undergo extensive metabolism, being mainly excreted unchanged, and there are no active metabolites found in plasma [9,32]. The predominant metabolite that is formed is a posaconazole glucuronide produced by UGT1A4 [123]. UGT1A4 is polymorphic, and some of the resultant enzymes have reduced catalytic activity [124]. This, then, is the only point at which genetic polymorphisms might affect posaconazole metabolism, but because most of the drug is excreted unchanged, their potential impact is limited.

Itraconazole is largely metabolized in the liver, with only 3–18% of the parent drug excreted in the feces. The main metabolic pathways include oxidation and N-dealkylation [125], resulting in at least 30 metabolites, of which hydroxy-itraconazole is microbiologically active and present in higher concentrations than the parent drug [19]. Metabolism is mainly carried out by CYP3A4, for which itraconazole is both a substrate and a potent inhibitor [19]. Initial metabolism results in production of hydroxy-itraconazole, which remains attached to the CYP3A4 enzyme complex which further catalyzes the conversion to keto-itraconazole and then N-desalkyl-itraconazole. In addition to itraconazole being a potent CYP3A4 inhibitor, its metabolites have a higher inhibitory capacity than the parent drug, which may explain why such potent CYP3A4 inhibition is seen with itraconazole [126]. Because CYP3A4 is the most abundant isoform in the human intestines, it is estimated that first-pass metabolism may remove up to 50% of the itraconazole dose before it reaches the systemic circulation [18]. Although there are no data in humans, up to 76% of the oral dose and 21% of the IV dose in rats was metabolized by this mechanism, resulting in much lower drug exposure than predicted [127]. This suggests that first-pass metabolism may have significant impact on drug exposure in patients.

Multiple SNPs have been described in CYP3A4, but most of them are low frequency and usually heterozygous with a wild-type allele. However, CYP3A5 is highly polymorphic and, if it is involved in itraconazole metabolism, there is significant potential for genetic variants to cause an impact, both on first-pass and later metabolism; this might go some way to explaining the very variable levels of drug exposure seen in patients. At the moment, there are no data on how these polymorphisms might affect the onward metabolism of hydroxy-itraconazole—the first metabolite formed in the pathway. Because it too is metabolized by CYP3A4, it may be that it has similar potential to be as affected as the parent drug.

In addition, itraconazole is known to be a substrate for UGT1A4, another polymorphic enzyme [118]. The exact role that this enzyme plays in human itraconazole metabolism is not clear, but it too is polymorphic and so is another point at which itraconazole metabolism may be influenced by genetic variability. Although to date there have been no studies examining this area, the data indicating that polymorphisms may be important for itraconazole suggests that such studies may reveal more about itraconazole's pharmacokinetics.

The last of the antifungal drugs to consider is voriconazole, for which there is the most evidence that genetic variability plays a clinically significant role in its metabolism. Voriconazole is extensively metabolized, with over 75–80% excreted via the urine and 20–25% via the feces [22] as multiple metabolites. The main circulating metabolite is voriconazole N-oxide, which is produced by CYP2C19 and CYP3A4, with 2C19 being high-affinity but low-capacity and 3A4 being a low-affinity but high-capacity. CYP2C9 also plays a minor role in voriconazole metabolism [21]. Another metabolite, 4-hydroxyvoriconazole is produced by CYP3A4, and it has been suggested that the abundance of CYP3A4 over CYP2C19 in the liver means that this metabolic pathway is also significant [128]. In addition to CYP-mediated metabolism of voriconazole, which makes up 75% of the metabolic pathway, 25% of voriconazole metabolism is mediated by the FMO enzymes [129]. Although FMOs contribute to the production of voriconazole N-oxide, they are less important than CYP2C19. Voriconazole has recently been found to inhibit UGT2B [130], although the significance of this is unclear.

Patients receiving voriconazole have been shown to have significant variability in their pharmacokinetics, with trough plasma concentrations in one study of 122 patients ranging from <100–9700 mg/L despite the same dosing regimen [131]. CYP2C19 is the most important enzyme involved in voriconazole metabolism and, as discussed previously, its variants give rise to poor metabolizers, heterozygous wild-type metabolizers, and homozygous extensive metabolizers [110]. Voriconazole drug exposure in patients who are poor metabolizers is up to 5 times higher than in those who are homozygous extensive metabolizers [132]. Conversely, the rapid metabolizer phenotype leads to concentrations of voriconazole that are much lower than those seen in extensive or poor metabolizers [133]. Indeed, the variability in drug levels due to polymorphisms in CYP2C19 have been estimated to account for 49% of drug clearance variability. Thus, these polymorphisms are very important in voriconazole pharmacokinetics [134]. However, when multiple CYP genetic polymorphisms coexist, this does not lead to an additive effect on metabolism [135]. In addition to drug exposure variability caused by genetic variants of CYP2C19, there is also variability caused by FMO genetic variants [112], but the extent to which this impacts voriconazole metabolism is unknown.

Because it is known that CYP2C19 variability is important in voriconazole exposure, voriconazole was one of the first drugs for which pharmacogenomic data were included in the manufacturer's FDA submission. It has also been suggested that genome analysis should be performed in the future for all patients receiving voriconazole, in addition to therapeutic drug monitoring to optimize exposure [136].

For voriconazole, more than for any other drug, understanding how genetic polymorphisms affect its metabolism have been pivotal in explaining the pharmacokinetic variability observed in patients who are treated with it.

38.4.4 Elimination

Elimination of drugs from the body is via the liver or kidneys. In the liver drugs are eliminated with bile via the feces, while in the kidneys they are eliminated via urine. Efflux transporters in the liver and kidneys are therefore critical to removal of drugs from the body. Transporters that are responsible for transit of substances across the canalicular membrane and into the bile include P-gp, MRP2, BCRP, BSEP, MDR3, and multidrug and toxin extrusion type transporter 1 (MATE1) [137]. In the kidneys, excretion into urine is mediated via various transporters, including OCTN1, OCTN2, MATE1, MATE2, P-gp, BCRP, MRP2, and MRP4 [138]. Transporters that are responsible for effluxing drugs into the intestinal lumen include P-gp, BCRP, and MRP2 [73], and these may mediate antifungal drug efflux directly into the feces.

Amphotericin B is predominantly eliminated via the bile, with 43% excreted unchanged, while 21% is excreted via the kidneys. Several drug transporters are important in transporting drugs across the canalicular membrane and into the bile, which suggests that amphotericin B must be a substrate of at least one of them. Limited evidence suggests that amphotericin B may be transported via P-gp [139], and this might represent a route for its elimination via both the liver and kidneys. P-gp polymorphisms could potentially impact elimination if indeed amphotericin B is a substrate of P-gp.

Fluconazole and flucytosine are largely excreted unchanged in the urine. Because of their hydrophilic nature and limited protein binding, they may diffuse into the urine passively. However, at the moment there are no data on whether drug transporters contribute to this process, and hence whether genetic variants influence the elimination of either drug.

Elimination of itraconazole is mainly via the feces as metabolites, with some excreted as either metabolites or unchanged in urine. Itraconazole is a substrate of P-gp and CYP3A4, and up to 50% of it may potentially be excreted directly into bile or feces via first-pass metabolism without absorption. Similarly, itraconazole that has been absorbed is likely to be eliminated via P-gp efflux into the intestines. The route of excretion of itraconazole's main metabolite, hydroxy-itraconazole, is not well established and so there are no data as to whether it is eliminated via drug transporters or via passive diffusion. P-gp represents one point at which itraconazole elimination may be affected by genetic polymorphisms.

Voriconazole is mainly excreted as metabolites, with 80% in the urine and about 20% in the feces. It is not a substrate for BCRP, and there is only limited evidence that it is a substrate for P-gp [76,140]. Also, it is currently unknown whether any of voriconazole's metabolites are substrates for drug transporters, but at the moment there is little to suggest that genetic variants impact its elimination.

Posaconazole is predominantly eliminated unchanged in the feces, with some metabolites in the urine. It is a substrate of P-gp, and the presence of large amounts of unchanged drug in the feces suggests that it may undergo some direct efflux from the systemic circulation into the intestines because of P-gp [32]. This may be partly why its absorption is limited. Thus, excretion of posaconazole may be affected by polymorphisms in P-gp, resulting in more or less being left in the circulation depending on the particular effect of the polymorphism.

Caspofungin and anidulafungin are eliminated mainly as metabolites: caspofungin equally in the urine and feces and anidulafungin mainly via the feces. Most of the metabolites for both drugs are peptides, so they are likely to be eliminated by transporters that excrete peptides from the body. It is unknown which transporters eliminate the metabolites from these drugs, and hence whether they have polymorphisms that may affect this process.

Micafungin is eliminated mostly in the bile via the feces. The rate-limiting step in its hepatic elimination is biliary excretion rather than hepatic uptake, and the main drug transporter involved in transport across the canalicular hepatocyte membrane is BSEP, with BCRP having little importance. MRP3 is responsible for transport of micafungin across sinusoidal hepatocyte membranes [100]. Both of these transporters have genetic polymorphisms, and hence there is the potential that the elimination of micafungin is affected by them.

Terbinafine is metabolized to five main metabolites which differ in their excretory route. In plasma, the main metabolite is carboxybutylterbinafine, which, along with the parent drug and three other metabolites, accounts for 80% of the total dose [141]. In urine the major metabolite is demethylcarboxybutylterbinafine, which with the parent drug and three other metabolites accounts for only 14% of the total dose over a 48-hour period. There are currently no data on the interaction of terbinafine with drug transporters, and hence no indication as to whether polymorphisms may affect its elimination.

38.5 CURRENT SUCCESSES IN STRATIFIED MEDICINE

The risk of developing IFD is determined by many factors, including the degree and duration of immunocompromise, the presence of other infections, and underlying disease. As detailed previously, there are various ways of managing patients, including prophylaxis, the enhanced diagnostic approach, and empiric antifungal therapy. Therefore, it has long been understood that not all patients are equally likely to develop infections and so there is a need to quantify each patient's risk. In one study, this concept of risk stratification was formalized in neutropenic patients by dividing them into four categories: low-risk, intermediate low-risk, intermediate high-risk, and high-risk [142]. Patients who had lymphoma, autologous HSCT, or childhood acute lymphoblastic leukemia were considered low-risk; those who had been neutropenic for more than 5 weeks, had graft versus host disease, received steroids at doses >2 mg/kg for more than two weeks, and various others were considered high-risk. Using these, the researchers found that the evidence supported prophylaxis in high-risk groups but not in the intermediate or low-risk groups. This risk stratification was evaluated and found to be valid as a way to define high-risk patients in the clinical setting [143].

Stratification has also been helpful in the interpretation of biomarkers. The *Aspergillus* GM ELISA is used as part of the diagnostic pathway for invasive aspergillosis, but has also been found to have prognostic value. The amount of GM in each sample is expressed as a ratio, with GM indices >0.5 considered positive. The GM index and its rate of decay are also predictive of mortality. If the GM index in the first week increases by 1 unit, the risk of mortality at 6 weeks increases by 25%, whereas each unit of fall decreases the risk of mortality at 6 weeks by 22% [144]. This ability to predict mortality based on the GM index provides another possibility for stratifying patients and in this way appropriately targeting management.

Another developing area in stratified medicine is our understanding of differences in immune recognition mechanisms between individuals that affects their predisposition to fungal disease, particularly invasive aspergillosis. Immune recognition of fungi involves multiple aspects of the immune system. Innate immunity, particularly phagocytic cells, is important in the uptake and clearance of fungi, using a range of ligand–receptor interactions. Triggering of the cytokine release that coordinates the interplay between innate and adaptive immune responses is also important in driving the host response toward either a Th1 proinflammatory and usually protective response, or toward a Th2 anti-inflammatory and often unfavorable response. Polymorphisms within many of the genes coding for the receptors and cytokines have been described and found to correlate with changes in IFD risk. For example, one study found that the presence of two specific haplotypes for TLR4 increased the risk of invasive aspergillosis in HSCT recipients [145]. Our understanding of this area is expanding rapidly, and with it our ability to define which patients are likely to develop IFD and so tailor their care to minimize the risk of disease.

38.6 FUTURE PERSPECTIVES

Successful treatment of IFDs relies on patients receiving an antifungal that achieves sufficient drug exposure at the site of infection; therefore, improving the absorption and distribution of drugs is of paramount importance. As we understand more about the pharmacokinetics of antifungals, it is becoming clear that many interact with genetically polymorphic enzymes and/or transporters, which means that there is significant potential for these polymorphisms to affect a drug's journey through the body. For some drugs, such as voriconazole, polymorphisms in the CYP2C19 enzyme cause most of the variability in drug exposure between patients. For other drugs, there is less evidence for this, but this is probably a result of the lack of relevant studies. A priority now should be to systematically examine the pharmacogenomic data that do exist for all antifungal drugs and conduct clinical studies, including appropriately chosen populations with relevant polymorphisms, to determine how much these polymorphisms impact clinical patient outcomes. Understanding this is pivotal to our ability to tailor the management of each patient and provide truly personalized medicine.

Once such studies have been conducted, the use of next-generation sequencing [146] will allow screening for polymorphisms as part of a patient's diagnostic workup. For some patients who undergo intensive diagnostic investigations before procedures—for example, tissue typing before HSCT or solid organ transplantation—the addition of screening for specific polymorphisms involved in a patient's susceptibility to either IFD or drug pharmacokinetics is an obvious additional step. The ability to use the right drug at the right dose, limiting toxicity but achieving efficacy—all informed by an understanding of a patient's genetic profile—is becoming a more achievable goal. Ultimately this will not only provide personalized medicine for the patient, but also save resources in an era in which financial constraints increasingly influence patient care.

39.1 OVERVIEW

Human African trypanosomiasis (HAT), also commonly known as sleeping sickness in its second, CNS-involved stage, is endemic to Sub-Saharan Africa (Figure 39.1) but also reported, although very rarely, beyond the African subcontinent [1]. The disease has been known to mankind for many years [2] and most probably played a key role in shaping early evolution, given that the causative trypanosome parasites are found in those regions of Sub-Saharan Africa where human beings are proposed to have first evolved [3]. Two subspecies of *Trypanosoma brucei* are commonly pathogenic for humans: *T. b. gambiense* and *T. b. rhodesiense*. The two diseases present different epidemiology, the causative parasites can be distinguished at the molecular level, and the clinical progression of disease caused by both is distinct [1,2]. Furthermore, treatment of rhodesiense or gambiense disease is different, and separate diagnostic algorithms are required for both [4]. It has recently become clear that it is possible for other African trypanosome subspecies to cause disease in humans, but only in rare cases where individuals are deficient in trypanosome lytic factor(s) that kill the trypanosome species that have not evolved specific mechanisms to resist lysis [5].

T. b. rhodesiense causes acute and rapidly progressive infection in Eastern and Southern Africa. *T. b. gambiense* infection is found in West and Central Africa and progresses more slowly. Although the two subspecies do not colocalize geographically at the moment, *T. b. rhodesiense* has been spreading northward in Uganda and there is a risk that it will reach areas currently occupied by *T. b. gambiense* [6]. A large majority of HAT infections are today due to

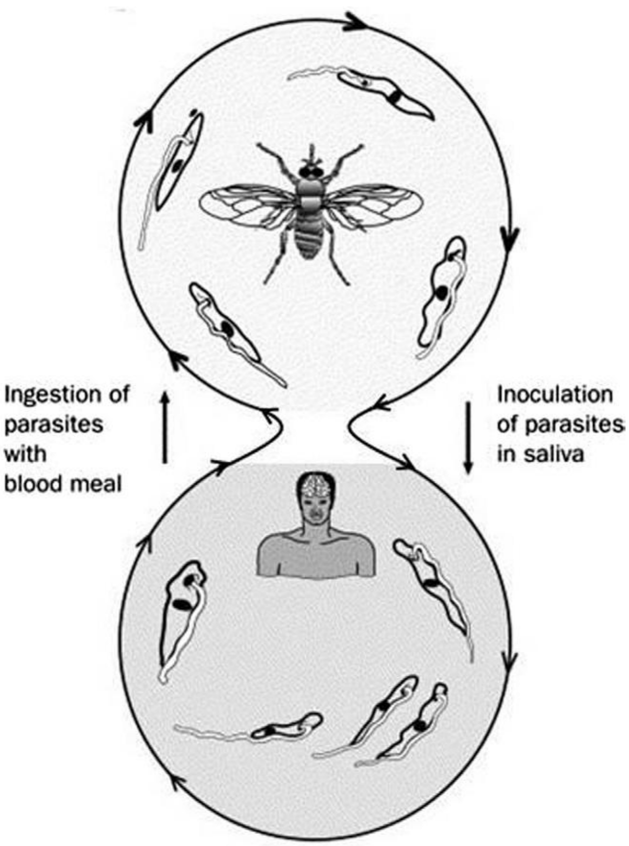
T. b. gambiense, representing 97% of the reported cases [7]. Although currently rare, *T. b. rhodesiense* tends to emerge in large epidemics (e.g., more than 250,000 people were estimated to have been killed in Uganda between 1900 and 1915) [8].

T. b. gambiense and *T. b. rhodesiense* are transmitted through the bite of an infected tsetse fly (Figure 39.2). Congenital transmission and transmission through direct blood contact have been reported, but rarely [1,2]. Tsetse flies of the genus *Glossina* are commonly divided into the fusca group, which inhabits forested locations, the morsitans group, which inhabits savannah, and the palpalis group, which inhabits riverine/forest habitats [9]. *T. b. gambiense* are most commonly transmitted by palpalis group flies (*G. fuscipes* and *G. palpalis*). Unlike in malaria, where only female mosquitoes transmit *Plasmodium* parasites, both male and female tsetse flies feed from humans and can transmit trypanosomes. It takes 18–35 days for trypanosomes to complete their life cycle within the tsetse fly, emerging in the fly's salivary glands as human-infective metacyclic forms, after having been through several life-cycle forms within the insect.

In addition to infection of humans, the parasites can infect other mammals. In the case of *T. b rhodesiense*, the animal reservoir is an important part of the epidemiology and the disease is zoonotic. *T. b. gambiense* was classically believed not to infect animals other than man; however, sensitive molecular tools have, in recent years, shown these parasites to be capable of infecting animals, although the role of these reservoirs in disease epidemiology is not known [10].

The prevalence of both gambiense and rhodesiense HAT has been declining in the twenty-first century, and fewer than 7000 cases were reported in 2011 [11]. However, the epidemic nature of the disease was associated with several periods of resurgence and remission over the twentieth century. For example, gambiense disease was estimated to have killed nearly a million people in equatorial Africa over the years 1896–1906 [12]. It has yet to be established which factors influence the ebb and flow of HAT epidemiology,



Ingestion of parasites with blood meal
Inoculation of parasites in saliva

FIGURE 39.2 **Life cycle of *Trypanosoma brucei* subspecies.** *T. brucei* parasites proliferate in the mammalian bloodstream as long slender forms, which can also enter the central nervous system. Some parasites differentiate into a nonreplicative short, stumpy form that has altered its biochemical physiology to enable survival in the midgut of the tsetse fly when taken up in a blood meal. Within the tsetse midgut, the parasites differentiate into a replicative procyclic form and in this form migrate to the fly's salivary gland, where they ultimately differentiate, via several other stages on route, into the metacyclic form that is preadapted to survive when taken back into the human host. *Reproduced, with permission from WHO (2013). Control and surveillance of human African trypanosomiasis. TRS 984;* [*in press*].

although an inverse relationship between surveillance efforts and disease prevalence is apparent. There is currently optimism that our improved understanding of the disease's epidemiology, the availability of drugs and pathways for their distribution, and other intervention tools, such as tsetse fly control, might enable HAT to be eliminated as a public health problem by 2020 and eliminated (fewer than one case per 10,000 people in endemic regions) by 2030 [13].

39.2 THE GENETICS OF TRYPANOSOME LYTIC FACTORS AND PARASITE FACTORS ENABLING PROTECTION AGAINST LYSIS

The African trypanosomes branched early in eukaryotic evolution and are classified within the phylogenetic order Kinetoplastida in the Protozoan subkingdom [2]. African trypanosomes belong to the salivarian section of the genus *Trypanosoma*, being injected into mammalian blood via the bite of a tsetse fly (or other biting flies for some nonhuman infective trypanosome species). The stercorarian section describes parasites that include the American trypanosome, *Trypanosoma cruzi*, that is transmitted in the feces of its reduviid bug vector. *T. cruzi* causes Chagas disease, endemic across large parts of Latin America [14], but it is not discussed in this chapter, which confines itself to human African trypanosomiasis.

T. b. gambiense and *T. b. rhodesiense* are identical by microscopical analysis (Figure 39.3). However, in recent years, specific molecular markers have emerged for these two subspecies. The so-called serum resistance-associated (*SRA*) gene [15,16] is ubiquitous in *T. b. rhodesiense* isolates, while type 1 *T. b. gambiense* isolates possess a distinctive gene called *TGSGP* [17]. A second *T. b. gambiense* lineage, defined as human infectious trypanosomes found in West and Central Africa but lacking the *TGSGP* gene, was defined as type 2 *T. b. gambiense*, but no representatives of this group have been isolated in over 20 years; for this reason, their relevance today is uncertain [18]. Both *SRA* and *TGSGP* play roles in protecting trypanosomes against trypanosome lytic factors found in human serum.

The best understood of these lytic factors is apolipoprotein L1 (APOL1), which is part of the high-density lipoprotein fraction of plasma, long known to be a primary determinant of trypanosome lysis [19]. Particles carrying APOL1, along with a haptoglobin-related protein that is recognized as a ligand by a specific haptoglobin-binding receptor (HPR), brings this complex into trypanosomes by receptor-mediated endocytosis [20,21]. It appears that when APOL1 is released from the complex it can bind to and permeabilize the parasite's endosomal membrane, causing ion imbalances, cell swelling, and death of the parasites. The *SRA* gene product in *T. b. rhodesiense* binds to, and thus neutralizes, APOL1, rendering these parasites resistant to human serum [22].

SRA appears to be a truncated derivative of a variant surface glycoprotein (*VSG*) gene, probably generated by a rare mutation but subsequently selected in parasite lines that gained human infectivity as a trait [23]. The mechanism by which TGSGP inhibits the activity of APOL1 has yet to be characterized. It has also been proposed that *T. b. gambiense* internalizes trypanosome lytic factors less readily than other species because of lowered expression of the HPR [24] and because changes to membrane fluidity might affect uptake. A second trypanolytic factor is less well understood but also critical in nonimmune-mediated trypanolysis [20].

The central role of APOL1 in trypanolysis was confirmed when an individual in India was shown to be infected with *Trypanosoma evansi*, a parasite related to *T. brucei* subspecies but with a key biological distinction [5,25]. *T. evansi* do not depend on the tsetse fly for transmission, instead being transmitted mechanically between mammalian hosts by other biting flies such as tabanids,

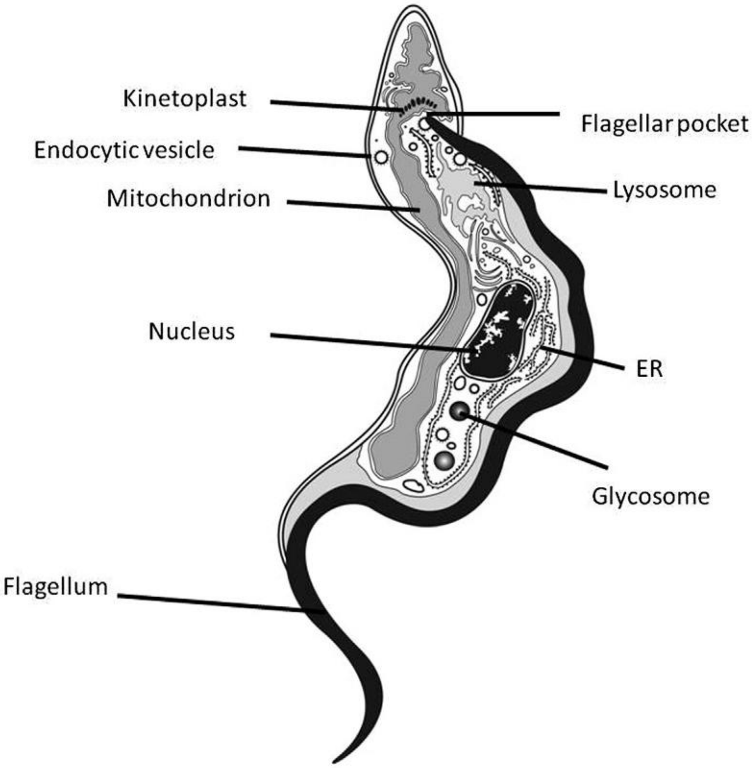


FIGURE 39.3 **Morphology of *Trypanosoma brucei*.** Trypanosomes are protozoa, around 20 micrometers in length and 5 micrometers in width. They are characterized by several organelles, including a flagellum that protrudes from the front of the cell. The single mitochondrion contains an intercatenated network of circular DNA molecules called the kinetoplast. Endocytosis can only occur within the region of the cell from which the flagellum emerges, called the flagellar pocket. This is the only part of the cell not defined by a subpellicular microtubule array. Other unusual organelles include glycosomes, peroxisome-related organelles in which glycolysis occurs, and acidocalcisomes, which serve as repositories for intracellular cations and might play roles in cellular pH and volume homeostasis.

including horse flys [26]. Tsetse-transmitted trypanosomes undertake a proliferative life cycle within the fly, and their biochemical physiology is adapted to enable them to use substrates (e.g., proline) as key energy and carbon sources [27]. For this purpose, the mitochondrial metabolism that is repressed during life in the mammalian bloodstream is derepressed in the insect stage. Here in the tsetse fly, a partial TCA cycle and electron transport chain operate to provide sufficient energy to the parasites to complete this life cycle [28]. Having lost a dependency on tsetse transmission, *T. evansi* has also lost a dependency on these key aspects of mitochondrial metabolism and in many instances has also lost its mitochondrial genome, known as the kinetoplast [29]. The loss of dependency on tsetse flies for transmission has enabled *T. evansi* to extend its geographical range beyond Sub-Saharan Africa, reaching Latin America and Asia. *T. evansi* does not, however, have any molecular mechanisms allowing avoidance of APOL1 or other trypanosome lytic factors. Therefore, it is restricted to nonprimate mammalian species, representing an important veterinary health risk in many parts of the world.

In 2005 an Indian farmer presented with fever and malaise and blood tests revealed a fulminating *T. evansi* infection that was successfully treated with suramin [5]. The same patient was later shown to be defective in APOL1 [25]. Other cases have come to light since then, but the true extent of infection of APOL1-defective individuals with *T. evansi*, or other trypanosome species that are not normally infectious to man, is not known.

The APOL1 story has recently taken another intriguing twist. As genetic data accumulated in the United States on the prevalence of kidney disease, including end-stage kidney disease (ESKD) and HIV-associated nephropathy (HIVAN), the presence of heritable susceptibility in African American and, to a lesser degree, Hispanic populations in the United States became clear [30]. Genome-wide association studies (GWASs) using admixture mapping to seek ancestral associations showed that a region on chromosome 22q12.3 is associated with chronic kidney disease [31]. The associated locus contains 30 genes, including the *APOL1* gene. The over-representation in African Americans is proposed to derive from the forced emigration of people from West Africa as part of the historical slave trade. Common variants, designated G1 and G2, found in these populations have been proposed to allow lysis of SRA-expressing *T. b. rhodesiense* that resist lysis by other APOL1 variants. In the case of the G2 variant, this relates to a lessened ability to bind to SRA, although the reason for the G1 variant not lysing is uncertain given that it continues to bind to SRA. Neither variant lyses *T. b. gambiense*, the trypanosome species endemic to West and Central Africa today [32].

Based on these observations, it has been proposed that African trypanosomes expressing a protein similar to SRA might have been a strong selective force in West Africa at some point in the evolution of human populations. This would have led to the evolution of the G1 and G2 alleles of *APOL1* that remain prevalent there today. *T. b. gambiense* then would appear to have emerged later, having the ability to infect individuals with the G1 and G2 alleles (its ability to resist lysis being independent of SRA). This theory is at odds with the notion that *T. b. rhodesiense* arose relatively recently (perhaps as recently as the early twentieth century in East Africa) [8], although a plausible scenario is that ancestral trypanosome populations in West Africa with an *SRA*-type gene were later lost as human populations were selected with the resistance alleles. The current *T. b. rhodesiense* subspecies could have emerged independently in East Africa at a later date.

The discovery of allelic variants of genes that appear to have emerged in human populations because of parasite-imposed selection pressures is not restricted to trypanosomes. *Plasmodium* parasites that cause malaria have been known for many years to have selected various traits through gene variants whose protection against malaria outweighs the deleterious effects associated with those variants [33]. Inheritance of sickle cell anemia, through the protective effects of sickle cell trait in heterozygous individuals, is one example [34]. The other best known example has been the selection of variants of glucose-6-phosphate dehydrogenase (G6PD) where reduced levels of that enzyme lead to reduced production of cellular NADPH, which in turn is critical to maintenance of cellular redox balance through glutathione [35]. The widespread prevalence of G6PD deficiency was noted in African Americans treated with primaquine, an oxidative stress–inducing antimalarial agent. Ironically, the diminished ability to deal with oxidative stress provides protection of red blood cells against infection with malaria parasites, and various *G6PD* alleles were selected in evolution in malarious regions, including the *G6PDA−* allele in Africa and the *G6PD* Mediterranean allele in the Middle East. Only later, when oxidative stress–inducing drugs like primaquine were used, did the linkage come to light [36].

To date, the geographical prevalence of *APOL1* alleles that protect against *SRA*-bearing trypanosomes and the association of those alleles with kidney disease have not been investigated for other associations with enhanced toxicity when treating with trypanocidal drugs. However, it is noteworthy that both suramin and pentamidine have nephrotoxic liabilities; thus, it would be of interest to determine whether the distribution of host responses to those drugs in any way related to *APOL1* alleles.

The APOL1 story has emerged as a key paradigm in the so-called evolutionary arms race between host and parasite. At the level of the parasite, apart from genes such as *SRA* and *TGSGP*, which have clear effects on infectivity, other genes affect virulence. For example, although the classical description of *T. b. rhodesiense* infection indicates a rapidly progressing, virulent disease, in Malawi this subspecies is associated with a more insidious progression, similar to that of classical *T. b. gambiense* [37,38]. Conversely, there are reports of rapidly progressing *T. b. gambiense* [39] along with the textbook chronic form. There are also cases of gambiense infections where patients have never reported any symptoms of HAT and yet carry the parasites [40,41]; these individuals may represent a cohort of asymptomatic carriers. Sensitive PCR-based diagnostic tools are making it easiser to identify such cases. Their role in the epidemiology of the disease may be of great importance, considering the WHO goal of HAT elimination, as they may act as long-term reservoirs. Ethical issues pertaining to the treatment of such asymptomatic cases are lessened with the availability of nifurtimox-eflornithine combination therapy (NECT), which is much safer than the highly toxic melarsoprol that would have previously been required to treat stage 2 cases. Several reports of gambiense parasites adapting for growth in rodents have shown a range of virulence types [42,43], although parasite genes controlling this variation in virulence are not known.

39.3 IMMUNE RESPONSES AND IMMUNOAVOIDANCE

In addition to the innate immune system, adaptive immunity also plays a role in HAT progression. Immunological responses to trypanosomes have been studied in rodent models, where it has been shown that B and T cells along with macrophages play key roles in antitrypanosome responses [44]. Type 1 cytokines (IFN-γ and TNF-α) accompany production of nitric oxide (NO), which has a trypanotoxic effect. Interestingly, trypanosomes appear to have the ability to stimulate host arginase, which converts arginine to ornithine and thus diverts arginine from NO production [45]. In humans, cytokine analysis has suggested that IL6 and IL8 are produced in stage 1 infections while IL10 is significantly elevated in stage 2 patients [46], although inter-study variability has made it difficult to provide definitive trends [39].

Nevertheless, other works have suggested using cytokine profiles as diagnostic biomarkers to assess the disease (see later). Rodent models (and cattle models) have allowed genetic studies to seek quantitative trait loci (QTLs) that have an impact on parasite progression in African trypanosomiasis [47,48]. In mice infected with the veterinary trypanosome *T. congolense*, an association was shown between infection and loci on chromosomes 17, 5, and 1. These loci were designated *Tir*1, *Tir*2, and *Tir*3. Although individual genes that are associated with infectivity have not been proven, within these loci are genes encoding TNFα (*Tir*1), IL10 and a regulator of its expression called *CYPr2* (in *Tir*3b), and another IL10 regulatory factor called *CYPr3* in *Tir*2. In humans, analysis of polymorphisms in cytokine genes has shown a weak association to particular IL6 and IL10 variants while IL1 and TNFα have been proposed as useful contributors to possible diagnostic tools [49].

The demonstration of associations between molecules of the adaptive immune response and trypanosome infection shows how parasites must avoid the adaptive immune system. Trypanosomes are immunogenic and stimulate antibodies of the IgM and IgG classes [50]. A dense coat (~15 nm in thickness), comprising dimerized variant surface glycoproteins (VSGs), excludes antibodies and complement proteins from the plasma membrane, where various vital functional proteins, including the transporters involved in nutrient acquisition and various communication-related processes, are located. Antibodies aimed at the immunogenic coat proteins kill parasites. However, African trypanosomes possess up to 1000 individual *VSG* genes. They express these one at a time, more commonly by duplicating basic copies of the *VSG* genes and transposing them to telomeric expression sites of which only one can be activated at a time [51–53].

Many of the genes are actually pseudogenes in their nascent state, but recombination events can recombine parts of multiple genes to create new variants. Parasites expressing one VSG type are killed by the antibodies raised to that particular type, but a small number of parasites then express a separate VSG and change to a new coat. These variants then proliferate until antibodies to this VSG emerge, but this serves only to select another VSG switch variant. In this way the parasite population can survive immunological assault more or less *ad infinitum*.

Trypanosomiasis is also associated with general immunosuppression that also enhances the parasite's ability to survive [54,55]. The so-called trypanosome-suppressive immunomodulatory factor (TSIF) [56] has been identified as a mediator of this immunosuppression, although more details on how it achieves this effect are required.

39.4 PATHOLOGIES ASSOCIATED WITH HAT

The pathology of human African trypanosomiasis depends on the causative species and the stage of the disease. While the general symptoms are similar for both HAT types, the onset and severity are divergent. Rhodesiense HAT progresses to stage 2 within weeks and death normally happens within 6 months of infection. Gambiense HAT, on the other hand, takes around 18 months to reach second stage and a further 18 months, or more, prior to death [57]. Interestingly, a number of instances have been reported where disease progression of gambiense infection can be much slower; indeed, as mentioned above, asymptomatic carriers have been described [40]. However, little information exists that relates the host or parasite factors that lead to these variations in disease progression.

After infection, through the tsetse bite, the disease enters its first hemolymphatic stage, with parasites confined to the blood and lymph systems [58]. The second, or meningoencephalitic, stage involves invasion of the central nervous system (CNS) by the trypanosomes. While stage 1 is generally accompanied by nonspecific symptoms such as headache and malaise, stage 2 is characterized by progressive neurological breakdown, including the change in sleep/wake patterns that led to the disease being referred to as sleeping sickness [59].

For gambiense HAT, a trypanosome chancre at the site of the tsetse fly bite is only rarely observed, while it is common with rhodesiense HAT. The first stage is then accompanied by fever, headache, anemia, pruritus, lymphadenopathy, weakness, and asthenia. These symptoms seldom prompt a person to seek health services. A lymphadenopathy in the cervical lymph nodes is typical for gambiense disease. It was classically termed "Winterbottom's sign" after the British physician Thomas Winterbottom and used by slave traders to distinguish those likely to die during shipment to the Americas. This lymphadenopathy is seldom seen in rhodesiense infections. Pruritus, too, is seen in only a cohort of patients, but to date the reasons that populations show variability in this complaint are not known, although coinfection with different helminthiases (e.g., loiasis or onchocerciasis) might provoke different responses in different individuals [60]. Cardiac involvement is common, with ECG alterations recorded in around 50% of patients in stage 1 and 70% in stage 2 gambiense HAT [61], although clinical heart failure is rare.

Somnography has been used to reveal dysregulation of circadian rhythms in the sleep/wake cycle and fragmented sleep, with sleep-onset rapid-eye-movement (SOREM) episodes being characteristic of the HAT-associated sleep disorder [62,63]. Various other nonspecific neurological changes occur in stage 2 HAT, including headaches, mood and behavioral changes, irritability, aggressive behavior, hyperactive or apathetic attitudes, indifference, depression, and/or delirium with hallucinations. Peripheral neuropathy is also evident, and tone disorder with abnormal movements is common. Motor weakness, tremor, bradykinesis, and a Parkinson-like rigidity are also observed [58,59]. Most of these disorders are reversed on treatment with trypanocidal drugs.

In very advanced cases, dementia and epilepsy are frequent, and incontinence, malnutrition, and cachexia can become evident. Patients can fall into a coma prior to death.

Dysfunction of the endocrine system is frequent with thyroid and adrenocortical function compromised [64]. Estrodiol levels are decreased in females and testosterone levels in males. Sexual impotence is often seen [65].

HIV coinfection influences the outcome of many parasitic and other microbial diseases. However, there is no evidence that HIV prevalence is higher in HAT patients than in controls [66], although there is some indication that immunosuppression might influence treatment outcomes. For example, in one study, 14 HIV-negative patients treated with melarsoprol left the hospital cured, while 4 HIV-positive patients in the same study suffered relapse [67], although further evidence is lacking.

Interestingly, when visitors to endemic regions become infected with trypanosomes, they appear to develop symptoms quickly, irrespective of the infecting subspecies. Fever appears rapidly, and the trypanosomal chancre is seen in most rhodesiense patients and in around half of those infected with gambiense [68]. Most travelers seek medical help prior to stage 2 onset; hence, little is known about this stage in individuals from nonendemic countries. The causes of different disease progression in nonindigenous visitors to HAT endemic regions compared to inhabitants of those areas are not known, but genetics or nutritional status might play a role.

39.5 DIAGNOSIS OF HAT

Because HAT is a lethal disease, diagnosis is vital. Different drugs are required to treat the disease depending on the causative subspecies and also on the stage of disease. Therefore, it is necessary to diagnose the presence of parasites, to identify the causative subspecies, and to stage the disease according to whether it is in the first, hemolymphatic, or in the second, neuroencephalitic, stage.

In stage 1 the general nature of symptoms makes symptomatology-based diagnosis difficult. Furthermore, given the dangers associated with current drugs (see later), treatment cannot begin without positive diagnosis, which generally requires identification of parasite by microscopy [4].

A confirmed case is defined as one in which parasites have been identified in blood or CSF. A suspected case is one in which antibodies to parasites are noted or parasite nucleic acids are detected, but parasites have not been found by microscopy. Currently, since *T. b. gambiense* and *T. b. rhodesiense* have distinct geographical localizations, identifying trypanosomes in people from a region where one or the other parasite is known to be present can be enough to speciate (unless patients have traveled to regions endemic for the other parasites), although molecular markers are now available to provide precise characterization.

For *T. b. gambiense* infections, an antibody test, usually in the format of card agglutination, is available [69]. This assay was made possible because most gambiense parasites express particular variant surface glycoproteins during early stages of infection; these stimulate antibody production, which can be detected through their binding to the cognate antigens. The same VSGs are not generally present in *T. b. rhodesiense*; hence, these serological tests cannot be applied to rhodesiense infections, and presently diagnosis of this subspecies starts immediately with microscopic investigation of blood.

In the card agglutination test for trypanosomiasis (CATT), trypanosomes expressing the LiTat1.3 antigen are cultivated, freeze-dried, and then used as an agglutination source on cards, where they are mixed with blood from a suspected patient's finger prick [69]. The freeze-dried material agglutinates if antibodies specific to the parasite are present. Whole blood, undiluted, is most easily used, but plasma in serial dilutions (up to 32-fold diluted or more) can offer better specificity [4]. The CATT can be performed on blood-impregnated filter paper for delayed testing, with the drawback of reducing sensitivity.

Recently, the same antigens were purified and incorporated into dipstick-based tests [70], where patient serum can interact with the antigen on a solid state matrix and create a color change to a strip in the event of antigen-antibody forming. The fact that 3–4 weeks must elapse prior to seroconversion to the salient antigens hampers the approach in early diagnosis. Moreover, there are *T. b. gambiense* strains that lack the LiTat1.3 antigen [71] and therefore do not cause seroconversion to this test antigen. It is also possible to determine whether patient serum can induce lysis of trypanosomes, which will indicate the presence of those trypanosome-specific antibodies. Indirect immunofluorescence can be used, by applying trypanosomes to glass slides and then adding patient serum and secondary anti-human IgG antibodies with fluorescent labels [72]. ELISA tests based on the same basic antigen–antibody interaction are also available [73]. However, such tests are more expensive and require fluorescence microscopy; thus, they are not widely used.

The serological tests have received widespread use in mass screening campaigns, and this has underpinned some of the advances in bringing the disease under control in the twenty-first century. However, their fallibility means that parasite identification by microscopy has remained the diagnostic gold standard. Since trypanosomes are highly motile, inspection of wet blood smears can be the best means of detection. Lymph node aspirate or CSF from a lumbar puncture can be used as well.

The very low parasitemia associated with *T. b. gambiense* infections offers a particular challenge to microscopic evaluation. With fewer than 1000 parasites per mL of blood in many instances, microscopy can require great patience and skill to find just a single trypanosome. Methods for concentrating parasites in blood are therefore used where possible.

When enlarged cervical lymph nodes are present in early stages of infection, aspirate microscopy can be easier than seeking parasites in blood [4]. However, because of the nonuniformity in presentation with enlarged lymph nodes, this cannot be routinely used. For this reason, blood films are prepared. These can be either thin films, where parasite motility can be used to assist identification, or Giemsa-stained thick films, where the trypanosome's unique shape and staining of the nucleus and kinetoplast characterize the parasites. The development of relatively cheap and robust fluorescence microscopes that use light-emitting diodes (LEDs) [74] and the fact that various fluorescent stains, including acridine orange, accumulate in trypanosomes [75] have recently been shown to facilitate microscopical identification of trypanosomes in blood.

Enrichment of parasites from blood samples also improves sensitivity. For example, lysis of red blood cells by ammonium chloride followed by centrifugation and examination by microscopy of a thin or thick smear of the sediment (stained with Giemsa or acridine orange) improves sensitivity [75]. Other parasite concentration tests include the Woo test, a microhematocrit centrifugation technique (mHCT) [76], also called the capillary tube centrifugation technique (CTC), which uses capillary tubes sealed with plasticine that are three-quarters filled with blood from a finger prick. These are centrifuged at 12,000 × g for 5 minutes, after which parasites, along with white blood cells, concentrate at the layer between the erythrocytes and plasma, allowing targeted microscopy of this region. The technique allows identification of parasites in infections as low as 500 trypanosomes/mL.

A related approach, the quantitative buffy coat technique, involves adding parasites to a capillary tube that has been precoated with EDTA and acridine orange. After centrifugation, parasites can be identified by virtue of having taken up the acridine orange, which can be detected readily with UV fluorescence [77]. This technique is a little more sensitive than the Woo test, but it requires a fluorescence light source and a supply of the acridine orange–coated capillary tubes.

The most widely used parasite concentration technique is mini-anion exchange centrifugation [78]. This technique works because the trypanosome's surface coat is neutral in buffered solutions at pH 8 while the phospholipids of red cells leave them negatively charged. The anion exchange matrix diethylaminoethyl (DEAE) cellulose then binds red cells to the matrix, while the parasites elute from the column. Columns are manufactured to enable application of 100 or more microliters of blood, and the eluted parasites are captured in a pipette that can be centrifuged and viewed by microscopy. The use of precentrifuged blood, with volumes up to 5 mL, allows to capture parasites in a buffy coat between the erythrocyte and plasma layers, improving the sensitivity to as few as 10 parasites per mL of blood.

Molecular methods that detect parasite DNA are of increasing importance to diagnostic algorithms. The ability to detect frozen, or filter paper–dried, samples increases their attractiveness. Multicopy DNA sequences specific to the *T. brucei* group are very sensitive [79] and can be combined with the highly specific (but lower copy number and thus less sensitive) subspecies-defining probes: *SRA* for *T. b. rhodesiense* and *TGSGP* for *T. b. gambiense* [80].

The requirement for a thermocycler and electricity supply can hinder the use of PCR in regions where HAT is endemic. For this reason, the loop-mediated isothermal amplification (LAMP) approach has been developed [81], which allows amplification of target DNA without a need for thermal cycling. *Trypanozoon*-specific multicopy DNA sequences and the *T. b. gambiense*-specific *TGSGP* gene [81] have both been used in LAMP assays, which use the dye hydroxynapthol blue in detection of double-stranded DNA produced during the reaction.

Microscopical approaches can be easier for rhodesiense infections than for gambiense infections, since parasitemias are generally higher in the former. The relatively frequent development of a chancre at the site of the tsetse bite means that this can be biopsied and examined microscopically for parasites soon after infection. Otherwise, thin and thick film blood smears can be prepared, using parasite motility to aid identification in thin smears and Giemsa staining to identify parasites in thick smears. DNA-based tests, including PCR and the LAMP method, are equally applicable to rhodesiense, with the *SRA* gene serving as a subspecies-dependent marker.

39.6 STAGING THE DISEASE

In stratifying patients for treatment, determining the stage to which the disease has progressed is vital. The drugs used to treat stage 1 and stage 2 disease differ and, since stage 2 drugs generally are more difficult to administer and dangerous, they should only be given to the relevant stage.

Currently, staging depends upon analysis of CSF obtained by lumbar puncture. Identification of trypanosomes in CSF is considered diagnostic of stage 2 disease, although in some cases low parasite numbers mean that high white cell count (higher than 5 cells per microliter or 20 in some endemic countries) can be taken as diagnostic [4,82]. For many years cases where no parasites were found in CSF, but 5–20 cells were found, were considered to be "early second stage," and recommendations to treat with pentamidine, which appeared curative [83], were made, given the exceedingly toxic nature of melarsoprol. Now, however, nifurtimox-eflornithine combination therapy (see below) is preferred for stage 2 disease; since this therapeutic choice is relatively safe, it is also given to patients in the early second stage. Generally, even in the absence of parasites, patients with >20 WBC per microliter are judged to be in stage 2 and treated accordingly.

Because of the difficulties in finding parasites in CSF and the imprecise utility of white cell counts, efforts have been made to look for other surrogate markers. Protein concentration was considered to have potential [84]; however, the low sensitivity precluded widespread application. In recent years, more specific tests were proposed for IgM [85], and other protein biomarkers were considered.

Biomarker research has sought both proteomic and metabolomic markers that might diagnose HAT and also offer stage prediction without needing to find parasites. In one study, quantification of a range of known inflammation-related proteins were determined in CSF of *T. b. gambiense* patients [86]. CXCL10 most accurately distinguished stage 1 and stage 2 patients with a sensitivity of 84% and a specificity of 100%. Moreover, using a panel of proteins including CXCL10, CXCL8, and H-FABP improved the detection of stage 2 patients to 97% sensitivity. Further analysis using 2-dimensional gel electrophoresis to identify quantitative differences in protein levels between stage 1 and stage 2 patients showed that levels of osteopontin and β-2-microglobulin could also stage the disease with sensitivities of 68% and 78%, respectively, and 100% specificity [87]. Combining the two markers increased sensitivity to 91%. A third study investigated another panel of proteins and showed that ICAM-1 and MMP-9 accurately discriminated between stage 1 and stage 2 HAT patients (95% sensitivity, 100% specificity) [88]. The inflammatory metabolite neopterin was also measured and was shown to predict stage 2 disease [89]. To date, a combination of all of these antigens has not been tested, although it should be interesting to see how sensitivity and specificity perform in a panel of the full set. No successful efforts have yet been published reporting markers derived from untargeted approaches in blood or urine that might predict the stage of the disease without requiring invasive lumbar puncture. As methods in proteomics and metabolomics become more sensitive, however, it seems likely that better functional biomarkers will emerge.

The identification of the metabolite neopterin indicates that metabolomics offers a potential route to biomarker discovery [89]. Early studies showed that *T. b. gambiense* metabolizes tryptophan, tyrosine, and phenylalanine to indole 3-pyruvic acid, 4-hydroxphenylpyruvic acid, and phenylpyruvic acid, respectively, *in vitro*, and that rodents infected with *T. b. gambiense* also secreted catabolites of these aromatic amino acids [90,91]. ^{1}H NMR was also used to probe metabolic responses in *T. brucei* infection in mouse urine and plasma over seven days. Plasma and urine of infected animals showed elevated lactate levels, and plasma from infected mice also showed depletion of glutamine, leucine, isoleucine, and valine [92]. In urine, there were increases in the branched chain amino acid metabolites 3-methyl-2-oxovalerate and 2-oxoisovalerate, as well as D-3-hydroxybutyrate. Lipid concentrations varied, and diminished quantities of hippurate were reported along with increases in trimethylamine and 4-hydroxyphenylacetic acid. The major distinguishing metabolites were the elevated levels of urinary 3-methyl-2-oxovalerate, 3-carboxy-2-methyl-3-oxopropanamine, and 4-hydroxyphenyl acetic acid [92]. A potential drawback in translating information relating to heavy infections in rodents to very low parasitemia situations in humans relates to whether these biomarkers are proportional to parasitemia; if so, levels may fall below the detection limit in humans. LC–MS offers enhanced sensitivity for quantification of specified metabolites [93], and work is under way to determine whether markers for infection and stage 2 involvement can be detected using these platforms.

As described in the next section, HAT treatment is stratified based on the causative parasite and the stage of the disease. No treatments are 100% efficacious, and reports of resistance to current drugs have increased in recent years. Therefore, it is necessary to assess treatment outcome through post-treatment follow-up. Recent WHO recommendations suggest that follow-up of patients treated for stage 1 is necessary only if patients feel symptoms indicative of relapse (other than in clinical trials, when mandatory follow-up, six monthly for 18–24 months, is required).

For stage 2 HAT, however, the difficulties associated with cure are such that patients should be followed up every six months for two years. If parasites cannot be found and CSF white cell counts are below 5 cells per microliter, patients can be considered cured. If white cell counts are greater than 50 per microliter, these patients should be considered a failure and retreated. If white cell counts are 6–50 cells per microliter, patients should be re-evaluated at 12 months. Guidelines for rhodesiense follow-up are not available but, given the more rapid progression, a similar regimen, but with shorter time frames, should be considered.

39.7 TREATMENT

39.7.1 Current Drugs

The history of chemotherapy is entwined with the history of HAT therapy [94]. The pioneering German physician/scientist Paul Ehrlich experimented with various agents to kill trypanosomes. His research led directly to the introduction of napthalene dyes with trypanocidal activity, themselves the precursors of the suramin still used today, and also the organic arsenicals, which served as precursors of melarsoprol, which remains the only drug available to treat stage 2 rhodesiense disease.

Today five compounds are used in the treatment of HAT, depending on the causative subspecies and the stage

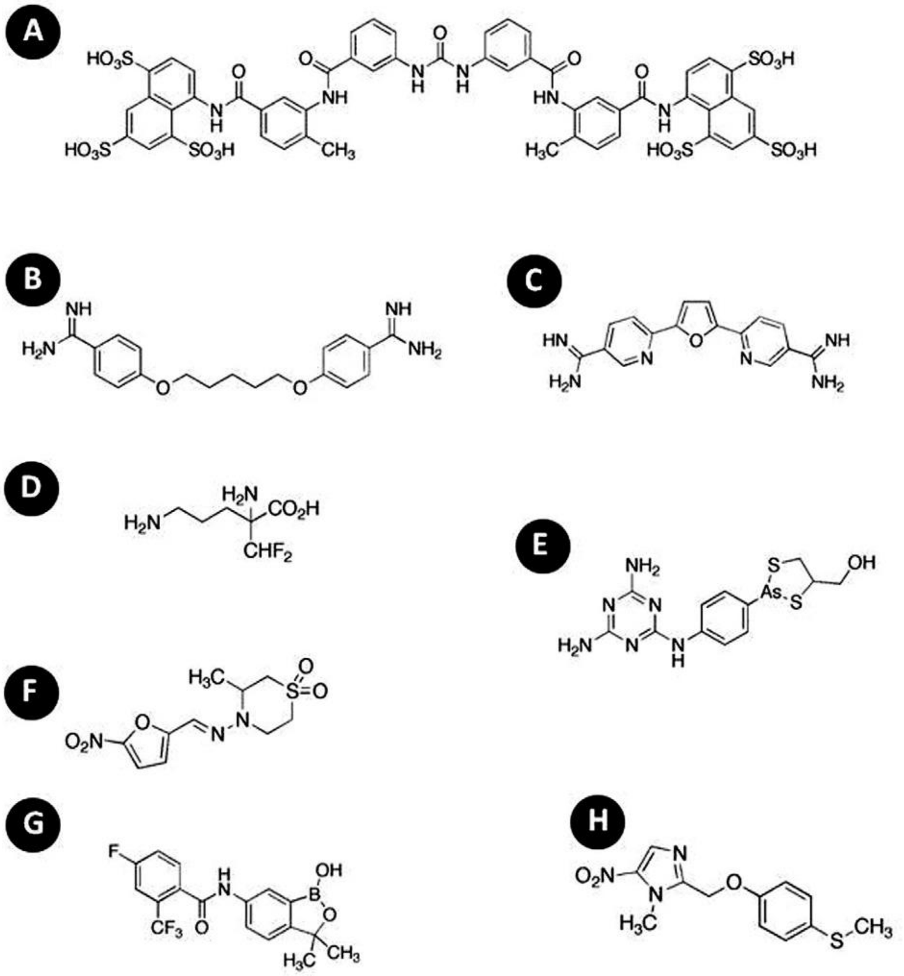

FIGURE 39.4 **Structures of current drugs and compounds in HAT trials.** (a) suramin; (b) pentamidine, (c) CPD-0801; (d) eflornithine; (e) melarsoprol; (f) fexinidazole; (g) SCYX-7158; (h) nifurtimox.

of the disease. For gambiense HAT in stage 1, pentamidine is used, while in stage 2 the preferred treatment today is nifurtimox-eflornithine combination therapy (NECT), although eflornithine alone, or occasionally melarsoprol, are still used. For rhodesiense disease in stage 1, suramin is the drug of choice, while in stage 2 melarsoprol is used. The twenty-first century has witnessed the emergence of new paradigms in the discovery and development of new drugs for neglected and other infectious diseases, including HAT.

Most of the available HAT treatments were introduced many years ago, without the kinds of evaluation required for drugs being trialed in the modern era. Suramin, for example, was introduced in the 1920s, pentamidine in the 1930s, melarsoprol in the 1940s, nifurtimox (for Chagas disease) in the 1970s, and eflornithine in the 1980s. Given that all available drugs suffer various drawbacks—the need for protracted parenteral administration, insecure manufacture and distribution, serious adverse events in some cases, and increasing incidence of treatment failure—a robust pipeline for new medications is essential. Structures of current drugs and compounds in late preclinical or clinical trials are given in Figure 39.4.

39.7.2 Stage 1

39.7.2.1 *Pentamidine*

Pentamidine is used to treat stage 1 *T. b. gambiense* disease [95]. Administration is by intramuscular injection once daily at 4 mg kg^{-1} over seven days (intravenous injection provokes a transient hypoglycemia). The drug is highly trypanocidal; IC_{50} values are in the order of 1–10 nM in a typical 3-day drug sensitivity assay in rich medium, falling to even lower levels in a novel minimal medium developed using a metabolomics approach that showed how most components of the classical rich medium were unnecessary for parasite growth [96]. Pentamidine is concentrated to very high levels in trypanosomes using several transporter systems, including the P2 amino-purine transporter and a high-affinity pentamidine transporter (HAPT1) that has recently been shown to be encoded by the aquaglyceroporin-type transporter (*AQP2*) [97]. A further low-affinity pentamidine transporter (LAPT1) is also involved in uptake [98]. How pentamidine exerts its activity within cells is unknown, although it is possible that activity is multifactorial through concentration to high levels. Metabolomics experiments failed to identify a clear single enzymatic system affected by the drug [99]. Diamidines bind avidly to DNA, and mitochondrial dysfunction has been associated with diamidine treatment.

Extensive tissue retention and binding to serum proteins contribute to a large volume of distribution and a long terminal half-life. Since the drug is positively charged at physiological pH, it cannot diffuse across membranes, precluding oral availability as well as brain permeation. Pentamidine is also metabolized to a substantial degree by cytochrome P450 systems [95]. Although it has been used for many years, pentamidine can be toxic. Injection-related pain, nephrotoxicity, leucopenia, and liver enzyme abnormalities are all common, as is the risk of hypoglycemia. Of note is that the clinical trials of DB289, a methoxy prodrug precursor to the diamidine DB75, was abandoned when serious incidence of nephrotoxicity accompanied anticipated hepatotoxic effects [100]. Further development of other diamidines is now dependent on an early and clear understanding of likely nephrotoxicity and hepatotoxicity. Several aza analogs of DB75 have shown the remarkable capability of clearing stage 2 infections in rodent models, which indicates uptake into the brain, presumably via specific transporters; these compounds have been shown to be substrates of organic cation transporters in brain endothelia [101].

39.7.2.2 Suramin

Suramin is used in treating stage 1 rhodesiense disease [102]. It is usually confined to use in Eastern and Southern Africa because in West Africa coinfection with the nematode *Onchocerca volvulus* is common and suramin's activity against microfilarial worms can induce a profound, even fatal, anaphylaxis. Typically, the drug is administered in a course of five injections, every 3–7 days over 4 weeks, with a loading dose given to ensure that patients can tolerate the drug [94]. Most drug (99%) is bound to serum protein, and the clearance half-life is remarkably long (41–78 days). Suramin fails to penetrate the blood–brain barrier, so it is useful only in stage 1. Uptake into trypanosomes involves binding of drug (as a drug-protein complex) to the ISG75 receptor on the cell surface, followed by uptake inside endocytic vesicles [103]. A high-throughput approach, to determine genes whose loss of function could lead to drug resistance, indicated that loss of ISG75 and various components of the endocytic pathway could all promote resistance. Precisely how suramin finally kills cells is not known. Although suramin resistance has rarely been reported in the field, it can be selected in the laboratory with ease, via the molecular RITseq approach and also through selecting in increasing doses [104]. Various side effects are common, including reversible nephrotoxicity, neuropathy, nausea, anemia, and urticaria [102]. When the drug was trialed in HIV patients in higher doses, these toxic effects became more pronounced; generally, however, the dosing in HAT treatment is less aggressive and thus tolerated.

39.7.3 Stage 2

39.7.3.1 Melarsoprol

Melarsoprol, a melaminophenyl-based organic arsenical, is extraordinarily toxic, with 5–10% of patients taking it experiencing a reactive encephalopathy that is fatal in around half of these cases [94]. The cause of this reactive encephalopathy is not certain. Interestingly, melarsoprol, or its *in vivo* metabolite melarsen oxide, enters mammalian cells via a thiamine transporter [105], and it would be of interest to see if heterogeneity in host thiamine transport is related to marlsoprol toxicity and, indeed, to variability in efficacy, should these transporters be involved in melarsoprol uptake in the brain. Moreover, if uptake via thiamine transporters contributes to the drug's toxicity, it might also be related to dietary status with respect to thiamine. To date, this theory is untested. Melarsoprol is given as a 3.6% solution in propylene glycol by intravenous injection, predominantly using the ten-day course [106]. This protocol replaced earlier regimens when new pharmacokinetic data revealed that the drug does not accumulate in tissues, as had been true for previous arsenic-based trypanocides.

Melarsoprol's trypanocidal mode of action has yet to be established. A variety of enzyme systems are known to be inhibited, and interactions with intracellular thiols are potent. An increased incidence of treatment failures through the 1990s led to speculation that resistance might have arisen. Resistance was shown to relate to loss of a carrier protein—the so-called P2 amino-purine transporter—that is capable of accumulating melarsen oxide into trypanosomes. [107]. The RITseq approach showed that AQP2 is also involved in resistance [103], which explains earlier work showing the HAPT1 transporter's role in melarsen oxide resistance [108], given that AQP2 is equivalent to HAPT1.

The spread of resistance and the acute toxicity associated with melarsoprol, coupled with the improved availability of eflornithine and NECT, mean that melarsoprol's use in gambiense disease is waning. An oral formulation of melarsoprol complexed with cyclodextrins [109] has been proposed as a potentially less toxic administration, particularly for rhodesiense patients for whom treatment with NECT is not currently indicated. However, it is not certain for how long melarsoprol will be produced. Because it is currently used for fewer than one thousand cases per year, the cost of production and the environmental problems associated with toxic residue from its manufacture make it hard to justify continued production. This is particularly true if NECT can find utility in the treatment of rhodesiense disease, and if compounds in the pipeline for HAT reach the clinic and can also be shown to be effective in rhodesiense disease. Notwithstanding, the risk that these newer developments will not reach the clinic means that sustained manufacture and distribution of melarsoprol should be encouraged until new options are proven and available for use.

Melarsoprol is rapidly metabolized to melarsen oxide *in vivo*, and this active compound shows a mean elimination half-life of 3.5 hours [94]. The active principle does cross the blood–brain barrier but only to levels that are around 2% of maximum plasma levels. This is sufficient to kill parasites in the CSF; however, the drug remains at trypanocidal concentrations only just long enough to effect cure. Given the fact that sensitivity levels can change through reduced expression of the P2 and/or the AQP2 transporters, risks of treatment failure are high. It has been proposed that this proximity between drug dosing into the brain and trypanocidal activity is responsible for treatment failures [110]. However, one study did show that the prevalence of alleles of the *TbAT1* gene known to be associated with treatment failure increased when treatment failures were common in northern Uganda and, then, dropped once melarsoprol had been replaced by eflornithine [111] as the primary treatment. Furthermore, heterogeneity in expression of human transporters, such as the thiamine transporter believed to play a role in uptake into mammalian cells, might contribute to host sensitivity to the drug.

Adverse effects with melarsoprol extend beyond the reactive encephalopathy with other neurological sequelae: pyrexia, headache, pruritus, and thrombocytopenia are all common, as are occasional reports of heart failure. The use of corticosteroids (prednisolone) has been reported to offer some protection against reactive encephalopathy [94].

39.7.3.2 Eflornithine

Eflornithine (D,L-α-difluoromethylornithine, marketed as Ornidyl), is an analog of the nonproteinogenic amino acid ornithine. It inhibits the enzyme ornithine decarboxylase (ODC), which is a key component of the polyamine biosynthetic pathway [112]. The drug is active against *T. b. gambiense* but less so against *T. b. rhodesiense*. The reasons for this are not known, although it has been proposed that they might relate to the fact that the target enzyme, ornithine decarboxylase, is turned over more rapidly in rhodesiense parasites than in gambiense parasites [113]; moreover, since the drug is an irreversible inhibitor of the enzyme, its relatively fast replenishment in rhodesiense could render the parasites less susceptible. The same mechanism describes the difference in susceptibility of mammalian and trypanosomal cells.

Other possible mechanisms have also been proposed [114]. For example, a relatively high uptake of putrescine, the target enzyme's product, in rhodesiense as compared to gambinese was suggested, to allow some strains of the former parasite to resist the drug, since acquisition of host-derived putrescine enables them to bypass the drug-induced lesion.

As monotherapy, eflornithine administration involves slow intravenous infusion (up to 30 minutes) of 100 mg kg^{-1} body weight drug at 6-hour intervals (i.e., 400 mg kg^{-1} per day) for 14 days.

In vitro, IC_{50} growth inhibitory values for eflornithine are high (81–693 μM). The drug's activity *in vivo* appears to depend on a functioning immune system. It has been shown that eflornithine enters trypanosomes via an amino acid transporter, TbAAT6, and resistance is easily selected in the laboratory when that transporter is lost [115].

The mean half-life in plasma following intravenous injection of eflornithine is only in the order of 3 hours. CSF-to-plasma ratios in humans have been reported between 0.1 and 0.9, but in mice apparently very little eflornithine enters the brain. It is possible that brain transporters for eflornithine exist and that differences between such transporters in mice and man could account for different PK. Polymorphisms in such a transporter could also explain variability in brain permeation of the drug and why efficacy never reaches 100% in treatment within different foci. Although generally considered safe, eflornithine's side effects have been noted. These include fever, headache, hypertension, macular rash, peripheral neuropathy, tremor, and gastrointestinal problems such as diarrhea.

39.7.3.3 Nifurtimox-Eflornithine Combination Therapy

Antimicrobial combination chemotherapies are increasingly used because they improve efficacy, decrease dosing, and reduce the risk of drug resistance. In a series of clinical trials involving various combinations of registered trypanocides with nifurtimox (previously used exclusively for Chagas disease), it was concluded that eflornithine with nifurtimox was the most successful treatment [116]. A regimen using eflornithine by intravenous infusion at 200 mg/kg every 12 hours for 7 days (rather than every 6 hours for 14 days, as in monotherapy), with nifurtimox given orally three times a day for 10 days, offers significant advantages in cost and convenience yet is of equal efficacy to that of the longer eflornithine monotherapy.

Curiously, eflornithine and nifurtimox are not synergistic in *in vitro* assays [117], possibly because, rather than oxidative stress as previously assumed, nifurtimox's mode of action appears to involve reduction by an unusual nitroreductase in *T. brucei* followed by further metabolism to a highly reactive nitrile derivative. Loss of the nitroreductase causes resistance to nitroheterocycles [118]. Clearance of nifurtimox is fast, with a plasma elimination half-life of approximately 3 hours, but the drug can accumulate across the blood–brain barrier to levels approximately half of those found in plasma [94]. African trypanosomes are not very susceptible to nifurtimox, with IC_{50} values of approximately $5\,\mu M$ *in vitro*, and resistance is easily selected in the laboratory. Toxic effects to the central and peripheral nervous systems have been reported with nifurtimox.

In the combination therapy trial, the only significant adverse events reported to occur at a higher frequency in the nifurtimox-eflornithine combination therapy cohort versus the eflornithine monotherapy cohort were an increased incidence of tremors and increased gastrointestinal disturbance, including anorexia and nausea. NECT has thus become the treatment of choice for stage 2 gambiense disease.

39.7.4 Compounds in Clinical or Advanced Preclinical Trials

39.7.4.1 Fexinidazole

Fexinidazole, a 2-substituted 5-nitroimidazole, was originally synthesized by Hoechst in the 1970s and shown to have trypanocidal activity [119]. Clinical development started nearly 40 years later, when the Drugs for Neglected Diseases initiative (DNDi) investigated the potential of nitroheterocyclic compounds as potential drug candidates for treatment of stage 2 HAT [120]. In spite of the feared genotoxicity potential and expected Ames test positivity, fexinidazole was found to be safe in phase I trials, where its metabolism to sulfoxide and sulfone derivatives was confirmed. These metabolites have trypanocidal effect similar to that of the parent compound. Although substantially lower than that of other trypanocides, such as melarsoprol, suramin, and pentamidine, this effect remains at trypanocidal levels in the brain long enough to cure a stage 2 infection [120].

Fexinidazole succeeded in phase I trials, although substantial food effects were noted, and it is currently undergoing evaluation in a phase II/III trial. If successful, it will be the first orally available drug suitable for use in stage 2 HAT and promises to revolutionize treatment by removing the need for parenteral administration.

39.7.4.2 SCYX-7158

A second compound, SCYX-7158, recently entered phase I clinical trials following successful progression through preclinical testing [121]. The benzoxaborole-6-carboxamide class, initially developed by Anacor, was expanded by Scynexis, which combined *in vitro* potency data against trypanosomes with *in vivo* pharmacokinetic data in mice to work on structures whose brain concentrations stayed high enough, for long enough, to effectively cure stage 2 infections [122]. The compound has a long terminal half life in humans, and phase I safety testing is under way, with entry into phase II trials planned for 2014 if the safety profile is satisfactory.

39.7.4.3 Dicationic Molecules

A third class of compounds that has shown activity in stage 2 disease in rodents and primates comprises the aza-diamidines. These molecules are analogs of DB75 (furamidine) and are the active principle of the prodrug DB289 (pafuramidine). Pafuramidine was dropped from clinical testing following the identification of unacceptable nephrotoxicity in an extended phase I safety trial [100], in spite of its having proven efficacious and relatively safe in a phase III trial. CPD-0802 (or DB829 as the hydrochloride salt) and its prodrug, DB868, are aza analogs of DB75 and DB289, in both of which the ring structure possesses a nitrogen. The active diamidine compounds are highly potent in rodent and primate models (123). The corresponding asymmetric compounds, in which just a single ring contains the nitrogen, demonstrate similar potency. Further work is underway to assess the toxic potential of these compounds compared with that of DB75, given the unexpected nephrotoxicity that led to the cessation of pafuramidine development. Current information suggests that the aza diamidines have a greatly reduced propensity to accumulate in the kidney, and there is hope that these compounds can be considered for entry into clinical trials at some point.

39.8 CONCLUSIONS AND FUTURE PERSPECTIVES

Human African trypanosomiasis is caused by protozoa of the *Trypanosoma brucei* subgroup. Classically, the disease is stratified based on its causative subspecies (*T. b. gambiense* versus *T. b. rhodesiense*) and whether it is in stage 1 (hemolymphatic) or stage 2 (neurological). Recently a third type of infection was discovered in which *T. evansi* can infect humans defective in specific genes that confer resistance to most trypanosome species.

Trypanosome lytic factors, including apolipoprotein L1 (APOL1), have been selected to combat trypanosome infections. However, the human infectious subspecies have evolved mechanisms to counter APOL1 activity. *T. evansi* infections have been seen that involve rare genetic defects in *APOL1*. Other genotypes (e.g., some cytokine gene alleles) are also associated with the severity of trypanosome infection. Pathogenesis depends on parasite and host genes in addition to those genes already characterized.

Recent successes in HAT control might mean that there will be insufficient human cases to provide the statistical power to find other genetic associations to the disease status. However, caution must be exercised in considering HAT to be a disease whose decline means that further efforts at control are unnecessary. It is a disease with the capacity for rapid resurgence; thus, enhanced efforts toward its elimination are required. Surveillance should be maintained and efforts to improve diagnostic capability and chemotherapy continued.

GLOSSARY

HAT (sleeping sickness) Human African trypanosomiasis is the correct term for human infections caused by the African trypanosomes of the *T. brucei* species: *Trypanosoma brucei gambiense* and *T. b. rhodesiense*. The disease is commonly referred to as sleeping sickness when in its second, CNS involved stage. At this stage, trypanosomes cause various perturbations to the neurological system, including the changes to sleep/wake patterns that led to the disease acquiring its common name

Serum resistance–associated (*SRA*) gene The *SRA* is found in *Trypanosoma brucei rhodesiense*. It is derived from a *VSG* gene and is expressed from a single expression site; hence, trypanosomes carrying the gene are only resistant to serum when the particular *VSG* expression site with which they are associated is expressed. Expression sites are found at the telomeres of the parasite's chromosomes and contain a strong RNA polymerase 1 promoter that allows expression of a single *VSG* gene at a time, in addition to several expression site–associated genes (*ESAGS*) that are also found there

***T. b. gambiense*–specific glycoprotein gene (*TGSGP*)** *TGSGP*, like *SRA* in *T. b. rhodesiense*, is found only in one subspecies. It is also a mutated version of a variant surface glycoprotein gene and can confer resistance against trypanosome lytic factors in human serum, apparently by influencing membrane fluidity in ways that affect uptake of TLF

Trypanosome lytic factors (TLFs) TLFs are components of human blood that are capable of killing trypanosomes. Initially identified as being part of the high-density lipoprotein fraction of plasma, it was shown that a key individual component was apolipoprotein L1 (APOL1). APOL1 is capable of lysing trypanosomes other than those subspecies that have evolved molecules that neutralize its activity. Other components—such as a haptoglobin-like protein that is part of the complex particle that also contains APOL1—are required for the binding of these particles to the trypanosome and contribute to activity since specific receptors are required for this binding

Tsetse fly The tsetse fly is a dipteran insect of the genus *Glossina*. Various species can transmit trypanosomes, which replicate within the tsetse fly midgut as procyclic forms. Some of these forms migrate to the salivary gland, where they transform to metacyclic forms that are preadapted to survive within the insect host

Variant surface glycoproteins (VSGs) VSGs are expressed one at a time, and acquire a glycosylphosphatidyl inositol (GPI) anchor that links them to the plasma membrane. The trypanosome has up to a thousand different *VSG* genes, but expresses only one of them at a time. The proteins form dimers that pack tightly at the parasite's surface and prevent host immunological proteins, including components of the complement complex and immunoglobulins, from reaching the cell surface. Eventually the host produces antibodies that bind to a given antigen type, and cells carrying that VSG are killed. However, a small number of parasites change expression to a new VSG that is not recognized by those antibodies. These cells then proliferate until a specific antibody response is raised to them. In this way, the parasites can evade the immune system *ad infinitum*

40.1 OVERVIEW

Clinical genetic testing began over 30 years ago with the identification of the β-globin mutation responsible for sickle cell disease [1]. As the genetic causes of many other disorders have been identified, molecular testing has grown dramatically to include population carrier-screening programs for autosomal recessive disorders [2], targeted genotyping and gene sequencing for molecular diagnosis, prenatal mutation analyses, and preimplantation genetic diagnosis. These testing scenarios predominantly involve Mendelian disorders; however, recent candidate gene and genome-wide association studies (GWASs) have identified variant alleles that contribute to some common diseases and complex traits, prompting the possibility of predictive genetic testing to evaluate personalized disease risk. Testing for these variant alleles is not common beyond direct-to-consumer (DTC) testing companies; however, as these associations become more robust, it is possible that predictive genetic testing may become more common in clinical laboratories. Importantly, early recommendations for DTC companies and the personalized medicine community stated that inclusion of pharmacogenetic variants in these testing panels was warranted as they were perceived to be more clinically actionable than the predictive markers for later-onset diseases [3].

The role of germline genetic variation in drug response has been studied since the 1950s [4], and clinical testing for selected genes known to influence drug efficacy and/or toxicity has been available for several years. However, clinical adoption of pharmacogenetic testing has remained slow despite U.S. Food and Drug Administration (FDA) product insert relabeling with pharmacogenetic information for certain drugs. A number of barriers to clinical implementation have been identified [5], including the lack of professional education and practice guidelines; concerns over clinical utility, regulatory, and reimbursement issues; and the feasibility of integrating rapid-turnaround genetic testing into routine clinical practice [6], which is often required for the variants that are currently considered actionable. To address the specific challenge of testing feasibility and turnaround time, both point-of-care and pre-emptive pharmacogenetic testing programs,

initially centered on cardiovascular pharmacogenetics, have recently been deployed. This chapter aims to review pharmacogenetic implementation with a focus on testing for germline genetic variants implicated in drug response variability and their use at the point of care.

40.2 CLINICAL PHARMACOGENETICS AND IMPLEMENTATION

Pharmacogenetic discoveries are often followed by interest in clinical implementation. However, identification of genetic markers associated with drug response does not always equate to clinically useful predictors of efficacy or adverse outcomes, and independent replication of genotype–phenotype association is essential prior to pursuing clinical implementation [7]. Several academic health centers have invested in clinical pharmacogenetics and view its implementation as a logical first step toward incorporating genomics into routine and personalized healthcare; however, a number of challenges and barriers exist for widespread adoption.

40.2.1 Validity and Utility

The criteria for evaluating genetic tests are summarized by the four components of the ACCE analytic framework: analytical validity, clinical validity, clinical utility, and associated ethical, legal, and social implications [8]. Analytical validity refers to a test's ability to measure the genotype of interest accurately and reliably, which for germline pharmacogenetic variants is very robust [9,10]. More important is the appropriate selection of variants to interrogate for a particular drug response phenotype, also considering the ethnic group(s) that are being tested to maximize clinical validity.

Clinical validity refers to a test's ability to detect or predict the clinical disorder or phenotype associated with the genotype. Because most drug response phenotypes are multifactorial in origin, it is not always easy to achieve the high clinical validity for pharmacogenetic testing that is typically found in DNA testing for Mendelian disorders. Consequently, the positive predictive value of many pharmacogenetic assays can be low. For example, *CYP2C19*2* is a common variant allele (~15–25% allele frequency [11]) associated with high on-treatment platelet reactivity and increased risk for stent thrombosis, which is a rare clinical event (~0.5%) among clopidogrel-treated patients with acute coronary syndromes (ACSs) managed with percutaneous coronary intervention (PCI) [12–15]. These disparate allele and adverse clinical outcome frequencies result in a low positive predictive value for *CYP2C19* testing for these patients [16]. Many argue, however, that genetic testing in this scenario can still be useful and can help these patients avoid life-threatening and unnecessary risks, particularly when taken into consideration with other high-risk clinical factors. In this scenario, pharmacogenetic testing can be viewed as analogous to other nongenetic clinical variables with imperfect prediction (e.g., age, concurrent medications, comorbidities, liver function, etc.), but still provide useful and additive information [17,18].

The clinical utility of a test is a widely used measure of its usefulness in the clinic and in resulting changes in health outcomes. However, given the multidimensional nature of this kind of measurement, there is rarely consensus on precisely defining or adequately demonstrating it, particularly with regard to personalized medicine and pharmacogenetics [19]. The common benchmark for interventional evidence in medicine is a prospective randomized controlled trial, but such trials are often resource prohibitive for testing pharmacogenetic hypotheses, and they may be unethical to conduct for strong associations of severe adverse effects associated with high-risk genotypes. Nevertheless, two prospective randomized clinical trials have recently been completed that tested the utility of *CYP2C9* and *VKORC1* genotyping to guide warfarin dosing [20,21]. The results of these trials will likely greatly influence the future of pharmacogenetic testing for anticoagulation control and possibly other clinical scenarios with pharmacogenetic interactions. Still, in the absence of interventional clinical trial data, alternative evidence-gathering mechanisms are required, including incorporation of pharmacogenomics into premarket drug development, innovative clinical trial designs, and continued postmarket observational and mechanistic studies [22–24].

40.2.2 Education, Guidelines, and Recommendations

Clinician knowledge of pharmacogenetic testing significantly influences its successful integration into clinical practice. A previous study on medical genomics concluded that clinicians are generally not confident in providing genetic services because of insufficient training and knowledge [25]. Efforts are therefore needed to improve pharmacogenetic comprehension among clinicians, particularly by increasing its presence in medical school curriculums [26,27]. Moreover, the current significance of pharmacogenetics is not well understood by practicing clinicians, and they may not have adequate education on how to manage a patient based on pharmacogenetic test results. Consequently, there has been insufficient information and guidance available to help clinicians apply pharmacogenetic test results to individual patient management.

To address these educational needs, clinical practice guidelines that describe the utility of pharmacogenetic testing in different clinical scenarios are warranted to assist health professionals in evaluating and determining test utility

and to facilitate the overall adoption of clinical pharmacogenetic testing [28]. Some of the first pharmacogenetic practice guidelines were developed by experts for *CYP2D6*- and *CYP2C19*-guided antidepressant dosing [29,30]; however, since then other organizations have published more formal documents (Table 40.1). Although some guidelines seek to evaluate evidence and establish whether testing is warranted or not [31,32], others do not make recommendations for or against testing and more so provide evidence-based recommended clinical actions when a patient's genotype is already known [33–35]. Notable examples include the thorough guidelines established by Royal Dutch Association for the Advancement of Pharmacy-Pharmacogenetics Working Group (KNMP-PWG), which reports on 53 drugs and 11 genes [33]; the expert-derived guidelines of the European Science Foundation (ESF) [34], and the evidence-based gene/drug guidelines of the Clinical Pharmacogenetics Implementation Consortium (CPIC) of the National Institutes of Health's Pharmacogenomics Research Network (PGRN), which are published and updated regularly on the Pharmacogenomics Knowledgebase (PharmGKB) website (www.pharmgkb.org) [35].

Evidence-based practice recommendation statements for pharmacogenetic testing have also been published by the Evaluation of Genomic Applications in Practice and Prevention (EGAPP) Working Group (Table 40.1) [36], launched by the Centers for Disease Control and Prevention (CDC) Office of Public Health Genomics. Although EGAPP previously found insufficient evidence to support recommendations for or against *CYP450* and *UGT1A1* genotyping in patients treated with selective serotonin reuptake inhibitors (SSRIs) and those treated with irinotecan, respectively, their reports did identify important research gaps that could facilitate future implementation [31,32]. Unfortunately, the level of evidence required for pharmacogenetic testing is not always clearly defined and is therefore often debated [18,37–40], as some view pharmacogenetics as an entity unique from other elements of genomic medicine which in many cases is already clinically warranted, whereas others unwearyingly await additional clinical evidence.

40.2.3 Pharmacogenetic Testing Regulation

Over the past several years, the FDA has revised numerous drug labels to now include relevant pharmacogenetic information; however, most do not require testing prior to initiating therapy. For example, CLIA-certified laboratory-developed pharmacogenetic tests and FDA-regulated tests without clinical claims do not necessarily have to provide full evidence of clinical validity and utility before being offered by a clinical laboratory. Although a number of important pharmacogenetic genes can be currently tested by CLIA-certified laboratories using laboratory-developed tests, there are only a small number of DNA-based pharmacogenetic tests that are actually FDA-approved for *in vitro* diagnostic testing at the present time, including assays for warfarin sensitivity (*CYP2C9* and *VKORC1*), *CYP2D6*, *CYP2C19*, and *UGT1A1*. Notably, the first sample-to-result system for genotyping *CYP2C19*2*, **3*, and **17* from a noninvasive cheek swab in under 60 minutes was very recently granted 510(k) clearance by the FDA.

For quality assurance, clinical laboratories also have the option of participating in the pharmacogenetic proficiency testing program sponsored by the College of American Pathologists (CAP), which provides graded and educational proficiency testing surveys [41]. Regarding test quality control and reference materials, the CDC Genetic Testing Reference Materials Coordination Program (GeT-RM), in collaboration with members of the pharmacogenetic testing community and Coriell Cell Repositories, have characterized a large panel of commercially available cell lines for genes and variants commonly included in pharmacogenetic testing panels and proficiency testing surveys [42]. An expanded, ongoing pharmacogenomics reference material project by the GeT-RM is currently interrogating a larger panel of genes and variants using single gene-targeted assays, genotyping microarrays, and next-generation sequencing of custom-designed gene panels.

40.2.4 Pharmacogenetic Testing Turnaround Time

Although rapid genetic testing can be performed in some clinical scenarios, typical turnaround time for genetic testing in a clinical laboratory is usually days to weeks, depending on the testing technology. Unfortunately, for the majority of currently actionable pharmacogenetic variants, this is unacceptable for efficient implementation into routine clinical care. For example, in the cardiovascular pharmacogenetics field, *CYP2C9*/*VKORC1* and *CYP2C19* genotype data are most effective at the time of drug initiation for both warfarin and clopidogrel, respectively [43]. Moreover, given the demanding environments common to most anticoagulation clinics and cardiac catheterization laboratories, disruption of routine care by interfacing with an external clinical laboratory that has additional genetic testing logistics and unique laboratory information management systems can present further complexities for effective use of pharmacogenetic testing.

40.3 POINT-OF-CARE PHARMACOGENETIC TESTING

To address the issue of testing turnaround time for more efficient implementation, many commercial companies have been developing genotyping platforms that offer rapid sample-to-result assays that will be highly beneficial for integrating pharmacogenetics at the point of care [9,44,45]. A notable example comes from the Reassessment of Anti-Platelet Therapy Using An Individualized Strategy Based on Genetic Evaluation (RAPID GENE) trial, which recently reported use of *CYP2C19*2* (c.681G>A) point-of-care genetic testing for cardiac patients initiating clopidogrel therapy following PCI [46]. In this proof-of-concept study, patients were randomly assigned to rapid point-of-care genotyping or to standard treatment; those in the genotyping group were tested for *CYP2C19*2* using a cheek swab genetic testing device that reported results within 60 minutes. Carriers were treated with prasugrel, and noncarriers and patients in the standard treatment group were treated with clopidogrel. Importantly, no carriers in the rapid genotyping group had high on-treatment platelet reactivity (HTPR) at day seven (the primary end point), compared with 30% of patients given standard treatment ($p = 0.0092$).

Although this study showed that point-of-care genetic testing following PCI can be performed effectively by nursing staff, and that personalized antiplatelet therapy can reduce HTPR in this patient population, it has yet to be established that this testing strategy results in better clinical outcomes. To address this important question, a number of related trials are currently ongoing that measure clinical outcomes following rapid and/or point-of-care *CYP2C19*2* testing. For example, RAPID STEMI (Reassessment of Anti-Platelet Therapy Using an Individualized Strategy in Patients with ST-segment Elevation Myocardial Infarction; ClinicalTrials.gov Identifier: NCT01452139) is evaluating the feasibility, efficacy, and safety of pharmacogenetic-guided antiplatelet therapy for the treatment of STEMI patients following PCI using point-of-care *CYP2C19*2*, **17*, and *ABCB1* 3435C>T genetic testing. Although the primary outcome is high on-treatment platelet reactivity, there are a number of secondary outcomes of clinical measures (e.g., composite of death from cardiovascular causes, nonfatal myocardial infarction, and re-hospitalization; bleeding risk).

TAILOR-PCI (Tailored Antiplatelet Therapy Following PCI; ClinicalTrials.gov Identifier: NCT01742117) is a large trial with an estimated enrollment of almost 6000 patients that is testing the hypothesis that, following PCI and using a *CYP2C19* genotyping strategy, ticagrelor is superior to clopidogrel in reducing a composite end point of major adverse cardiovascular events (MACE). The primary outcome is the occurrence of MACE within one year following PCI, and recruitment is scheduled until 2016. PRU-MATRIX (Customized Choice of P2Y12 Oral Receptor Blocker Based on Phenotype Assessment via Point of Care Testing; ClinicalTrials.gov Identifier: NCT01477775) is another ongoing clinical trial that is comparing standard of care to a customized antiplatelet algorithm that includes both platelet reactivity and genetic (*CYP2C19*) variables. The primary outcome is the time to occurrence of cardiovascular death, myocardial infarction, stroke or bleeding, and the proportion of patients in therapeutic range for platelet aggregation (P2Y12 pathway activity according to PRU values).

Despite the enthusiasm for rapid-turnaround time pharmacogenetic testing and the success of the RAPID GENE trial, issues remain when one considers transferring this type of genetic testing from research study to routine clinical care. For example, the regulatory landscape of point-of-care testing, particularly that involving genetic testing, can be complicated. The recent FDA approval of the device used in the RAPID GENE trial does not support its use specifically as "point of care" because of the need for personnel with adequate genetics training. Instead, it is approved and marketed as a "rapid sample-to-result" platform.

Point-of-care testing is, by definition, clinical laboratory testing performed at or near the site of clinical care delivery by personnel (or patients) whose primary training is not in the clinical laboratory sciences. The pathways for FDA approval of point-of-care devices include either 510(k) clearance, premarket approval applications, or CLIA waivers when a device has a negligible likelihood of erroneous results and has no risk of harm if performed incorrectly. Point-of-care pharmacogenetic testing is likely not amenable to a CLIA waiver, which highlights a potential challenge when performing clinical genetic testing at the point of care in the absence of personnel with certified genetics expertise. Depending on regional regulations, it is possible that a local CLIA-certified genetics laboratory may be required to oversee point-of-care testing by remotely managing interpretation, performance, quality control/assurance, and participation in relevant proficiency testing programs. This could increase the complexity and overhead costs of point-of-care testing and add potential difficulties when defining the relationship between point-of-care clinical staff and CLIA-certified genetic laboratories.

A technical challenge for point-of-care pharmacogenetic testing involves the content of the genotyping assays themselves. The RAPID GENE trial was centered on a single polymorphic allele, which for future pharmacogenetic assays will not be adequate. This is even more relevant when deploying point-of-care pharmacogenetic testing across more diverse patient populations, as the frequencies of relevant variant alleles differ between racial groups and ethnicities. For example, the *CYP2C19*4B* loss-of-function allele has a frequency of ~2% among Ashkenazi Jewish individuals, but the frequency is lower in other racial and ethnic groups [11,47]. In addition, more genes and functional variants are necessary for some currently actionable pharmacogenetic examples (e.g., warfarin); also, ongoing genome sequencing studies are likely to identify more variants with appreciable effect sizes that will justify inclusion in future point-of-care testing panels.

Some of the more robust pharmacogenetic associations at the present time involve specific human leukocyte antigen (HLA) alleles of the major histocompatibility complex (e.g., *HLA-B*5701* and flucloxacillin-induced liver injury and abacavir-induced hypersensitivity [48]; *HLA-B*1502*/*HLA-A*3101* and carbamazepine-induced hypersensitivity [49,50]). Unfortunately, *HLA* genotyping is one of the more challenging molecular assays, requiring combinatorial multiplexing that is beyond the technical capacity of current point-of-care platforms. Ideally, future point-of-care genetic testing platforms will overcome the technical need for multiplexed sample-to-answer genotyping and be able to include larger variant panels with content specifically selected for clinically actionable alleles.

40.4 PRE-EMPTIVE PHARMACOGENETIC TESTING

Another recently actualized strategy for clinical pharmacogenetics that can circumvent some of the issues surrounding both traditional external laboratory and point-of-care testing is pre-emptive clinical genotyping. Although this model has its own set of obstacles for effective clinical implementation, pre-emptive pharmacogenetic testing programs are currently underway at selected academic medical centers [51–54]. This approach deposits clinical genotype data in patient records pre-emptively, usually through coordinated prospective sampling and/or biobanking, CLIA-certified testing and informatics, and alerts prescribers at the point of care through sophisticated electronic clinical decision support (CDS) systems when a drug is ordered for a patient with an at-risk genotype. The immediate knowledge of personalized and relevant pharmacogenetic variation, with interpretation and possible/recommended actions without disruption of routine clinical care, is the clear advantage to this strategy.

Additionally, pre-emptive genotyping can still utilize CLIA-certified laboratory testing, but without the usual concerns regarding turnaround time because it is done prior to drug prescription and possibly before clinical indication. However, the necessary institutional investments in informatics, CDS, healthcare provider participation and education, and infrastructure for sampling/biobanking and testing in a CLIA-certified environment suggest that this exciting mode of clinical pharmacogenetic delivery will be limited to large academic medical centers. Although not meant as a comprehensive listing, an overview of selected pre-emptive pharmacogenetic testing programs follows.

40.4.1 Vanderbilt University Medical Center: PREDICT

One example of pre-emptive pharmacogenetic testing is the Pharmacogenomic Resource for Enhanced Decisions in Care and Treatment (PREDICT) program at the Vanderbilt University Medical Center (VUMC) [51]. Launched in 2010, the initial phase of this program involves ~3000 patients scheduled for cardiac catheterization, coupled with pre-emptive genotyping with a multiplexed platform that includes *CYP2C19*. Genotype data are deposited into the electronic medical record (EMR), and point-of-care CDS is deployed when clopidogrel is prescribed for patients with variant *CYP2C19* genotypes (intermediate and poor metabolizers). The evidence for *CYP2C19* genotype and clopidogrel response is generally considered strong and amenable to initial implementation; however, the long-term goal of PREDICT is to establish a framework and comprehensive infrastructure for pre-emptive incorporation into the VUMC EMR of genomic and other high-dimensional patient-specific data. Notably, this program has highlighted many of the important issues surrounding implementation of pharmacogenetic testing, including the importance of engaging patients and relevant physician providers, the necessary institutional commitments, the multidisciplinary effort required in reviewing evidence and developing CDS, and the need for genotyping in a CLIA-certified laboratory. PREDICT is currently being expanded to include warfarin/*CYP2C9*-*VKORC1* and simvastatin/*SLCO1B1* drug/gene pairs.

40.4.2 University of Florida and Shands Hospital: PMP

The Personalized Medicine Program (PMP), of the University of Florida (UF) and Shands Hospital was launched in 2011 as a translational clinical implementation program within the UF Clinical and Translational Science Institute [54]. Its goal is to address some of the challenges of genomic medicine, including how to store and utilize genomic data for clinical use, define genetic data that are sufficiently robust for clinical use, and develop CDS to guide clinicians in the use of genomic data. A multidisciplinary PMP subcommittee evaluates the pharmacogenetics literature to identify clinical examples where there is sufficiently robust evidence to warrant clinical implementation. Like PREDICT, the initial PMP pilot, deployed in 2012, is also centered on clopidogrel and *CYP2C19*. However, its pre-emptive multiplexed genotyping panel includes a much larger number of genes and variants [55], tested under research consent for storage in the EHR and for possible use in future implementation efforts. This custom-designed panel, tested in a CLIA-certified laboratory, includes 252 pharmacogenetic variants and was designed in collaboration with PharmGKB (www.pharmgkb.org). Future plans for the UF PMP include expanding the clopidogrel/*CYP2C19* program to other private practices across Florida and implementing additional pharmacogenetic examples with CPIC guidelines in other practice settings (e.g., pediatric hematology/oncology).

40.4.3 University of Chicago: 1200 Patients Project

The 1200 Patients Project, recently deployed by the University of Chicago, is another pre-emptive pharmacogenetic genotyping program [52]. Here, patients receiving outpatient medical care who are taking one to six prespecified prescription medications under the care of recruited physicians (two cardiologists, one pulmonologist, one hepatologist, one gastroenterologist, three oncologists, and four general internists) are prospectively genotyped in a CLIA-certified laboratory with a large panel of clinically relevant germline pharmacogenetic variants. The panel provides comprehensive genotype results for a large number of variants known to influence response and/or toxicity of commonly used drugs. Patient-specific results are subsequently made available exclusively to the enrolling provider through an online genomic prescribing system [56]. Like other pre-emptive programs, the initial phase of the project is centered on the return of pharmacogenetic information and the overall examination of its use. Whether physicians take this information into consideration during clinic visits, and whether it results in altered patterns of prescribing in patients who are genetically at high risk of adverse drug outcomes/nonresponse, are the primary and secondary end points.

40.4.4 St. Jude Children's Research Hospital: PG4KDS

The St. Jude PG4KDS pharmacogenetics implementation program is migrating genotype data derived from a large microarray-based panel (1936 genomic variants in 225 genes) [57] that have been tested in a CLIA-certified laboratory, into the EMR as prospective patients are enrolled [58]. The patient population of the program are enrolled through pediatric clinics and are typically receiving multiple therapies. Like other programs, the majority of the genotype data are maintained in a research environment, with only selected genes and variants classified as priorities when there is sufficient evidence for deposit into the EMR. The EMR subsequently deploys CDS when an intersection between a prescription and an at-risk genotype occurs. Current priority genes being implemented by PG4KDS include *CYP2C19*, *CYP2D6*, *SLCO1B1*, and *TPMT*. These genotype results are aggregated into a single section in the EMR on a per-patient basis and can be easily expanded to accommodate additional genes and drugs as they are identified.

40.4.5 Icahn School of Medicine at Mount Sinai: CLIPMERGE–PGx

The CLIPMERGE–PGx (Clinical Implementation of Personalized Medicine through Electronic Health Records and Genomics—Pharmacogenomics) program of the Icahn School of Medicine in New York, is a pre-emptive pharmacogenetics initiative that is genotyping a panel of germline variants in reconsented patients initially enrolled in the school's Bio*Me* Biobank Program [53]. Notably, the CLIPMERGE platform is an independent and external system that communicates with the EHR and houses decision support rules based on actionable variants and relevant phenotypic data from the CLIPMERGE database, including longitudinal clinical data extracted from the EHR. A Clinical Risk Assessment Engine (CRAE) is included in this platform with a rules engine that relates actionable genotype–phenotype pairs to genome-informed advice messages. If predefined rules are met, decision support based on available CPIC guidelines is delivered in real-time at the point of care through the EHR. Patients for the pilot program are selected based on their regular attendance at the Mount Sinai Internal Medicine Associates (IMA) clinic for their primary care. In order to enrich the program with patients likely to have pharmacogenetic interactions, targeted patients include those currently taking clopidogrel, warfarin, simvastatin, tricyclic antidepressants (TCAs), and/or selective serotonin reuptake inhibitors (SSRIs). Consented patients provide a saliva sample for genetic testing in a CLIA-certified laboratory and genotype data are ultimately stored in the external CLIPMERGE database. Consistent with other programs, transactional data regarding CDS metrics, usage, and clinical parameters are collected on an ongoing basis from the EHR and CLIPMERGE CDS system. The CLIPMERGE PGx pilot program has 1500 consenting Bio*Me* participants; however, the eventual aim is to recruit all participants from Bio*Me* for further pharmacogenetic and other genomic medicine implementation initiatives.

40.4.6 PGRN: Translational Pharmacogenetics Program

In an effort to better identify and possibly address some of the barriers to implementing pharmacogenetics in a collaborative multi-institution effort, the PGRN (Pharmacogenomics Research Network) recently established the Translational Pharmacogenomics Program, which comprises six diverse healthcare systems (some detailed earlier): the University of Maryland, the University of Florida, St. Jude Children's Research Hospital, Vanderbilt University, the Mayo Clinic, and Ohio State University [59]. PharmGKB (www.pharmgkb.org) serves in a coordination and knowledge sharing/dissemination role. For this initiative, each site is implementing one or more pharmacogenetic tests, adapting evidence-based CPIC guidelines to local policies and practices, and identifying and attempting to overcome real-life policy, logistic, and translational barriers. Notably, both point-of-care testing (e.g., *CYP2C19* testing in PCI patients) and pre-emptive models are being executed and studied. Each implementation step will be systematically evaluated to develop a practical evidence-based toolbox of best practices for pharmacogenetics implementation that will be useful across a wide spectrum of healthcare systems. These tools will be disseminated through publication in peer-reviewed journals and updated regularly on the PharmGKB website. Other instruments that will be developed for dissemination include a best practices manual for implementation of pharmacogenetics testing, and questionnaires and surveys to assess implementation metrics and effectiveness.

40.5 CONCLUSION AND FUTURE PERSPECTIVES

The ongoing advances in point-of-care and pre-emptive genetic testing are greatly facilitating the implementation of efficient and effective clinical pharmacogenetics. Both strategies circumvent the barrier of test turnaround time and, therefore, provide the opportunity to integrate pharmacogenetic test results at the point of care. Although these strategies are very promising, the increasing accessibility of whole-genome sequencing suggests that the long-term future landscape may no longer have a need for targeted genotyping if patients already have their sequence data available. However, for the shorter-term future, the use of point-of-care genetic testing will undoubtedly be very useful in the clinic (if accepted by regulatory agencies and laboratory providers) and for prospective genetic intervention trials.

Pre-emptive pharmacogenetic testing is an exciting strategy for delivering genetic-based CDS at the point of care to help guide pharmacotherapy; however, the generalizability of this strategy beyond large academic medical centers may be limited by the necessary institutional investments, information technology infrastructure, and broad provider support. Regardless of how the pharmacogenetic data are derived (or when), of utmost importance will be to continue the necessary efforts toward provider and patient education, accessible and appropriate CDS, and rigorous assessment of clinical utility by the pharmacogenetics community.

41.1 OVERVIEW

Enterprises such as the Human Genome Project in 2003 and the International HapMap Project in 2007 have advanced our understanding of important genetic associations to drug responses. Growing from this new understanding, pharmacogenomic (PGx) testing is increasingly studied and used in children to improve pediatric dosing strategies. Pharmacogenomics is the subcategory of genomics research that has perhaps the most immediate potential impact in pediatric clinical trials and therapy. This area has enormous potential to benefit children, but also creates possibilities for social and economic discrimination, as well as abuse of information in genomic databases.

Pharmacogenomics combines human genomics with pharmacogenetics to study the role of the individual's genetic makeup in his or her response to a drug [1]. The promise of this approach is that patients can receive individually tailored medical therapy and dosing. This technology advances the important concept of risk stratification, which has historically led to better protection of children with lower-risk diseases from excess toxicity, at the same time ensuring that children with higher-risk diseases are not undertreated.

In identifying the specific genetic determinants involved in drug disposition, metabolism, and response throughout a child's development, the goal is for pediatricians and clinical investigators to be better able to choose the best drug for that child and to more accurately determine safe and effective dosing. However, as PGx technology evolves in pediatrics, several key ethical issues unique to children will need to be considered. Both ethical and political issues related to PGx testing have been extensively addressed in the adult population, and the issues that are raised in this chapter are relevant to adults for many reasons, including the difficulty of understanding the true implications of the testing. But when the patient or research participant is a child, these issues become more complex, in part because pediatric participants range from neonates who do not participate in decision making to older adolescents who often participate more but without the complete autonomy and legal status of adults. It should be noted that some of the ethical and regulatory issues presented in this chapter are specific to the American health system. It should also be

emphasized that these challenges are not static but change as a child grows, as our knowledge of PGx evolves, and as legislative responses mature in response to these new technologies.

In this chapter, we explore the historical background against which clinical and research ethics have developed as well some of the more important approaches to framing ethical questions in pediatric clinical practice and research. We then focus on three broad areas of ethical concern that arise in pediatrics. First, should PGx testing be performed in children and, if yes, what are the specific benefits and risks to the child? Second, what are the ethical considerations of pediatric PGx testing in the context of research and how are they similar to those in other forms of pediatric research in terms of informed consent, assent, and research risk assessment? Third, how do these general ethical concerns provide a foundation and guide for ethically sound practices by clinicians prescribing a drug with potential PGx variability, for the clinical researcher considering whether or not to study novel PGx markers in children, and for the investigator whose nontherapeutic PGx study may pose some risks?

In elaborating the concepts of benefit and risk, we consider several successful applications of PGx testing in pediatrics as well as historical cases in which the lack of information has led to harm. We also explore the ways in which the ethical issues involved in protecting a child's best interest go beyond concerns about physical well-being, drug dosing, or optimizing therapeutic benefit while minimizing bodily harm. Questions are currently being debated about how to appropriately obtain and manage the information that emerges through PGx testing in children.

There are many questions related to these concerns. For example, who should be responsible for ordering a pharmacogenetic genotyping panel that profiles responsiveness for a wide array of drugs such as those metabolized via the Cytochrome P450 isoenzymes? Given the wide variability in understanding of PGx testing and its relevance in a variety of situations, how should such information be transmitted to other clinicians and pharmacists who are caring for the child? When should genomic profiling be ordered, and when should it not be ordered? Are there situations in which a family requests testing and a clinician should refuse? If PGx testing is performed as part of a neonatal screening program, who should be the providers of such data? Should pediatricians be responsible for interpreting the data and facilitating patient management plans related to conditions that have an adult onset? At what age should children be informed of their specific liabilities? Should information be provided for conditions for which there is no known cure or treatment? If testing uncovers unexpected findings, what are the obligations regarding revealing this information? Is there ever harm that results from revealing information such as this? Who decides, and when? If a disease gene or disease susceptibility gene profile is discovered, should a subject be notified? Should the subject's family also be notified or is this a breach of confidentiality? [2].

It is important to note that these questions are also significant for adults and for the medical caregivers who treat them. This chapter focuses on children because of their vulnerability, but when adults are ill and their families are worried, many of the points that are made here are applicable: sick adults and their frightened families are not so different from sick children and their frightened families.

Pharmacogenomics raises other ethical questions that supersede issues centered on an individual patient and issues related to protection of information. For example, there is an important economic question: might pharmacogenomic criteria eventually become regulatory requirements for the development and testing of medicines? [3] Because the pharmaceutical industry functions on a business model, it is unlikely that it will develop medicines that benefit only a small, narrowly defined group of patients. Orphan drugs might therefore become more common. How should economic risk be weighed against the potential clinical benefit for a small group of patients? Furthermore, if pharmacogenomics information suggests only that a child is more or less likely to benefit from a drug, what threshold would exclude him or her from the use of that drug? Ten percent? Thirty percent? If a child is less likely to respond to a drug, is an insurance company obligated to pay for it? [4] If genetic variance peculiar to an ethnic group is found, what are the political, social, and economic implications? Might these be used to decide whether or not to develop certain medicines for certain populations? [5].

Finally, there are ethical issues related to social justice that are often uncomfortable and even contentious: in a time when tens of millions of people in the United States have limited access to basic healthcare, is the development of personalized medicine the most appropriate use of our resources as a society? Answers to questions such as these are influenced by changing realities accessible to study and description. If directing therapies to individuals based on their particular genetic (or other) features truly mitigates harm, this may provide long-term reduction in total healthcare costs. The application of PGx testing to patient care is already being facilitated by the increasing availability of genetic tests in clinical labs and relatively decreasing analytical costs.

On the other hand, if this technology cannot be meaningfully and broadly translated into the lives of individuals, or if harm outweighs benefit in a subset of the population, the priority of PGx testing might change. The question of whether or not PGx testing contributes to the societal goal of providing the best medical care at the lowest cost to the greatest number of people is an empirical one that can only be answered through careful investigation. The ethical question specifically related to testing in children is whether or not, and to what extent, children should be allowed (or asked) to participate in investigations or nonresearch testing while the final answers to the empirical questions are still uncertain.

The emergence of specific genetic variations, and their effects on drug therapy, has heightened pediatricians' awareness of the clinical application of PGx testing in the pediatric population, including both its potential benefits and its potential risks. Pediatricians also recognize important multifactorial challenges to widespread implementation of PGx testing in children, among them the following:

- Genetic factors are not the only influence on drug response; most children cannot provide informed consent to testing.
- The use of PGx test results to drive personalized medicine requires tests that are reliable and inexpensive and that provide fast turnaround time.
- The clinical relevance of genetic variations must be validated, and until this occurs it will be difficult to articulate the ways in which such testing can legitimately be viewed as in "the best interest" of a child.
- Clinical applications are currently limited to relatively few therapies.
- Health professionals need to receive education and training prior to integrating PGx testing, and this kind of training can be labor intensive and variably received by busy clinicians accustomed to the traditional approach to medical practice. There are unique ethical dilemmas associated with PGx testing and research in children, some of which may emerge only in the course of continued development of this technology.

When thinking about ethical issues related to children in any therapeutic or medical research setting, the primary goal is, and should be, to deepen our understanding of a child's changing ability to participate in ethical decision making, to be given the opportunity for meaningful assent or dissent where appropriate, to offer consent when developmentally mature or legally permitted, and to articulate the concepts of "best interest" in relation to a particular child. Just as medicine is "personalized" through these growing technologies, so moral deliberation regarding the appropriateness of pharmacogenomic testing should be "personalized" in the sense that decisions not only are grounded on moral consensus in the scientific and medical community, drawing on all that we have learned from past research efforts with children; they also align with the values of the families and children involved in studies.

41.2 HISTORICAL PERSPECTIVE

Medical research has involved children as subjects for hundreds of years [6]. Edward Jenner first used an experimental smallpox vaccine on his own 1-year-old son at the end of the eighteenth century. At the end of the nineteenth century, a 9-year-old child was the first human recipient of Louis Pasteur's rabies vaccine [7]. However, it was not until the first half of the twentieth century that regulations governing such experimental therapy began to be established and the importance of consent, assent, and parental permission became clearer.

Informed consent by human research subjects was first officially advocated in the Nuremberg Code, a code of ethics that was developed after the trials of German physicians who conducted morally outrageous human experiments in Nazi concentration camps during World War II (Table 41.1). Unfortunately, because this important code emphasized the absolute requirement of informed consent, it implicitly excluded children from participating in research on human subjects because they cannot give "informed consent" as framed by early codes of research ethics [8].

This issue was addressed more explicitly in 1964 when the World Medical Association adopted a set of research ethics principles now known as the Declaration of Helsinki [9,10]. These principles established the priority of human subjects' interests over those of science and society, and it sanctioned the participation of children in research if the child's responsible guardian gave permission.

After the publication of the Nuremberg Code, which implicitly excluded children from research, and before the Declaration of Helsinki, which explicitly allowed such research under specific conditions, experiments were nonetheless performed on children. Understanding this historical background illuminates the potential risks involved in any pediatric research, as well as those that emerge in nonresearch settings where testing or therapy is initiated without adequate evidential support. One of the most important of these was a series of radiation exposure experiments, in which children from the Fernald School in Framingham, Massachusetts, and researchers from the Massachusetts Institute of Technology participated, and which was funded by the Quaker Oats Company. In this experiment, children deemed mentally retarded were fed radioactive iron and calcium in their cereal [11]. President Clinton's advisory committee on human radiation experiments revealed the ethical consequences of inadequate parental permission in these experiments [12].

Another important set of experiments on children at around this time occurred at the Willowbrook institution (located on New York's Staten Island). These experiments were designed to follow the natural history of hepatitis in children also deemed mentally retarded [13,14]. Newly arrived children were infected with hepatitis virus by housing them with children already known to be infected. Participating children were kept in a special unit with better conditions and nutrition; if parents agreed to allow their children to participate, the children were admitted to Willowbrook more rapidly. The lead investigator did require

a thorough consent process that included a two-week waiting period for full deliberation. But because Willowbrook was so crowded, critics subsequently argued that the expedited admission and special treatment amounted to coercion.

Both the Fernald and the Willowbrook cases underscored the need for ethical review and oversight of human subjects research involving children, even when parental permission is obtained.

During the early 1970s, Congress became increasingly concerned about research ethics, in part because of the syphilis study involving economically poor black men that was conducted by the US Public Health Service at the Tuskegee Institute. The investigation of this study led to the formation of the National Commission for the Protection of Research Subjects of Biomedical and Behavioral Research, which published the Belmont Report in 1979 [15]. This report embraced three principles that are now familiar and accepted as foundational for research involving human subjects: (1) respect for persons, (2) beneficence, and (3) justice.

The principle of beneficence grows out of the Hippocratic maxim "do no harm" and extends it to include maximizing the possible benefits and minimizing the possible harms to research subjects (minimizing harms is often formulated separately as a fourth principle, nonmaleficence) [16]. The principle of beneficence is operative in any discussion weighing the risks and benefits of human subjects research, especially when the subject is a minor. The principle of justice concerns the right and fair distribution of both the benefits and the burdens of research. This is an issue that has a particular urgency when clinical treatment and research are considered globally, and it is one that has become important as the ethics of pharmacogenomics mature. The concept of respect for persons includes two principles: that individuals be treated as autonomous agents and that those with less autonomy be entitled to protection. The latter principle is especially relevant in pediatrics and is somewhat fluid in its definition because of the growing autonomy of pediatric patients as they approach adulthood.

Because of the past abuse of research subjects who were harmed in studies that they did not understand or for which they had not given meaningful permission, it is understandable that "informed consent" has become the dominant concept in discussion about ethical research on human subjects. However, recent arguments have been put forth that informed consent is not always necessary for ethical clinical research, nor is it sufficient to qualify research as ethical. A recent review of major codes and declarations relating to human subjects research led to the proposal that there be seven requirements for ethical clinical research. These are worth keeping in mind both for pharmacogenomic research projects involving children and for the complex analysis of how to use such technology outside the research setting when evidence for efficacy is incomplete [17,18]. The requirements are these:

- The research must lead to enhancement of health or knowledge.
- The research must be methodologically rigorous.
- Selection of study sites and of individual subjects should be determined by scientific objectives and the potential for and distribution of risks and benefits.
- Given standard clinical practice and the research protocol, risks should be minimized, the potential for benefits should be enhanced, and risks must be outweighed by potential benefits to individuals and knowledge for society.
- Individuals should be informed about the research and should provide voluntary consent.
- Research subjects should have their privacy protected.
- Participants should have the opportunity to withdraw and have their well-being monitored.

These requirements are thorough and persuasive, but they must still be adapted to the conditions under which the research is conducted. Factors of health, economy, culture, religion, and technology affect how these requirements are translated into concrete, ethical action. For this reason, the specific context in which the research is conducted affects ethical deliberation.

In therapeutic and research efforts for children, ethical decision making comprises all of the considerations just discussed, in addition to the salient fact that the recipient of the risk or benefit is not generally the person who makes the decisions. A child may not be capable of assimilating sufficient information to meaningfully participate in an "informed choice." One need not enter the arena of international bioethics to find challenges to the role of "autonomy" in ethical decision making: such challenges are the daily fare in pediatric medicine and research because children's "autonomy" is an issue that changes from day to day.

41.3 ETHICAL SIGNIFICANCE OF BENEFIT, RISK, AND UNCERTAINTY IN PEDIATRIC PHARMACOGENOMICS

Many children are afflicted with potentially devastating diseases that are treated with medications that either can be, or will be, capable of being personalized with the aid of PGx testing. The history of pediatric medicine leaves little doubt about whether or not pediatric drug research is needed to improve medical care for children, and understanding this history can contribute to a better articulation of potential benefit to them—benefit that must always be weighed against the potential for harm. Accurate dosing of medications that carry risk is a compelling potential benefit, and the range of children for whom this benefit might be relevant is fairly broad: currently, there are ongoing studies to elucidate the relationship of pharmacogenetic variations and potential adverse drug reactions [19] for children with asthma, psychiatric and neurodevelopmental disorders, seizures, atopic dermatitis, human immunodeficiency virus (HIV), sickle cell disease, venous thrombosis, and acute lymphoblastic leukemia (ALL). Many of these conditions have an impact that goes beyond individual moral concern, extending to broader social and national concerns [20].

In the pediatric population, clinicians have often been forced to take a "trial and error" approach to using medications because of the lack of sufficient studies in children. Awareness of the potential harms involved in such an approach date back to 1938, when sulfanilamide elixir was prepared using diethylene glycol as the solvent. This led to 107 pediatric deaths, and there have been many pediatric drug misadventures since then. In the 1950s, widespread use of chloramphenicol resulted in grey baby syndrome, and sulfonamides were found to induce kernicterus. In the

1960s, tetracycline use led to bone and tooth deposition of the drug with functional and cosmetic consequences.

Two decades later, in the 1980s, it was discovered that additives in medications, rather than the drugs themselves, could cause adverse events. Heparin was thought to cause "gasping syndrome" in infants. However, it was discovered that accumulation of the preservative, benzyl alcohol, was to blame. Polysorbate found in intravenous Vitamin A products led to renal and hepatic failure and caused thrombocytopenia. An accumulation of propylene glycol, a solvent in many intravenous products administered to children, including multivitamins, lorazepam, and phenobarbital, caused iatrogenic hyperosmolality, metabolic acidosis, and clinical deterioration.

Understanding the behavior of medications in children, and the ways clinicians might use pharmacogenomic information to mitigate harm, requires participation by children in clinical trials. Children are vulnerable and developmentally dynamic, and they often lack the cognitive and conceptual ability to fully understand potential risks and participate in the decision making related to clinical care of research subjects. Therefore, parents, legal guardians, and healthcare professionals must be trusted to act in their best interests and make those important decisions for them. This is, of course, true for many areas in a child's daily life. For example, if we have to pick up a child at school and must take a younger sibling in the car as we do so, we are putting the younger sibling at risk for injury or death if we get into an accident, and we are doing so without any obvious direct benefit to the young child—we could have found a neighbor, a babysitter, or a relative to stay with the child if we had taken the effort to plan ahead. And yet we regularly make decisions that add risk to the lives of our children, and we take this in stride as part of life because such decisions are made in the context of a family's mutual goals and values. In biomedical research, where goals often arise from the broader priorities of the medical research community that is focusing on a more general notion of benefit that affects whole populations, questions about who takes the risk, and who receives the benefit, have a different status.

This vulnerability to risk without obvious direct benefit has meant that children are often excluded from clinical research in order to protect them. This in turn makes it harder to study the pediatric population in order to optimize therapies for it. There is an important and necessary tension between the desire to protect vulnerable children from exploitation in clinical research and the desire to benefit (often future) children through advances in our understanding of pediatric diseases and therapies.

In June 1996, the Eunice Kennedy Shriver National Institute of Child Health and Human Development (NICHD) and the American Academy of Pediatrics (AAP) reviewed reports indicating that 10–20% of NIH-sponsored clinical research inappropriately excluded children. NICHD and AAP concluded that there is a tremendous need to include children in research. Indeed, balancing efforts to protect children from exploitation while working to advance discoveries that will benefit them is one of the most pressing and persistent parts of the ethical work that must pervade medical innovation in pediatrics.

From the time of the Nuremberg trials, the dangers of exploitation in medical research have been attended to and much harm averted. But with medical advances, we are also learning more about the real-world consequences in children's lives of being excluded from research. For example, asthma in children can truncate their ability to participate in many activities we associate with the joy of childhood, and in severe cases it can bring a child's life to an end. Can PGx testing help clinicians tailor therapy to maximize a child's ability to live fully despite asthma? Genetic variations in proteins acting as drug receptors can affect drug response in children.

Recent discoveries in asthma patients have shown that polymorphisms in the β-2 adrenergic receptor (coded by the *ADRB2* gene) may alter a child's response to β-2 receptor agonists. Several single-nucleotide polymorphisms (SNPs) have been identified that can heighten adverse effects or cause tachyphylaxis. Variants of the enzyme involved in leukotriene production, ALOX5, may affect response to the medications affecting these pathways, such as montelukast. A small subset of children with asthma may be poorly controlled because of steroid resistance due to decreased response to glucocorticoids and their anti-inflammatory effects related to genetic variations in cytokine production [21]. These insights are clinically relevant, and yet PGx data in children with asthma are scant.

As mentioned before, pediatricians often have to treat their patients in the absence of reliable data about the effects of the drugs they prescribe for them. This is reasonably construed as potentially harmful to children, so one relevant question that requires ongoing study is how the potential harm from this clinical practice compares to the potential harm of research trials or decisions made based on PGx testing in contexts where the meaning of the results is unclear. A child's response to pharmacotherapy is highly variable, and adverse drug events in some are often unpredictable. While certain children require a high dose of a medication to achieve a therapeutic response, other children with similar demographics have significant adverse drug reactions (ADRs) to the same medication in small doses.

The differences in response to drugs between children and adults are profound, and specific examples might serve to deepen ethical analysis of the nature of "benefit" and "harm" in pharmacogenomics. For example, in comparison to adults, infants and young children can develop acute central nervous system and hyperpyretic reactions to anticholinergic drugs, such as atropine and scopolamine, as well as life-threatening adverse reactions to valproic acid. Some drug response differences can be explained by pharmaco kinetic (PK) and pharmacodynamic (PD) variations in patient populations. However, studies have shown that children are at greater risk for severe ADRs than are adults, and this is a reasonable motivation to assess genetic variation and gene expression in order to make children's medications safer.

ADRs may be dose-dependent or dose-independent. Dose-related reactions can be predicted from the drug's known PK and/or PD. Certain populations, such as premature infants, are at high risk for dose-dependent ADRs because of the immaturity of their drug-metabolizing enzymes (DMEs). In the pediatric population, little is known about the PK and PD of the majority of medications used. Clinicians individualize drug therapy for infants and children by considering factors such as age, weight, drug allergies, organ function, concomitant medications, and historical drug response. The clinical drug response likely results from a combination of effects, including drug absorption, distribution, metabolism, and receptor site action, but it is possible that some medications are affected by specific DNA-sequencing variations. Human genes may affect the use of medications through several mechanisms, including drug-transporting proteins, metabolizing enzymes, and drug receptors. In children, the effects of ontogeny on PK and PD add an additional layer of complexity to PGx testing. For this reason, it is difficult to identify all causes of altered response in every patient. PGx testing provides additional information and a potential tool to guide appropriate therapy. The role of ontogeny and the effects of pharmacogenetic and developmental variations in DMEs, ion channels, transporters, receptors, and signaling pathways on the occurrence of ADRs in children require further exploration.

With the advent of pharmacogenomic analysis, it is possible to identify patients at risk of ADRs prior the administration of drugs. Cancer therapy is one very important area where PGx testing holds promise. For example, mercaptopurine is metabolized by the enzyme thiopurine methyltransferase (TPMT), which has a number of polymorphisms leading to the expression of three basic phenotypes. Approximately 89–94% of the population demonstrates "high activity" of this enzyme, while 6–11% display "intermediate activity." Importantly, a segment of the population, approximately 0.3%, displays "very low activity." In a single study of 147 patients receiving mercaptopurine for the treatment of ALL, homozygotes for low metabolic activity demonstrated severe hematologic toxicity despite a 50% reduction in dose. Prior to the understanding of the PGx testing results, this type of observation would have been idiotypic.

In addition to various mechanisms that can alter drug response, several families of drug-metabolizing enzymes have been identified that can have genetic polymorphisms with unique effects on PK/PD in children. These have potential for benefit, but also raise the important question (discussed later in the chapter) of implications of the connection between genetic polymorphisms and ethnic/racial background. For example, most Caucasians and half of African Americans do not functionally express the Cytochrome P450 enzyme 3A5. A commonly used benzodiazepine in pediatric patients is metabolized by CYP3A5 and CYP3A4. Polymorphisms of these enzymes result in decreased midazolam clearance and higher ADR risk. Another commonly used medication in the pediatric population is carbamazepine. There is a black-box warning from the US FDA about the potential of serious dermatologic adverse reactions, such as toxic epidermal necrolysis (TEN) and Stevens-Johnson syndrome (SJS) in those with the HLA-B*1502 allele of the HLA-B gene. This allele is found nearly exclusively in individuals of Asian descendent. The drug's labeling includes recommendations for testing for the HLA-B allele before initiation of use.

Codeine, a commonly prescribed opioid analgesic in children, recently created increased public awareness of variations in drug metabolism. Koren et al. published a case report in 2006 about an infant death believed to have been caused by morphine intoxication from breast-feeding [22]. The typical concentration of maternal codeine transferred from breast-feeding is 1–2 ng/mL. The authors noted that the infant's serum morphine concentration was 70 ng/mL. The mother was found to be heterozygous for the CYP2D6*2A allele and was an ultrarapid metabolizer of codeine. She was taking normal doses of acetaminophen with codeine for postpartum episiotomy pain, but this genetic polymorphism resulted in excessive production of morphine, which was distributed into her breast milk and transferred to the infant.

In August 2012, the FDA released a statement warning the public that a danger exists for children who are ultrarapid codeine metabolizers. It then conducted a safety review of its Adverse Event Reporting System (AERS) database from 1969 to May 2012. Ten deaths and three overdoses associated with codeine were found. These children were receiving doses of codeine following surgery, and many had a tonsillectomy or adenoidectomy. The doses of the opioid analgesic were within the typical dose range, and the signs of morphine overdose developed in 24–48 hours after consumption. The ages of the children ranged from 21 months to 9 years.

On February 20, 2013, the FDA added its strongest warning, a black box, to the drug label of codeine-containing products about the risk of codeine in postoperative pain management in children following tonsillectomy and/or adenoidectomy. Codeine is now contraindicated for that select patient population. Despite these warnings, the FDA does not recommend routine CYP2D6 genotype testing for use in this setting. The concern is that, although only up to 7 in every 100 individuals are CYP2D6 ultrarapid metabolizers, certain ethnic groups have been found to be more profoundly affected. Twenty-nine percent of North African and Ethiopian populations are ultrarapid metabolizers, whereas approximately 1% of Scandinavians, 10% of Spaniards and Greeks, and 6% of African Americans and Caucasians are affected. The only way to identify those who are at the highest risk for these adverse effects would be to perform PGx testing on children prior to administration of the drug.

Only a small number of all drugs and biological products marketed in the United States have had clinical trials performed in children. The majority of marketed drugs are not labeled for use in the pediatric population. Prior to the passage of the FDA Modernization Act (FDAMA) in 1997 and the Best Pharmaceuticals for Children Act (BPCA) in 2002 [23], fewer than 25% of drugs marketed in the United States were labeled for pediatric use [24]. While PGx testing provides an opportunity to optimize therapy, nearly half of all drug labeling still has insufficient information on safety, efficacy, or appropriate dosing for use in children.

Although there has been a slow decrease in "off-label" use of drugs in general pediatrics, neonatal information in labeling is even less available because neonates are a vulnerable subpopulation for whom end point development is lagging and in whom studies are more challenging. PGx testing can help explain or describe factors that influence drug absorption, drug metabolism, and drug disposition in children, especially given the many developmental factors in the early years of life that affect drug response, including organ development and protein levels [25]. But with the dynamic maturation of an infant's organ function, which has faster metabolism and more efficient clearance in the early years of life, it is arguably even more important to understand the effects that pharmacogenetic variations have in these children than in many other populations. The ethical challenge is this: Given that the potential benefits of PGx testing for a population, or a population subset, can be compellingly argued, and even though adults can consent to participate in clinical trials without obvious direct benefit to themselves, can children participate in studies that have more promise for benefiting future children than for benefiting the participating child?

41.3.1 What is "Consent" in Pediatrics?

The Nuremberg Code provides one starting point for understanding the meaning and importance of informed consent. The statement that "the voluntary consent of human subjects is absolutely essential" has been interpreted as legal capacity, the power of free choice based on knowledge and comprehension [26]. Consent, once seen as a single event, has come to be understood as more of a process [27]. It is not surprising, with the development of guidelines and goals for consent, that the process has become more intentional and more highly scrutinized.

The dominant theoretical framework for morally valid informed consent requires that four criteria be met: disclosure, understanding, voluntariness, and competence. Briefly, the core set of information that must be *disclosed* includes (1) the facts (such as risks, benefits, and alternatives) that patients (subjects) and providers believe relevant to the decision; (2) the recommendation of the professional; and (3) the purpose, nature, and limitations of consent. *Understanding* goes beyond disclosure because, while the elements disclosed can be objectively stated, true understanding involves many variables and is more difficult to assess.

Establishing and documenting understanding remains a great challenge, because information that has been disclosed but not understood contributes little to the ideal paradigm of informed consent. *Voluntariness*—another complex notion susceptible to interpretation—means at least that a decision is made without coercion or manipulation. Finally, *competence*, which is conventionally understood as the ability to perform a task, has also become a complex concept whose definitions derive from law, psychiatry, and philosophy. At base, a person's competence (or perhaps more accurately cognitive capacity) to make a particular decision relates to his or her ability to understand and think rationally about available choices, weigh the benefits and burdens and risks within the context of his or her life and values, and then use that understanding and logic to make a rational decision.

In the context of complex pediatric medical therapy or research, the process of consent can be influenced by the fact that parents are making high-stakes decisions on behalf of their own child. Even among clinicians, assessment of informed consent varies, and the experience of the clinician is relevant in it. Simon et al. found that clinicians with ten or fewer years of experience were more likely to say that the most important goal of informed consent is to explain the disease and treatment, and were more likely to suggest to parents that other children might benefit from the research [28]. The same study found that in the end, when reports from clinicians and parents are compared, clinicians are dissatisfied with aspects of consent that parents seem far more satisfied with. For example, clinicians expressed concern about information overload and about the fact that the consent discussion often occurs while the parents are still in a state of shock about the diagnosis.

Further insights into this difference have been gained from a number of studies addressing the perspectives of parents of children with cancer, a disease for which therapies are likely to be increasingly guided by technologies such as PGx. One study used three focus groups of parents of children with cancer to retrospectively examine their perceptions of the informed consent process [29]. High levels of stress were consistently reported, which were attributed to efforts to cope with multiple demands, including assimilating their child's diagnosis, nurturing and supporting the child, understanding the information given to them about diagnosis and treatment, getting to know an entirely new group of people involved in the child's care, and participating in the child's treatment.

Another important point was that the parents did not consistently distinguish research from their child's medical treatment. This finding underscores the importance of clearly explaining that research is optional during the process of "informing." If no distinction is made between research and treatment, the goal of informing has not been met. Physician-investigators often experience tension between their role as the patient's physician and their role as a researcher offering participation in a clinical trial designed to contribute to generalizable knowledge. This suggests that someone other than the physician-investigator should conduct the consent process. The study also suggested that the nature of clinical research, as well as the difference between research and proven current therapy, might be difficult for parents to grasp.

A second study in which parents of children with newly diagnosed cancer were interviewed supports these conclusions [30]. All of the participants recalled the diagnosis, and most (80%) recalled survival statistics. But only slightly more than half knew that the treatment protocol involved research and understood the concept of randomization. This finding is particularly important given that three-fourths of the parents thought that alternatives to enrollment in a randomized protocol had been insufficiently discussed. Because randomization is such an important tool for answering certain clinical questions of the sort that might involve PGx testing, this finding suggests that greater emphasis should be placed on explaining unfamiliar concepts during the process of "informing." Again, in this study the majority of participants were satisfied with the consent process.

A study by Kodish et al. confirmed the difficulty of effectively conveying the meaning of randomization during the consent process in pediatric leukemia trials [31]. In this multisite study, informed consent conferences were observed and audiotaped and were then compared to information acquired in interviews with parents shortly after the conference. The investigators found that while randomization was explained in 83% of cases, 50% of the parents did not understand it. Further, parents who did not understand randomization were more likely to consent to the randomized study than were those who did understand it, although this difference was not statistically significant ($p = 0.07$). These findings led to several recommendations for improving understanding, including a clear explanation of the differences between the randomized trial and off-study therapy, assessment of parental understanding of randomization, and further explanation when the idea was not yet grasped.

Other efforts have been made to improve the process of informed consent in pediatrics, especially in the case of complex clinical trials of the sort that increasingly incorporate PGx testing. For example, in a study assessing the possibility of staged consent for complex clinical research protocols, investigators had the option of obtaining consent over a 28-day period using a staged approach [32]. This option allowed parents and patients more time to discuss and absorb facts about the disease, the purpose of the trial, the design of the study, and the potential risks. Several measures in this study suggested that benefit accrues from the staged approach. There was greater understanding of treatment choices and of the distinction between a randomized controlled trial and standard therapy with the staged approach (80% understanding) than was found in the other studies (62.5%, $p = 0.05$).

Contemporary medicine that relies ever more on developing technologies such as PGx testing requires the introduction of new methods of informing patients and parents to meet the ethical imperative of informed consent in pediatric trials. Informed consent documents for clinical research trials are sometimes long and difficult to understand, with language that serves less to protect human subjects than to minimize institutional liability [33]. Therefore, some advances may take the form of technological and educational methods to explain ever more complex medicine and research to people not formally trained in a medical discipline, or even to busy medical professionals who cannot reasonably be expected to keep up with the explosion of information that is available. Potentially important are (1) the need for a "big picture" overview that would create a context for details, (2) delivery of information in small chunks, (3) use of multiple modes of information delivery, and (4) prioritization of information. Because of children's apparently natural affinity for interactive electronic devices, this approach may be helpful in addressing assent as well.

Concepts about the nature of consent in pediatrics are evolving with changes in contemporary medicine, including technologies that yield information the significance of which may not be certain. For example, some argue that informed consent may be too restrictive a concept and that "valid consent" should be substituted [34]. The three aspects of valid consent are personal competence (does the patient have the capacity to make the decision?), procedural competence (is the consent given correctly?), and material competence (is the procedure consented to appropriate for valid consent?). The concept of valid consent has been explored in the pediatric context [35]. Its value is that it emphasizes the patients' or parents' understanding of what is being consented to and recognizes that there are both rational and nonrational aspects to the decision-making process that must be understood.

The underlying concern is that informed consent has come to mean legally signed documentation rather than real understanding, insofar as that is possible. Because parents come from different backgrounds and because children of different ages differ in their ability to grasp complex concepts, the level of understanding that is attainable may vary from situation to situation. The notion of valid consent acknowledges this fact and counters the idea that a signed document is equivalent to informed consent.

The four elements of informed consent mentioned previously—disclosure, understanding, voluntariness, and competence—are useful for informed consent in adults, but informed consent in pediatrics is complicated by the fact that three parties are involved (parent, child, and clinician-investigator) and that the research subject is the child. In pediatrics, it is not autonomy (the basis of the four components of consent) that takes precedence but rather the *best interest* of the child [36]. The best-interests notion is clearer in a purely clinical setting than in a research setting, in which interventions are designed to contribute to general knowledge. Despite the difficulty of approximating truly informed consent in the setting of pediatrics, and especially pediatric research, the obligation to advance pediatric medicine lends urgency to continued efforts to offer the closest possible approximation to informed consent, which in pediatrics is a combination of parental permission and (as appropriate) the more complex concept of the assent of the child.

41.3.2 Assent in Pediatric Research

The ethics of assent is one of the most difficult issues faced in pediatric clinical trials, therapeutic interventions, and diagnostic or medical assessments such as PGx. Many adolescents, and even some younger children, possess the elements of competence or healthcare decision-making capacity (setting aside for the moment the legal definitions, which hinge on age rather than capacity). This is especially true, perhaps, of those who are exposed to long-term clinical trials and to the environment of a children's hospital for long periods of time. Certainly, younger children are not developmentally capable of comprehending complex protocols, but they do have some level of understanding that increases with age and experience [37]. How should assent be understood and when should it be required? But first, what do we actually mean by "assent" and how can it be distinguished from consent?

Consent refers to an active affirmative agreement to something by an autonomous agent (i.e., a person). It can be given by anyone who meets the minimal criteria of being in the state of mind and body to be an autonomous agent; generally most adults qualify as long as they have not been placed in a situation in which their decisions might be suspected to be the result of some form of coercion. The ability to give consent is also context and subject dependent in the sense that most people are generally not competent in all spheres of their lives: for instance, many individuals who are perfectly capable of making healthcare decisions or even agreeing to participate in research may not be competent to make (informed) decisions about automobile repair. For the purposes of this discussion, the relevant area in which cognitive capacity is important is in the domain of healthcare (and associated human subjects research).

In the United States, the legal age of consent is 18 years for most realms (nearly all jurisdictions, however, permit older adolescents who have not yet reached their majority to make some kinds of healthcare decisions—i.e., give consent), usually in regard to reproductive medical issues [38]. Assent is a more complex concept, and in general it describes a less active form of agreement to a proposed procedure or action than the more active and involved consent. It is employed in an attempt to engage children and adolescents in the process of consent that must be given by parents or other authorized surrogate decision makers [39,40]. However, what may qualify as acceptable assent (a grudging or sullen nod of the head, or a more energetic and participatory form of positive interaction) remains an area of reasonable concern.

Far less is known about assent than about consent. Much remains to be learned about the practices of institutional review boards (IRBs); the perceptions of parents, clinicians, and children about consent; and the methods that might be most effective in the assent process. Several studies have looked into these issues and documented the need for further work to address variability in IRB practices and the implementation of assent. One found that half of IRBs have a method they require investigators to follow when determining which children are capable of assent, while half have no such method; the majority rely on investigators' judgment [41]. IRBs need guidance on the implementation of requirements regarding assent.

A second study compared standards for assent as well as consent forms approved by 55 local IRBs reviewing three standardized multicenter research protocols [42]. Standards varied widely; 35 had separate forms and simplified language for assent, and 31 specified lower age ranges for obtaining assent in three studies. For a hypertension study, the age at which assent was required was 6–15 years. For a pain study, the age range was 6–12 years. And for a respiratory failure study, the range was 7–12 years. It is not clear why some IRBs consider a child of 6 capable of assent while others do not require assent until a child is 15 years old.

Do federal regulations help us understand assent? Most research on children is governed by subpart D of 45 CFR 46, which provides additional protections for children (as vulnerable subjects) beyond those specified in subpart A of this regulation. Subpart D, added in 1983, outlines three categories of research that a local IRB can approve: research not involving greater than minimal risk to participants (45 CFR 46.404), research involving greater than minimal risk but with the prospect of direct benefit to individual participants (45 CFR 46.405), and research involving no greater than a minor increase over minimal risk (with no prospect of direct benefit) but likely to provide generalizable

BOX 41.1 Principles Governing Children's Participation in Research Decisions

- Investigators should always respect children as persons. In particular, investigators, together with parents, should honor children's developing autonomy in decisions about research.
- Investigators should respect parents' roles in guiding their children's moral development and assessing their best interests. For example, parents should have discretion to determine the degree to which children should be encouraged to participate in activities that benefit others.
- Policies regarding assent, as well as IRBs' decisions with respect to particular protocols, should be sufficiently flexible to accommodate the wide range of medical, psychological, and contextual circumstances seen in pediatric oncology

Source: *From Joffe et al.* [44]

knowledge of the subject's condition or disorder that is vital to understanding or ameliorating it (45 CFR 46.406) (Box 41.1) [43].

Local IRBs cannot approve research that does not fall into one of these categories, and performance of the research is possible only if two conditions are met: (1) the local IRB finds that the research provides a reasonable opportunity to further the understanding, prevention, or alleviation of a serious problem affecting the health and welfare of children; and (2) the protocol is approved by the Secretary of Health and Human Services, after soliciting the opinions of an expert panel and providing for a period of public comment (45 CFR 46.407).

According to these regulations, assent means "a child's voluntary affirmative agreement to participate in research. Mere failure to object should not, absent affirmative agreement, be construed as assent" (45 CFR 46.402). If the IRB determines that the participants in certain categories of age and maturity are capable of providing assent, investigators must obtain it to proceed. When assent is required, a child's refusal is generally binding.

Can an IRB waive the requirement for assent? Yes, but only if (1) the intervention or procedure offers the possibility of direct benefit that is important to the health or well-being of the child, and if this intervention or procedure is available only in the research context (45 CFR 46.408(a)); or (2) the IRB determines that children below a certain age in a certain situation or with a certain condition have such a limited capacity to participate in the decision that they cannot reasonably be consulted.

The requirements are difficult to apply, especially in clinical trials for complex diseases in which there is uncertainty about the significance of aspects such as PGx testing. Cancer therapy is an excellent paradigm for considering issues such as this, in part because most of the children are enrolled in research studies in which the therapy is prolonged and carried out in the context of profound physical, spiritual, and psychological stress, and in part because cancer protocols are some of the most likely places where PGx testing will be used.

The Bioethics Committee of the Children's Oncology Group (COG) convened an international multidisciplinary task force to address assent in 2003. It identified a number of problems with the regulatory framework [44]. In brief, the regulations do not take adequate account of the dynamic moral and cognitive development of children and so allow a child either to have no formal role in decision making or to have the power of veto. Nor do the guidelines make clear what constitutes meaningful assent and so leave IRBs and investigators uncertain about when they have or have not hit the mark (though other groups have provided guidance in this area) [45,46].

Moreover, according to the COG task force, the regulations do not take into account the fact that some types of clinical research are more complex than other types, and so may be more accessible to the understanding of children. The regulations say that permission from the guardians and assent from the child are distinct decisions and they do not take into account the manner in which parents and children make decisions together. Finally, cultures in which autonomy is less emphasized are not accommodated by a regulation that potentially sets parental prerogatives against a child's veto power [47].

Considering these factors, the COG task force offered three principles governing children's participation in research decisions (see Table 41.2), from which a number of specific recommendations followed. The task force acknowledged that in some settings the principles will occasionally conflict. Therefore, the recommendations emphasize the importance of establishing procedures for the resolution of conflict rather than attempting to define universal rules. In that way, the absence of universal rules governing decisions in families with, perhaps, different cultural backgrounds and assumptions does not end conversation and negotiation. This approach is especially valuable in an increasingly pluralistic society and a global culture of information sharing. Much work remains to be done to understand the processes of communication and learning and the interactions that make up the permission-assent process. The flexibility of conflict resolution acknowledges that the obligation to obtain assent may change, depending on the time and situation, even for the same child. Developmentally appropriate ways to help the child understand the experience do not have the restrictions and limitations that accompany the binding aspects of assent.

For older adolescents, assent should be approached in the same way as for adult informed consent, even though

TABLE 41.2 Four Categories of Pediatric Research and Requirements for IRB Approval (45 CFR 46, Subpart D)

Level of Risk	Prospect of Direct Benefit	
	No	Yes
Minimal risk	Approval by IRB permitted(§46,404), conditioned on: • Permission from one parent/guardian • Assent of child, unless waived on capacity grounds	
Greater than minimal risk	Approval by IRB permitted(§46,406), conditioned on: • Minor increase over minimal risk • Research involves experiences that are commensurate with those inherent in children's actual or expected medical, dental, psychological, social or educational circumstances • Intervention or procedure is likely to yield generalizable knowledge about the subjects' disorder or condition that is of vital importance for understanding or ameliorating that condition or disorder • Permission from both parents if reasonably available • Assent of child, unless waived on capacity grounds	Approval by IRB permitted (§46,405), conditioned on: • Risks are justified by anticipated benefit to subjects • Relation of anticipated benefit to risk is at least as favorable as that presented by available alternatives • Permission from one parent/guardian • Assent of child, unless waived on capacity grounds or grounds of prospect of direct benefit that "is available only in the context of the research"
Not otherwise approvable, but presents opportunity to understand, prevent, or alleviate a serious problem affecting the health or welfare of children	Approval requires Department of Health and Human Services approval after consltation with an expert panel and opportunity for public review and comments (§46,407), conditioned on: • Research presents reasonable opportunity to further the understanding, prevention or alleviation of a serious problem affecting the health or welfare of children • Permission from both parents if reasonably available • Assent of child, unless waived on capacity grounds

parental permission may be required [48,49]. Some adolescents may have the capacity for consent but may choose to have their parents make decisions about their participation in research [50]. Several studies recently assessed assent in adolescents [51,52]. Our understanding of the differences between parents' and adolescents' perceptions of research is growing as we learn more about the assessment of risk (i.e., concern for physical safety) versus aversion (psychological discomfort) [53]. More than 3000 adolescents in the United States alone die of chronic illness and cancer each year. In such situations, when adolescents meet the criteria for functional competence, the broad ethical consensus is that decisional authority should be granted to them regardless of their legal decisional status [54]. However, this is an area in which there is wide divergence between what ethics may demand and what the law allows.

Most states and jurisdictions do *not* permit minors to be sole participants in medical decision making, including consenting to participate in research, unless they have been emancipated according to the laws of the state in which they reside. This restriction does not imply that adolescents should not fully participate in the decision-making process, and there certainly is no legal proscription against their doing so; it simply underlines the difference between ethical clinical (and research) practice and the legal framework. It might perhaps be better stated that in these situations, if the adolescent is going to be a research subject, assent is necessary but not sufficient.

41.3.3 Minimal Risk

One important ethical concept that guides discussion of pediatric research with no prospect of direct benefit is "minimal risk." With technologies such as PGx testing, articulating benefit can be complex because there is clear potential for harm if "trial and error" is used to assess best practices (as discussed earlier), and yet the significance of PGx testing in children, at this point, is often hypothetical or inadequately supported by evidence. The Belmont Report defines minimal risk as "the probability and magnitude of physical or psychological harm that is normally encountered in the daily lives, or in the routine medical or psychological examination, of healthy children."

The question that immediately arises is which children's lives should be the basis for deciding what is "normally encountered in daily life." These risks can vary widely, not only from country to country but within subgroups in a single country. Even if the notion of "harms or discomforts that average, healthy, normal children" may encounter" (as clarified by the National Bioethics Advisory Commission) can be roughly agreed on as a standard, the question remains whether it is ever acceptable for a parent to give permission for any risk greater than minimal risk in the absence of direct benefit to the child.

Because of concern that the "minimal risk" standard may exclude some pediatric research that is important and appropriate, the National Commission allowed parental discretion in giving permission for research that exposes children to a "minor increase" over minimal risk, given the fact that parents routinely permit their children to participate in activities, such as contact sports, that present more than a minimal risk, and given the potential benefits of such research to others. Therefore, a "minor increase" over minimal risk is permissible if the proposed research involves only procedures that such children might normally experience because of their medical condition, and if the proposed research has the potential to yield vitally important knowledge for understanding or ameliorating the child's particular condition.

The permissibility of a "minor increase" over minimal risk provides a conceptual way to avoid barriers to important pediatric research. But a difficult question remains: exactly what constitutes a "minor increase"? The term is used in the federal regulations, as previously noted, but it is not defined. Wendler and Emanuel proposed five possible standards for defining "minor" increase consistently among IRBs [55]. Their standards are (1) a fixed percentage above daily risks, (2) the confidence intervals around the risks of daily life, (3) the risks an ill child might encounter in an examination, (4) the "scrupulous parent" standard, in which minor risks are sufficiently similar to the child's experiences in daily life, and (5) the "socially acceptable" risk standard.

Wendler and Emanuel argue that the fifth standard is the most reasonable one. The "socially acceptable" risk standard takes as its starting point the fact that some children encounter greater risks in daily life than do others. Thus, it allows risks that are greater than those faced every day by healthy children, but it limits them to those that are socially acceptable. The socially acceptable risks that are greater than those experienced by the average healthy child may be more closely defined through research. In any case, this standard tethers the concept of "minor increase over minimal risk" to an evaluation that is nonarbitrary, that does not impede important beneficial research, and that does not justify greater risks for ill children simply because their daily lives are filled with more risk (because of their disease and its treatment) [56].

An alternative to the approach taken by Wendler and Emanuel has been suggested by Nelson and Ross. They argue that the "scrupulous parent" standard is ethically justifiable and that such an approach incorporates both minimal risk and a minor increase over minimal risk within a uniform standard that should be applicable to all children [57].

In PGx studies, as in other pediatric research, assent or dissent from a child with developing capacity can be overridden if the child's participation in the research involves a prospect of benefit to him or her such that the child's welfare is significantly jeopardized by failing to participate and the benefit in question cannot be obtained otherwise. The ethical tension arises when there is uncertainty about whether or not a child has the potential to benefit from a PGx trial. The weight of a child's assent or dissent is proportional to the uncertainty regarding benefit or harm. With relatively new technologies such as PGx, the potential clinical risks and benefits, as well as the social and legal ramifications, are still being tested; assessment and clear articulation of these risks and benefits thus become especially challenging.

Reducing harm in children while maximizing benefit is a primary driving force for advocates of PGx research and clinical testing in the pediatric population. The goal of PGx testing is ultimately to optimize therapy and to do so while decreasing unnecessary risk to children. Where it can be done without loss of benefit, risk reduction is a moral imperative, and so the ethical complexities related to PGx testing must be continually addressed as we learn more about its actual value to children.

41.4 FEDERAL REGULATIONS AND NATIONAL HEALTHCARE PRIORITIES RELATED TO PHARMACOGENOMICS

An active question in the healthcare community is whether or not advancing PGx testing into clinical practice should be a national healthcare priority. PGx research in children could lead to the formation of a new orphan disease group for which pharmaceutical companies fail to develop pharmacogenetic treatments for children because developing them for a minority among the population has no economic incentive. As a result, children would not benefit from the PGx developments. The sequencing of the human genome and the identification of links between specific genetic variants and diseases have created excitement over the potential of genomics to direct patient treatment toward more effective or less harmful interventions in all patients. However, many stakeholders disagree on whether our current understanding of genomic information is ready for clinical use. This is especially true in pediatric care because there have been limited studies and because there is worry that related technologies will add costs to the healthcare system without providing commensurate benefits. Others believe that healthcare costs could be reduced by identifying unnecessary or ineffective treatments. The answers to these concerns require careful study.

In order to address the lack of information available for pediatric dosing, the FDA began requesting data on pediatric medications on a voluntary basis in 1994. However, the number of new studies generated was small, and in 1997 Congress passed FDAMA, which included the Pediatric Exclusivity Provision, providing an incentive of an additional six months of patent protection in return for performing pediatric drug trials specified by the FDA. Given the success of the program, the BPCA of 2002 extended the economic incentives provided by pediatric exclusivity and the program was renewed in 2007.

The Pediatric Rule, which became effective in 1999, requires drug manufacturers to provide adequate labeling of their products in pediatric patients if the drug is likely to be used in this population. Although it was challenged in court in October 2002, the rule was codified by the Pediatric Research Equity Act (PREA), enacted in 2003, which also gave the FDA the authority to require pediatric studies of certain drugs. These regulatory changes have increased the number of drugs that undergo testing in children. By the late 2000s, still only 30% of all drugs used in the pediatric population had been studied in children. The lack of pediatric-specific drug indications and limited knowledge about PK/PD in children should facilitate further PGx research because it can be predictive prior to the first dose and offers the opportunity to improve our current strategies for dosing determination in children with a variety of pediatric diseases.

The FDA has provided guidance to aid in the translation of pharmacogenomic research findings into tools that can be applied to clinical care. It identified PGx as one of the areas of research that should be applied during drug development and subsequently launched its Critical Path Initiative in 2004. The following year, the FDA encouraged the voluntary submission of PGx data obtained during the drug development process in a document released to pharmaceutical manufacturers.

In 2008, the Pharmaceutical Research and Manufacturers of America (PhRMA) released its own white paper recommending that drug-metabolizing enzymes and transporter genotyping be incorporated into the drug development process. In September 2010, NICHD awarded a contract to establish a Pediatric Trials Network (PTN). PTN's primary objective is to provide an effective infrastructure for the ethical conduct of pediatric clinical trials for the BPCA drug development program, which include PK, safety, and efficacy studies. To continue its promotion of studies involving PGx, in February 2011 the FDA released a guidance in draft form entitled *Clinical Pharmacogenomics: Premarketing Evaluation in Early Phase Clinical Studies*, which provided recommendations on "when genomic information should be considered to address questions arising during drug development, and in some cases, during regulatory review." In early 2013, the FDA released an updated final guidance document in an attempt to help sponsors better conduct premarket evaluations in early-stage clinical studies and to emphasize that, although PGx approaches are unique to each product, the general principles of study design, data collection, and data analysis are broadly applicable. These recommendations will be necessary to promote PGx research in children.

Along with the FDA, other federal organizations, including the National Institutes of Health (NIH), provide funding for a collaborative research network dedicated to the discovery of genetic associations of drug response (the Pharmacogenomics Research Network, or PGRN). The members of the PGRN conducted research that helped to create the Pharmacogenomics Research Knowledge Base (PharmGKB), which has grown to become a publicly available PGx database.

In 2009, the Clinical Pharmacogenetics Implementation Consortium (CPIC) was formed as an extension of the PGRN and PharmGKB with a mission to assist in facilitating the development of clinical guidelines that can help providers interpret genetic testing results in order to appropriately adjust drug selection and dosing. As a result of this group's push for clinical relevance, the first guidelines were established in 2011, providing dosing recommendations based on TPMT genotype for the thiopurine drugs, which are commonly used in pediatric oncology patients. CPIC guidelines are intended to assist clinicians in understanding how available PGx test results should be used to optimize pharmacotherapy. However, they are not designed to guide clinicians in deciding whether or not to order PGx tests.

The recognition of specific genetic mutations that significantly influence drug response and/or toxicity is fueling an aggressive effort by many companies to develop suitable *in vitro* diagnostic tests. In order to quickly evaluate a child's genotype as a means of guiding optimal pharmacotherapy, diagnostic tests need to be readily available for use in the clinical setting, without the need to employ remote laboratories. There are several FDA-approved pharmacogenetic-designated diagnostic tests, including AmpliChip™, by Roche Diagnostics, and Invader® UGT1A1 Molecular Assay, by Third Wave technologies. PRO-PredictRx TPMT®, by Prometheus Laboratories, is available for screening TPMT alleles associated with increased immunosuppressive toxicity with azathioprine and 6-mercaptopurine.

A pharmacogenetic test for CYP2D6 is xTAG®, by Luminex Corporation. The CYP2D6 enzyme is involved in the metabolism of approximately one-quarter of all prescription medications, including opiates, selective reuptake inhibitors (SSRIs), tricyclic antidepressants (TCAs), neuroleptics, antiarrhythmics, and beta-blockers. There are also four FDA-approved warfarin pharmacogenetic test kits. These particulars are worth mentioning because they underscore one important tension in PGx testing: this is a technology that has potentially concrete applications, but while the data to support value are being generated, most third-party payers are reluctant to reimburse for testing because it is not currently considered a standard of care.

Whatever the potential benefits might be, multiple barriers preclude widespread implementation of PGx testing for personalized medicine as standard clinical practice across all medical fields. One of the major challenges for this industry is correctly identifying which of the estimated 30,000 genes are appropriate markers for influencing the physiologic response to drug therapy. It has been challenging to develop validated biomarkers and genetic assays, although the prospect of affordable exome and whole-genome sequencing will attenuate this barrier in the near future. Diagnostic genetic testing may be very useful for patient management and recurrence risk estimation as well as potential reduction. Twenty percent of the human genome has been protected under US patents in the past 31 years.

There is a global ethical concern related to patent holders not allowing wide availability of diagnostic care and access of information to high-risk patients. However, on June 13, 2013, the Supreme Court made a significant ruling against a molecular diagnostic company, Myriad Genetics, stating that human genes cannot be patented. From an ethical standpoint, the implications of genetic testing are likely to be far more profound with respect to disease assessment and/or prediction. The application of genetic information for the purposes of rational drug selection and dosing should be much less controversial. Will all individuals have equal access to pharmacogenetics and its benefits regardless of their socioeconomic status? Until a societal commitment to benefit sharing is actualized, market forces will continue to drive access to PGx testing. However, medical experts and legal advisors believe that this unanimous decision will have a lasting impact on genetic testing, inclusive of PGx testing, by making varieties more widely available and more affordable to all patients, including children.

41.5 TRANSLATION OF PHARMACOGENOMICS INTO THE CLINICAL SETTING

Most clinicians lack general knowledge of PGx testing and the interpretation of its results for clinical application. This may be one of the most pressing challenges that is preventing broad implementation of personalized medicine. Medical providers are in need of education as well as reliable and accessible information sources on PGx testing and clinical relevance. Medical and pharmacy schools are developing curriculum content in PGx. This will prepare future generations of providers, but there is little infrastructure in place to facilitate the education of clinicians already in practice [58]. In a recent survey of over 10,000 US physicians, 39% indicated that they obtain PGx testing information from FDA drug labeling [59].

More than 120 drugs have incorporated PGx information in their FDA labeling, but only a small number are currently used in pediatrics, such as atomoxetine, carbamazepine, codeine, fluoxetine, phenytoin, rifampin, valproic acid, mercaptopurine, and warfarin. FDA drug labels may contain information on genomic biomarkers such as gene variants, functional deficiencies, expression changes, and chromosomal abnormalities. They also may describe drug exposure and clinical response variability risk for adverse events, genotype-specific dosing, mechanisms of drug action, and polymorphic drug target and disposition genes.

Nevertheless, there is little labeling guidance on clinical application of results. Contradictory results obtained for certain variants have contributed to the lack of guidelines for clinical implementation. In the recent years, however, there have been more consistent results from investigators and an increasing need to establish working groups focusing on evidence-based clinical guidelines. One noteworthy example of PGx testing in pediatrics that illustrates its potential impact in children is the use of TPMT genotype and/or enzyme assay results in children with acute lymphoblastic leukemia (ALL) to predict chemotherapy sensitivity. The activity of TPMT, a key enzyme in the metabolic pathway of thiopurines, affects the safety and efficacy profile of mercaptopurine and thioguanine, two agents used in standard childhood ALL treatment. TPMT genetic polymorphisms can help explain the considerable differences in toxicities such as myelosuppression, which is experienced by children with TPMT variants that result in reduced TPMT expression and activity [60]. PGx testing can then be used in practice to predict and determine appropriate dosing, minimize toxicity, and optimize dosing, a practice which has been shown to impact outcomes for children with ALL [61].

The influence of TPMT activity on drug tolerability has led to changes in labeling for mercaptopurine, which now includes TPMT testing in dosing guidelines [62].

Other examples of PGx in children are Factor V Leiden testing prior to prescription of oral contraceptives for adolescents with a family history of thrombophilia or thrombosis, and occasionally VKORC1 and CYP2C9 testing in children starting warfarin [63]. However, PGx testing is far from universal in children: leukemia protocols usually only recommend TPMT testing for children who experience severe myelosuppression; thrombophilia testing in children is often controversial [64]; and PGx algorithms for warfarin dosing in children have not been validated [65].

Warfarin has also seen changes to its package labeling with regard to PGx testing. It is eliminated by hepatic metabolism to inactive metabolites; CYP2C9 is the primary responsible enzyme. CYP2C9*2 and CYP2C*3 are two allele forms that have been identified as decreasing metabolism. The package labeling indicates that the respective alleles occur in 11% and 7% of the Caucasian population.

A genetic polymorphism of the vitamin K metabolism enzyme (VKOR) has also been studied. Combined, these two polymorphic enzymes may account for 30–50% of warfarin dosing variability. Testing for VKOR and CYP2C9 is available, but there is no consensus on the interpretation and clinical application of the results. In order to enable clinical decisions, PGx guidelines, reference databases, and electronic platforms to integrate personal pharmacogenomic data into the clinical workflow would all be helpful in overcoming education barriers. If the potential for PGx testing is to be realized, and if miscommunication and faulty interpretation are to be avoided, innovative strategies must be found.

41.6 FUTURE IMPLICATIONS OF PHARMACOGENOMICS TESTING IN CHILDREN

Despite emerging data, the clinical implementation of PGx in pediatric patients has been a slow process since the completion of the Human Genome Project a decade ago. In addition to the ethical dilemmas unique to children, this gradual progression has led experts to further evaluate the ethical issues associated with future implications of PGx testing in children.

PGx testing can potentially place children in prognostic categories that have real consequences for their future, even into late adulthood [66]. This ultimately creates long-term privacy concerns and ethical issues related to adult-onset diseases revealed by PGx testing in early childhood, with the following possible consequences: discrimination related to the ability to afford PGx testing [67], race-based rather than individualized testing [68], lack of access to a drug to which an individual is not sensitive or that has a higher risk of complications [69], and the risk of test-based denials of disability, long-term care, and life insurance [70].

In light of these fears, it has been debated whether or not children should participate in testing that may reveal genetic predispositions to adult-onset disease or resistance to therapy if such findings will potentially impact a child's ability to obtain appropriate insurance coverage as they age. The refusal by parents or guardians to gain information that might affect the health of their child because of fear of discrimination based on genomic variability will hinder the advancement of PGx testing and research. Although PGx testing might hold promise for early discovery of disease and adaptation of therapy, the fear of no longer being insurable, at the point of discovery or at a later time in the child's life, might lead some parents and guardians to avoid testing that is potentially beneficial to a child, and ultimately lead to harm. As noted throughout this chapter, one of the most important areas in which PGx testing is relevant (and already actively used) is cancer therapy, and so the issue has received considerable attention from professional cancer organizations.

The American Society of Clinical Oncology (ASCO) has recommended that genetic testing for cancer predisposition be offered when (1) the individual has a personal history, family history, or features suggestive of genetic cancer susceptibility; (2) the test can be adequately interpreted, and (3) the result will aid in a diagnosis or in the medical or surgical management of a patient or family member who has hereditary risk for cancer [71]. ASCO has also recommended that the regulatory oversight of laboratories providing such tests be strengthened and that federal laws be established to prohibit discrimination by healthcare providers, employers, and insurance agencies on the basis of such information. Although some maintain that genetic discrimination will not affect insurance coverage, several surveys have shown that the public fears this possibility [72–74].

One important legislative step that has been taken to address such concerns is the Genetic Information Nondiscrimination Act (GINA) of 2008 (Box 41.2) [75]. This act was passed and went into effect in 2010. The intent of this legislation was to protect patients from discrimination by their insurance company or employer based on genetic testing results or family history. Another important issue is one of privacy and confidentiality and the possibility that genetic information obtained might be used to the detriment of a child sometime in the course of his or her life if legislative protections are weakened. The level of risk associated with such issues remains partially hypothetical, but an additional concern relates to informed consent with the potential for hidden future implications of this cutting-edge and evolving technology as well as for the legislation that will accompany it.

BOX 41.2 Genotypic Approaches to Therapy in Children

- Genetic information, not including information about the sex or age of any individual.
- An individual's genetic tests (including those done as part of a research study)
- Genetic tests of the individual's family members (defined as dependents and up to and including 4th-degree relatives)
- Genetic tests of any fetus of an individual or family member who is pregnant, and genetic tests of any embryo legally held by an individual or family member utilizing assisted reproductive technology
- The manifestation of a disease or disorder in family members (family history)
- Any request for, or receipt of, genetic services or participation in clinical research that includes genetic services (testing, counseling, education) by an individual or family member

Source: *From Ross et al.* [19]

In several ways, diagnostic genetic testing in children parallels PGx testing. Such testing is controversial and generally avoided until adolescence unless there is an immediate medical benefit identified, such as preventive measures to delay the onset of the disease, limit its severity, or prevent secondary morbidities. Also, early childhood diagnostic testing may be performed if there is benefit to another family member but no anticipated harm to the child [76]. However, data are needed before investigators, clinicians, and policy makers can conclude that genetic testing and pharmacogenetic testing in children are the same.

Like genetic testing, PGx testing provides ancillary information pertaining to the classification or prognosis of disease, predisposition to diseases or conditions, or information relevant to other classes of drugs for which the child is currently seeking treatment or manifesting symptoms. Ancillary information may also carry potential implications for family members when related to inherited polymorphisms. For example, returning to the case of therapy for the most common childhood cancer, testing for TPMT genotype prior to or during treatment with mercaptopurine for pediatric leukemia will provide information about the risk of myelosuppression and guide dose adjustments. Test results can provide prognostic information for the child and make available drug response information for a parent who needs to take mercaptopurine or azathioprine. Some PGx testing can have immediate implications for the child and at the same time have a bearing on health events that will occur much later in his or her life. Although less commonly prescribed in children, apolipoprotein E (APOE) genotype testing can guide warfarin dosing or statin selection, but it may also reveal the risk of an untreatable condition that the child may develop late in life, such as Alzheimer's disease [77].

The ethical dimensions of PGx warrant ongoing reassessment of the risks and benefits as more data are obtained [78]. With the exponential increase in health information sharing internationally, any robust development of ethical standards related to PGx will require not only national standards but also standards that cross the boundaries of nations engaged in such research. The World Health Organization's (WHO's) *Review of Ethical Issues in Medical Genetics* states: "All susceptibility testing should be voluntary, preceded by adequate information and based on informed consent…. Testing [of] children or adolescents should be carried out only if there are potential medical benefits to the child or adolescent or if an adolescent requests it for purposes of reproductive decision-making." [79] The American Academy of Pediatrics (AAP) and the American College of Medical Genetics (ACMG) recommend against predictive genetic testing for late-onset disorders unless there are specific interventions during childhood that will reduce morbidity or mortality [80].

The right to know or not know one's own PGx testing results is another controversial issue. Is it ethical for researchers not to reveal information that may benefit the child if consent rules prevent them from sharing incidental findings? Ethical debate continues as to whether investigators have a moral obligation to inform study participants about findings that are actionable and risks that can be mitigated. The ACMG recently recommended that incidental findings obtained in a clinical setting be disclosed to the patient. This statement excluded research studies.

When the consequences of the genetic disorder are treatable, the benefits of testing outweighs the negatives. This philosophy has driven pediatricians to support either earlier genetic testing or PGx testing or both. There is increasing interest in exploring the possibility of rapid whole-genome sequencing (WGS) for diagnosing genetic diseases in addition to newborn screening (NBS)—a mandated state-administered public health program designed to identify children with conditions that require immediate medical action to avoid death or severe disability [81]. NBS began in the 1960s with screening for phenylketonuria.

A federal panel is currently recommending screening for 31 core conditions, allowing states to screen for others as well. The evolution of NBS panels has advanced with advancing technology, and WGS as a new technology has the potential to dramatically expand the number of conditions screened. In this neonatal age group, monogenic disease progression can be frequent and fast, mandating an accelerated turnaround for molecular diagnoses so they can have an impact on clinical care decisions and potential therapies. Although there are over 3500 monogenic heterogeneous diseases that can result in profound morbidity and mortality, making the apparent benefit of testing very high, there are risks associated with PGx testing in infants. The hope of the WGS panel is that PGx results will also identify polymorphisms that may facilitate medication choices and appropriate doses. WGS is poised to eliminate the need for individual genetic tests.

WGS raises ethical issues about the creation of personal genetic databases holding information that individuals may or may not want to know and which may or may not remain privately secured. An enormous range of information can be gleaned from results that are highly accurate and actionable to genetic variations. However, these variations may not currently be associated with any known diseases, but they may create an information overload that will confuse clinicians until more robust studies can be conducted to elucidate such findings. In addition, as genetic testing and PGx testing knowledge advances, the future implications of WGS findings need to be considered. Unlike the NBS programs, there is no infrastructure currently in place to interpret the results of newborn sequencing. However, advocacy groups believe that some untreatable disorders should nonetheless have WGS information readily available so that parents can anticipate what lies ahead for their child. This delicate ethical balance is tipped when the driving force is to alleviate preventable harm in children in the immediate future while ensuring protection of their personal genomic data for future implications.

The storage and management of PGx data are ongoing issues. Most stored genetic data are de-identified. Unfortunately, however, the privacy of individuals cannot be fully secured, and the process of anonymization can be undone because some data is stored publicly online. This adds another complicating layer to the ethical decision that parents and guardians must make for their child, not knowing what PGx testing will reveal and how the information disclosed and the breaching of confidentiality will affect the child's future. The management and disclosure of ancillary clinical information must be evaluated, and recommendations need to be developed to guide PGx testing in children.

41.7 CONCLUSION

PGx testing in children has the potential to provide personalized medicine that will increase drug efficacy, decrease rates of toxicity, and improve overall outcomes in the pediatric population. The ethical challenges of childhood PGx testing and research are dynamic, so it is critical to reassess them as the level of the child's autonomy changes, as new PGx technologies are discovered, and as our knowledge of personalized medicine continues to expand.

42.1 INTRODUCTION

PGx/biomarkers are among the most useful tools in drug development. They have substantially contributed to increased efficiency in drug development [1,2], which has resulted in major advances in personalized medicine as novel targeted drugs are being successfully developed for use in several therapeutic areas, including oncology. Because the application of PGx/biomarkers in drug development can reveal a drug's dose and target population more accurately than other conventional approaches, in the last decade more and more drugs have included PGx/biomarker information in their labels [3,4]. In this chapter, we describe the current regulatory guidelines on PGx/biomarkers and their qualification by regulatory agencies in different ICH regions. We also describe the design of clinical trials utilizing PGx/biomarkers for drug development, and we discuss the future challenges facing these new tools.

42.2 REGULATORY ACTIVITIES AND GUIDELINES RELATING TO PGx/BIOMARKER

One of the important roles of a regulatory agency is to evaluate relationships between the PGx/biomarker profile and the efficacy and/or safety of a drug. Thus, it is crucial to have guidelines detailing the points to consider in establishing evidence through the development of the drug. Since the early 2000s, the regulatory agencies of the European Union (European Medicines Agency; EMA), the United States (U.S. Food and Drug Administration; FDA), and Japan (Pharmaceuticals and Medical Devices Agency; PMDA) have worked to create frameworks for PGx/biomarker studies in drug development and have issued some guidelines (Table 42.1) [5]. In fact, two of them—ICH E15 and ICH E16—are harmonized guidelines prepared

TABLE 42.1 Regulatory Documents Related to PGx/Biomarker Studies in Drug Development

	EU	US	Japan
Terminology	Definitions for Genomic Biomarkers, Pharmacogenomics, Pharmacogenetics, Genomic Data and Sample Coding Categories (ICH E15) [6]		
General guideline on pharmacokinetics	• Guideline on the Investigation of Drug Interactions [8]	• Draft Guidance for Industry: Drug Interaction Studies—Study Design, Data Analysis, Implications for Dosing, and Labeling Recommendations [9]	• Guideline on Clinical Pharmacokinetic Studies of Pharmaceuticals [10] • Guideline on Methods of Drug Interaction Studies [11]
Sample collection and handling	• Reflection Paper on Pharmacogenomic Samples, Testing, and Data Handling [12]	• Guidance for Industry: Clinical Pharmacogenomics: Premarket Evaluation in Early-Phase Clinical Studies and Recommendations for Labeling [13]	• Guideline on General Principles for Clinical Trials Using Pharmacogenomics [14] • General Points to Consider in the Regulatory Submission of a Drug and Companion Diagnostics for Approval [15]
Assay (including companion diagnostics)	• Reflection Paper on Co-Development of Pharmacogenomic Biomarkers and Assays in the Context of Drug Development [16]	• Guidance for Industry and FDA Staff: Pharmacogenetic Tests and Genetic Tests for Heritable Markers [17] • Draft Guidance for Industry and FDA Staff: *In Vitro* Companion Diagnostic Devices [18]	• General Points to Consider in the Regulatory Submission of a Drug and Companion Diagnostics for Approval [15] • Technical Guidance on Development of *In Vitro* Companion Diagnostics and Corresponding Therapeutic Products [72]
Data submission	• Biomarkers Related to Drug or Biotechnology Product Development: Context, Structure, and Format of Qualification Submissions (ICH E16) [7]		
	• Guiding Principles: Processing Joint FDA EMEA Voluntary Genomic Data Submissions (VGDSs) within the Framework of the Confidentiality Arrangement [19]		
		• Guidance for Industry: Pharmacogenomic Data Submissions [20] • Guidance for Industry: Pharmacogenomic Data Submission – Companion Guidance [21]	
Clinical development and labeling (comprehensive documents)	• Reflection Paper on Methodological Issues associated with Pharmacogenomic Biomarkers in Relation to Clinical Development and Patient Selection [22] • Guideline on the Use of Pharmacogenetic Methodologies in the Pharmacokinetic Evaluation of Medicinal Products [23]	• Guidance for Industry: Clinical Pharmacogenomics: Premarket Evaluation in Early-Phase Clinical Studies and Recommendations for Labeling [13] • Draft Guidance for Industry: Clinical Pharmacology Section of Labeling for Human Prescription Drug and Biological Products—Content and Format [24]	
Clinical development in specific fields	• Reflection Paper on Pharmacogenomics in Oncology [25] • Reflection Paper on the Use of Genomics in Cardiovascular Clinical Trials [26]		• Partly described in the guidelines of clinical evaluation in each therapeutic area (e.g., anti-cancer drug [27])
Pharmacovigilance/ postmarketing activities	• Concept Paper on Key Aspects for the Use of Pharmacogenomic Methodologies in the Pharmacovigilance Evaluation of Medicinal Products [28]		• Request to Cooperate in research regarding severe adverse reactions (skin disorder, rhabdomyolysis and interstitial pneumonia) [29]

under the auspices of the International Conference on Harmonization of Technical Requirements for Registration of Pharmaceuticals for Human Use (ICH). ICH E15, reached step 4 of the ICH procedure in 2007, and provides international definitions of PGx terminologies to facilitate the integration of pharmacogenomics and pharmacogenetics into global drug development and the regulatory approval process [6]. On the other hand ICH E16 reached step 4 of the ICH procedure in 2010, and aims to develop context, format, and structure for the regulatory submission of biomarker data to facilitate easy review and exchange of assessments among ICH members [7]. In this section, current key concepts on PGx/biomarker, as defined by each regulatory agency, are introduced based on published guidelines. It should be noted that we include our personal interpretations which may differ from the formal opinion of each agency.

42.2.1 European Union: European Medicines Agency

The EMA recognizes PGx as an important emerging technology that promises to optimize the development and use of medicines [30]. In 2000, a meeting on the use of pharmacogenetics in drug development was held for agency representatives and an informal group of pharmaceutical industry representatives [31]. It concluded with a demand for harmonized terminology and announced a need for pharmacogenetic clinical trial protocols and guidelines. In 2005, the PGx Working Party (PgWP) was formally established to provide the agency with expert support. The PgWP offers recommendations to the Committee for Medicinal Products for Human Use (CHMP) on all matters relating directly or indirectly to PGx.

In 2012, the EMA published a comprehensive final guideline with an aim to clarify requirements related to the use of pharmacogenetics in evaluating pharmacokinetic data [23]. The issues referred to in the guideline are the following: (1) situations and stages where pharmacogenetics-related pharmacokinetic studies should be performed; (2) *recommendations* and *requirements* regarding studies investigating the effects of polymorphisms at the ADME level; (3) evaluation of clinical impact and recommendations for further studies; (4) possible consequences of genetically determined differences in pharmacokinetic parameters for treatment recommendations and labeling; (5) special considerations related to drug–drug interactions (see also the general guideline for this issue [8]); and (6) effects of impaired or immature organ functions.

The guidelines highly recommend prospective DNA banking for genotyping throughout all phases of clinical development, even when there appear to be no obvious genetic influences on pharmacokinetics. This is in case unknown genetic factors are discovered in the later phase, including postmarketing.

According to this guideline, studies on the effects of pharmacogenetics on pharmacokinetics are *required* when the magnitude of the interindividual variation in drug exposure is so high that it may likely influence the safety and/or efficacy of the drug in genetically variable populations. Required situations are clearly discriminated from *recommended* situations using pharmacokinetic thresholds. If human *in vitro* studies suggest that more than 50% of a drug is cleared by a single polymorphic enzyme, the pathway can be considered important because the systemic exposure of the drug will be doubled, which is comparable to stepping up to a next stage in early phase I studies. In such situations, genotyping the participants of the first-in-human study is advised to avoid the safety issues associated with elevated exposure. Throughout phase I exploratory pharmacokinetic studies, expanded pharmacogenetic evaluation is recommended when more than 25% of a drug (comparable to the threshold for drug–drug interactions) is cleared by a polymorphic enzyme. In such situations, genotyping for the indicated genes in as many phase I studies as possible is required. As for active metabolites, genotyping is considered when a metabolite is estimated to contribute to more than 50% of the pharmacodynamic effect and a polymorphic enzyme is responsible for more than 25% of the *in vivo* formation or elimination of the substance.

If a significant difference in drug or metabolite exposure or distribution in a genotypically or phenotypically defined subset was indicated in earlier studies, genotyping, or alternatively phenotyping, of all participants in phase III trials is required. Care should be taken in the case of polymorphic transporters because intracellular or interorgan distribution of the drug may change, even when systemic exposure does not differ between different genotypes. The clinical consequences of the observed differences in drug exposure in genetic subpopulations depend on several factors. Unless and otherwise altered exposure to an active substance is of little consequence, dose adjustment should be considered to achieve an exposure in every genetic subset that is shown to be effective and safe, by genotype/phenotype-based or individual dosing.

In a reflection paper released for public consultation in 2011, genomic biomarkers were classified into three categories: predictive, prognostic, and surrogate [22]. The third category is not discussed in this chapter. Predictive biomarkers should have pretreatment characteristics that help to determine whether a particular subject is a good candidate for the treatment, with a test agent whose clinical utility is facilitated by pivotal trials conducted in defined patient populations. Although they can be indicators of efficacy and/or safety, it would be important to consider that more than one marker might be linked to a disease and might also influence drug response predictability. Prognostic biomarkers may correlate with disease outcome in either untreated or heterogeneously treated patients; therefore, they do not necessarily contribute to the clinical decision for treatment or intervention. The reflection paper suggests that exploratory studies for genomic biomarkers include a set of classifiers that translate biomarkers into a set of markers that predict clinical outcome. The paper also described two major purposes of genomic biomarkers. One is for patient selection, where the biomarkers can be used for: (1) better defining the disease and/or its prognosis; (2) excluding patients with increased risk; and (3) predicting drug response. The other is for determining whether the treatment algorithm can be used in clinical trials or clinical practice. As for using genomic biomarkers for selecting treatment strategies in drug development, the crucial step is to define and detail the analysis plan, including the criteria prospectively used for defining a positive response.

As the complexity of generating signals from a genomic biomarker is expected to be higher than that from other biomarkers, the reflection paper recommends that the following factors be carefully considered: consistency in sample collection; sample processing; assay methodology; and opportunities for misclassification. For genomic DNA variation and mRNA, careful evaluation of reproducibility is encouraged to avoid subject misclassification. In many cases, a considerable sample size is needed for identifying low-frequency signals from genomic biomarkers, which may have been generated in earlier exploratory studies as well as during later stages of drug development, including postmarketing. Sometimes prospective clinical trials, although intended to be carried out, turn out, for a number of reasons, not to be feasible. Therefore, the reflection paper suggests two possible alternatives: extrapolate previous scientific knowledge; and obtain data from retrospective samples or analyses. However, both alternatives have significant limitations. In order for primarily retrospective studies to be credible, certain requirements must be met. Besides confounders, selection bias and measurement bias are important in genomic biomarkers development. The former can be minimized by properly designing the prospective study, but on the other hand, could impact retrospective analyses. The latter might affect retrospective analyses, especially meta-analyses with different instruments or methodologies. In addition, two distinct multiplicity problems can arise during genomic biomarker development: (1) the use of multiple markers to identify the one that has a sufficiently strong association with the outcome; (2) the issue of multiple testing during the clinical trial. The reflection paper points out the importance of characterizing the diagnostic performance of the biomarkers, as well as the factors that would affect their performance. The clinical validity of a marker is said to be a complex interplay of sensitivity and specificity and the penetrance of the genomic abnormality or mutation. For novel or specific genomic biomarkers, it would be necessary to develop specific assays as companion diagnostics (CDx) in parallel with drug development. If a particular assay specific to a genomic biomarker is employed in confirmatory studies, it may be necessary to link it to the marker's value.

The EMA provides current views on regulatory matters regarding pharmacovigilance. A concept paper was published in 2011 to address the scarcity of the PGx/biomarker information on drug effect during postmarketing [28]. It is anticipated that recognition of a genetic variant may permit estimation of the likelihood of adverse drug reactions (ADRs) or the effectiveness of genetic information or tests. It is expected that a draft guideline will be developed soon.

The agency has also published several other specified documents: reflection papers on PGx in cardiovascular clinical trials and oncology; on samples, testing, and data handling; and on co-development of certain biomarkers and their assay platforms [12,16,25,26].

42.2.2 Japan: Pharmaceuticals and Medical Devices Agency

The Pharmaceuticals and Medical Devices Agency (PMDA) has worked together with the Ministry of Health, Labor and Welfare (MHLW) to facilitate drug development utilizing PGx. In 2005, a notification was released to gather voluntary information from industries in order to gauge the development situation at that time [32]. Three years after the notice was circulated, a guideline on "General Principles for Clinical Trials Using pharmacogenomics" was published in 2008 [14]. Since the PGx in drug development would enhance drug safety and/or efficacy, increasing numbers of clinical studies are expected to include PGx analyses. The guideline mainly focuses on points to consider when collecting genomic samples, both pre- and postmarketing, for clinical trials. It describes three situations where genomic sampling is planned: (1) both target genes and time of analyses are predefined; (2) target genes are predefined but the timing of future analysis is not; and (3) neither the target genes nor the timing of analysis are predefined (note that the third situation may include analyses not directly related to a investigational drug). For all three categories, clarification of the purpose of the planned analyses and the available knowledge on the predefined or putative target genes in study protocols is required. Above all, written informed consent from participants and appropriate sample anonymization is necessary for any purpose. In addition, it has been recommended that clarification of the key information from pharmacogenomic analyses (e.g., analytic subset, sample handling including anonymizing method, and disclosure policy) in study protocols or other operational procedures is clearly documented.

Two guidelines, one on "Clinical Pharmacokinetic Studies of Pharmaceuticals" [10] and the other on "Methods of Drug Interaction Study" [11], were published in 2001. The guideline for drug interaction study is currently under revision to include the latest scientific knowledge, including PGx/biomarker, and will be available in the near future. In response to the globalization of drug development, a guideline entitled “Basic Principles on Global Clinical Trials” [33] and an accompanying document entitled “Basic Principles on Global Clinical Trials (Reference Cases)” [34] were published recently. These recommend performing PGx/biomarker analysis, including genetic tests using samples collected in global clinical trials.

In the PMDA, a “pharmacogenomics discussion group” was originally established in 2005 and was reorganized as “PMDA Omics Project (POP)” in 2009 to cover PGx and other omics issues, including proteomics and metabolomics. POP has worked to promote scientific discussion on PGx/biomarker and PGx/biomarker-guided drug development. Since 2009, a new scientific consultation service focusing on PGx/biomarker has been started to encourage discussions between the industry and the PMDA on the use of PGx/biomarker in drug development and regulatory submission. In 2012, the consultation service was reinforced by a new category: planned stage and follow-up consultations (for more details see Section 42.3).

In 2012, the “Companion Diagnostics Project Team” was established in the PMDA to promote co-development of a companion diagnostic with a drug. One achievement of this project is a guideline entitled “General Points to Consider in the Regulatory Submission of a Drug and Companion Diagnostics for Approval” published on December 26, 2013 [15]. Afterwards, more practical guidance for developing companion diagnostics entitled “Technical Guidance on Development of *In Vitro* Companion Diagnostics and Corresponding Therapeutic Products” was published [72].

In terms of PGx/biomarker use in the postmarket stage, a notification entitled “Request to Cooperate in Research Regarding Severe Adverse Reactions” [29] was published by the MHLW. In this research, relationships between the genetic profiles and severe adverse reactions, such as Stevens-Johnson syndrome (SJS), toxic epidermal necrolysis (TEN), rhabdomyolysis, and interstitial pneumonia, have been investigated. In this regard, it should be noted that cooperation between industry, hospital, and research institute is the key to facilitating research by effectively acquiring samples from patients who suffer from ADRs. Outcomes of this research have been published in several scientific journals [35–37].

42.2.3 United States Food and Drug Administration

In 2004, the Food and Drug Administration (FDA) released a white paper addressing the significant decrease in applications submitted on new drugs and biologics [38]. In this paper, the FDA regarded biomarkers as a powerful scientific and technical tool for improving the predictability and efficiency of medical product development. The FDA Genomics Group in the Office of Clinical Pharmacology works to advance the application of genomics for the benefit of patients and society. Genomics is recognized as an integral discipline in the discovery, development, regulation, and use of medications.

In 2005, to facilitate scientific progress in PGx and the use of pharmacogenomic data in drug development, the FDA published a guidance for genomic data submission [20]. This guidance, with the help of some decision trees, describes when to submit pharmacogenomic data during the development and review process, what format and content should be provided, and how and when the data are to be used in regulatory decision making. The guidance also makes a distinction between *valid* biomarkers, which may be appropriate for regulatory decision making, and either *observational* or *exploratory* ones, which alone are insufficient. Furthermore, the guidance proposes an additional distinction between *known* valid biomarkers and *probable* ones, the former “[having] been accepted in the broad scientific community” and the latter “[appearing] to have predictive value for clinical outcomes but may not yet be widely accepted or independently verified by other investigators or institutions.” Data on probable valid biomarkers are not necessarily required to be submitted to the Investigational New Drug (IND), but its submission is recommended for unapproved NDAs or BLAs. At the research stage of establishing the validity of a biomarker, pharmacogenomic data submissions are not required, but the FDA has been encouraging voluntary genomic data submissions (VGDSs) following the establishment of the FDA-EMA joint VGDS process [19]. Currently, this process is recognized for voluntary exploratory data submissions (VXDS). Any data submitted as VXDS will be reviewed for scientific and informational purposes, and will not be used for regulatory decision making. Based on review experience gained from the VGDS process, INDs, NDAs, and BLAs, a companion draft guidance mainly for data collection and handling was released in 2007 [21].

In 2013, the FDA published a guidance document for clinical evaluation entitled “Guidance for Industry: Clinical Pharmacogenomics: Premarket Evaluation in Early-Phase Clinical Studies and Recommendations for Labeling” [13]. This document focuses on when and how to evaluate, in the early stages of drug development, the contributions of pharmacogenomic variations to the individual differences observed in pharmacokinetics, pharmacodynamics, and safety or efficacy. Three key purposes of pharmacogenomic assessment in early-phase clinical trials are proposed in the guidance to identify: (1) populations that should receive modified dosage; (2) responder populations; and (3) high-risk groups. The genomic influences suggested in the early-phase or confirmatory trials may include subject enrichment according to genomic information, dosage based on genomic variability, or a priori primary end point testing in a genomically defined group. The FDA also emphasizes that baseline DNA sampling should be performed on all subjects employed in the clinical trial to eliminate any potential bias associated with incomplete sampling. Also suggested is storing of all samples or appropriate data for at least 15 years in case of later need, as otherwise any known genetic or other predefined potential factor will not be available at that time.

Preclinically identified pharmacogenomic factors should be taken into consideration for the design and analysis of clinical trials. When an exposure is variable among patients but correlated with drug response, the results may be considered for dose selection at a later stage. Use of approaches involving candidate genes is proposed when the factor that influences the pharmacology and pharmacokinetics of the drug is well known. High-throughput platforms can also be utilized, particularly when the pharmacologic property of the drug is not clear; however, in such cases it is important to experimentally confirm the physiological roles of the newly identified factors. To avoid misclassification as a result of not testing, efforts should be made to include rarer alleles of the factor of interest.

The FDA guidance proposes strategies for designing three types of clinical pharmacogenomic studies: PK/PD studies in healthy volunteers; PK/PD studies in patients; and dose–response studies. In general, collection of DNA samples from all healthy volunteers who participate in the single- and multiple-dose PK studies is encouraged, while taking notes on the drugs that convert inactive compounds into active metabolites through polymorphic pathways. In cases where important variability is found in PK/PD studies involving healthy volunteers, its significance should be considered when designing these studies on patients. The findings from such studies can increase the average effect, decrease toxicity, and increase the possibility of overall study success. Genomic factors should be taken into account for dose–response studies if any previous PK and/or PD study suggested genomic influence on systemic exposure–response, or on efficacy and safety responses. Genomic information obtained from such trials can be integrated into later analyses of dose–response or concentration–response models. The guidance also suggests specific considerations while designing studies. For example, to compare PKs in genomic subgroups, studies can be designed like those for evaluating the effects of hepatic or renal impairment. For PD, study designs are less well developed because, while genomic markers are usually explored in early-phase studies, clinical outcomes are evaluated later in drug development. The relationship between a genomic marker and PD suggested in later trials often needs to be prospectively confirmed with respect to genetic subsets.

The FDA guidance describes cases where patients with certain genotypes might be excluded: when the patients would experience toxicity; would not show response to the drug due to low exposure; and lack a drug target. However, it is cautioned that many quantitative markers do not lead to binary response, so early-phase trials should include subjects with a range of target levels in order to explore optimal cut-offs. In early-phase exploratory and observational trials, profiles of pharmacogenomic markers are often examined using nonrandomized designs, involving a small population, that are not adequately powered. Thus, the guideline provides five statistical concepts that are most relevant to clinical PGx: (1) avoid confounding factors; (2) control multiplicity; (3) characterize marker performance quantitatively; (4) address the potential of incorrect population stratification; and (5) assess the reproducibility of the genetic finding. Pooled analyses of trials with similar protocols are proposed, and replication of the findings or experimental studies are recommended. Any retrospectively defined relationship should be replicated to avoid false positive and potential bias. Using a case-control approach to investigate pharmacogenomic markers related to ADRs would lay weight not only on high sample acquisition rates, but also on a clinically meaningful definition of cases and clearly described controls. At the end of the guidance, the FDA states that drug labels should generally include information on PGx only if it is useful to inform prescribers about the impact of genotype on phenotype, or to indicate whether a genomic test is available.

The efforts described above clearly indicate that EU, U.S., and Japanese regulatory agencies work with similar concepts to promote PGx/biomarkers in drug development to achieve personalized medicine in clinical practice. However, their thinking is still different in some respects, such as regarding sample collection, qualification and the requirements for PGx-related PK studies. As a next step, more international cooperation is necessary to harmonize the PGx/biomarker guidelines because drug development has been radically globalized [39–41] and the same PGx/biomarker data may have been submitted to multiple regulatory agencies (see Section 42.5).

42.3 BIOMARKER QUALIFICATION

42.3.1 Significance

To obtain good PGx/biomarker-related scientific evidence in a study, it is very important to use a PGx/biomarker qualified by a regulatory agency for its proper use in the drug development [42]. Use of an unqualified and unacceptable biomarker may result in misinterpretation of the acquired data because of false signals (false-positive or false-negative), and therefore cannot be used in regulatory decision making. "Qualification" means that, within the stated context of use, the results of assessment with a biomarker can be relied upon to adequately reflect or forecast a biological process, response, or event, and to support its use in new drug development, ranging from discovery through post-approval [7]. A qualified biomarker not only has clinical use but also has nonclinical use. To qualify a biomarker, it is important to clearly define its "context of use" according to the ICH E16 guideline [7,42]. A biomarker's context of use with respect

Scope	• Innovative drug development methods and tools, including imaging and drug/diagnostic co-development.	• Any biomarker for clinical or nonclinical context of use, including imaging but not drug/diagnostic co-development.	• Any biomarker for clinical or nonclinical context of use, including imaging but not individual drug/diagnostic development such as drug/diagnostic co-development.
Option	• Qualification advice • Qualification opinion	• Not specified	• Consultations for planning a study • Consultations for qualifying PGx/biomarker data
Fee	• Full scientific advice: €75,500 • Follow-up advice: €37,700 • 90% reduced rate for small and medium enterprises	• Free	For evaluating study data • First consultation: ¥3,114,900 • Follow-up: ¥948,300 For a study plan and strategy • First consultation: ¥1,142,800 • Follow-up: ¥414,600
Output	• Formal regulatory opinion	• Formal regulatory opinion	• Formal qualification opinion
Standard timeline (from application to complete report)	• 190 days	• Not specified	• About 24 weeks

to qualification can be narrow or broad. Depending on the context of use, it might be used for several drugs within one class of drugs, or even for several classes of drugs.

42.3.2 Qualification Process

Prior to being widely used in drug development, a biomarker should be qualified by a regulatory agency in accordance with its intended objective and context of use. To confirm acceptability, each regulatory agency—EMA, FDA, and PMDA—has a biomarker qualification process as summarized in Table 42.2. Major points for qualification according to PMDA are as follows:

- The data submitted for qualifying a biomarker should be prepared according to the format and structure described in the ICH E16 guideline.
- The applicant should clearly define the "context of use of the biomarker" according to the ICH E16 guideline. The term "context of use" is a clear statement that describes the manner of use, interpretation, and purpose of use of a biomarker in drug development. The elements describing context of use should include (1) general area; (2) specific biomarker use; and (3) critical parameters defining when and how the biomarker should be used.
- A meeting is to be held having two main objectives: (1) to discuss the study design and strategy for qualifying a PGx/biomarker; or (2) to evaluate biomarker data for regulatory qualification.
- The applicant is required to answer all inquiries from the PMDA.
- Face-to-face meetings between the PMDA and the applicant will be held as needed.
- The qualification meeting covers PGx/biomarkers that are not directly linked to specific products; such biomarkers should be discussed during the PMDA standard scientific consultation process.
- The PMDA will provide an official consultation report to the applicant.

The concept of and required documents for the qualification meetings held by the EMA and the FDA are similar to those of the PMDA, although there are some differences, such as in fee, timeline, and implementation status (formal/informal). The ICH E16 guideline is expected to facilitate data submission for biomarker qualification on a global basis. An internationally qualified biomarker is one of the most useful tools for global drug development. In particular, PGx/biomarkers used in global clinical trials should be acceptable to multiple regulatory agencies, including those of the country where the trial is conducted; if not, the collected data cannot be used for regulatory purposes [39]. Therefore, an applicant is encouraged to seek parallel advice from EMA, FDA, and PMDA regarding biomarker qualification, although there is no formally established process for qualifying a biomarker across all three agencies at present.

42.3.2.1 Case Example of Qualification

Table 42.3 lists some of the biomarkers that have been qualified by EMA, FDA, and/or PMDA. Seven urinary biomarkers, such as KIM-1, cystatin-C, and beta2-microglobulin, have been qualified by these agencies for nonclinical use to detect nephrotoxicity in rats [43,44]. This means that the seven biomarkers, in the specific context "to detect drug-induced acute urinary tubular changes or acute glomerular changes/injury in rat GLP studies," are now qualified at the same level by all ICH agencies. Thus, they can be used for regulatory submissions during the drug development process. Moreover, EMA and FDA have qualified urinary clusterin for an additional context of use and a new urinary marker, renal papillary antigen-1 (RPA-1), for detecting acute drug-induced renal tubule alterations. The FDA also concluded that serum/plasma cardiac troponins T and I (cTnT and cTnI) can be used as qualified biomarkers for studies assessing potential cardiotoxicity in rats and dogs.

At present, no clinical biomarker is qualified by all three agencies. So far, only EMA has issued an opinion on the use of clinical biomarkers—namely, tau and Aβ42 in cerebrospinal fluid—for Alzheimer's disease [45]. Hippocampal volume (atrophy) and PET amyloid imaging have been qualified for Alzheimer's disease [46,47]. To promote the use of such biomarkers in clinical trials, especially global trials, it is necessary that the biomarker be qualified by not one agency but multiple regulatory agencies for acceptance as internationally qualified.

To increase the number of qualified biomarkers, it is important to have a discussion between industry, academia, and regulatory agency on how to collect necessary data effectively for regulatory submission from an early stage. In general, storage of samples collected during the clinical trials is encouraged for use in retrospective PGx/biomarker analysis at a later stage if necessary. However, caution should be exercised because the sample collection process may vary widely according to the requirements of different countries. [48,49].

42.3.3 Use of PGx/Biomarkers for a Specific Drug Product and Information in the Drug Label

To use PGx/biomarker information in clinical practice, it is important how such information is included in the drug label (known as "prescribing information" in Japan). In this regard, the FDA has published a "Table of Pharmacogenomic Biomarkers in Drug Labels" (see http://www.fda.gov/Drugs/ScienceResearch/ResearchAreas/Pharmacogenetics/ucm083378.htm, last accessed July 18, 2013). According to recent studies [50,51], PGx/biomarker information can include genetic types of metabolizing enzymes and pharmacological targets of drugs, and the like. Examples are given in Table 42.4. The aims of using a biomarker are (1) efficacy (including information about pharmacological mechanism and/or efficacy reduction and/or lack of efficacy); and (2) safety (including information about pharmacokinetics (PK) and/or dose adjustment). The number of approved drugs with important PGx/biomarker information in the label section "Dosage/Administration" or "Indication/Usage" has increased recently [3,4,52]. Anti-cancer drugs are the most prominent ones because a target molecule of a drug (e.g., HER2, EGFR, KRAS, or ALK) is usually also described in the section "Indication/Usage" to specify the drug's target patient [53]. An increase in the number of approved drugs whose labels contain PGx/biomarker information will contribute to promoting PGx/biomarker utilization in clinical practice. Accordingly, the FDA recommends inclusion of PGx/biomarker information in drug labeling [9,24].

The importance of PGx/biomarker information on drug labels, however, can vary depending on where in the label the PGx/biomarker information has been placed (i.e., information as a reference to or information as a requirement for drug administration). Information included in what is considered a higher-level section of the label will lead to the practical use of PGx/biomarkers, but presently such cases are still limited. Thus, examining relationships between biomarkers and clinical responses (efficacy, safety, PK) during clinical trials is encouraged to provide relevant information to healthcare professionals. Furthermore, the label should be updated on a timely basis when any new scientific information on a PGx/biomarker becomes available.

The grading level of PGx/biomarker information may also differ between countries, even when the target biomarker is the same [51]. Reasons for the differences depend on how much of the collected data were from the local population, how ethnic factors influence the collected data, and what types of companion diagnostics are available. As far as the

TABLE 42.3 Examples of Biomarkers Qualified by the Regulatory Agency (EMA/FDA/PMDA)

Biomarker (Applicant)	Context of Use	Agency (Qualified Year)
7 urinary markers: • cystatin C • β2-microglobulin • total protein • clusterin • KIM-1 • TFF3 • albumin (PSTC)	• Nonclinical drug development for the detection of acute drug-induced nephrotoxicity in rats, either tubular or glomerular with associated tubular involvement. • Biomarkers provide additional and complementary information to BUN and serum creatinine to correlate with histopathological alterations.	• EMA (2009) • FDA (2008) • PMDA (2010)
Urinary clusterin (ILSI/HESI)	• May be used to detect acute drug-induced renal tubule alterations, particularly when regeneration is present, in male rats and can be included along with traditional clinical chemistry markers and histopathology in GLP toxicology studies.	• EMA (2010) • FDA (2010)
Urinary RPA-1 (ILSI/HESI)	• May be used to detect acute drug-induced renal tubular alterations, particularly in the collecting duct, in male rats and can be included along with traditional clinical chemistry markers and histopathology in GLP toxicology studies.	• EMA (2010) • FDA (2010)
CSF biomarker: • Aβ 1-42 • T-tau (BMS)	• In patients with MCI a low Aβ 1-42 and a high T-tau can help predict evolution to AD dementia type. • The CSF biomarker signature is useful for the enrichment of clinical trial populations. • To identify MCI patients who most nearly equate to the prodromal stage of AD and who are at risk for AD dementia.	EMA (2011)
Hippocampal volume (C-path CAMD)	• Low hippocampal volume, as measured by MRI and a dichotomized variable (low volume or not), appears to help enriching recruitment into clinical trials aimed at studying drugs potentially slowing the progress/conversion to AD dementia of the included subjects. • Low hippocampal volume might be considered a marker of progression to dementia in subjects with cognitive deficit compatible with predementia stage of AD, for purposes of enriching a clinical trial population.	EMA (2011)
PET amyloid imaging (BMS)	• Amyloid related positive/negative PET signal identifies patients with clinical diagnosis of predementia AD who are at increased risk for an underlying AD neuropathology, for the purpose of enriching a clinical trial population.	EMA (2012)
• CSF Aβ 1-42 • tau and/or PET amyloid imaging (BMS)	• CSF biomarker signature based on a low Aβ 1-42 and a high T-tau: to identify patients with clinical diagnosis of mild to moderate AD who are at increased risk of an underlying AD neuropathology, for purpose of enriching a clinical trial population. • Amyloid-related positive/negative PET signal to identify patients with clinical diagnosis of mild to moderate AD who are at increased risk of underlying AD neuropathology, for the purpose of enriching a clinical trial population.	EMA (2012)
• Circulating cTnT • Circulating cTnI	• Safety assessment studies in rats and dogs for monitoring and management of potential cardiotoxicity.	FDA (2012)

TABLE 42.4 Examples of PGx/Biomarkers Included in Drug Labels

Biomarker	Purpose	Characteristics	Related Drug
Metabolizing Enzyme			
CYP2D6	Safety	Drug exposure variability	Drugs metabolized by this enzyme
CYP2C9	Safety	Drug exposure variability	Drugs metabolized by this enzyme
CYP2C19	Safety	Drug exposure variability	Drugs metabolized by this enzyme
DPD	Safety	Drug exposure variability	Capecitabine, etc.
UGT1A1	Safety	Drug exposure variability	Irinotecan
Pharmacological Targets of Drugs			
HER2	Efficacy	Drug response variability	Lapatinib
EGFR	Efficacy	Drug response variability	Cetuximab
KRAS	Efficacy/Safety	Drug response variability	Panitumumab
ALK	Efficacy	Drug response variability	Crizotinib
VKORC1	Efficacy/Safety	Drug response variability	Warfarin
Others			
*HLA-B*5701*	Safety	Risk for adverse events	Abacavir
*HLA-B*1502*	Safety	Risk for adverse events	Carbamazepine

ethnic factors are concerned, differences in allele frequencies of the target PGx/biomarker among populations may affect results of clinical trials because of different PK drug profiles and/or different drug sensitivities. For example, the prevalence of the poor metabolizer allele for CYP2D6, which is well known for showing polymorphic characteristics, varies among populations [54–56]. Some other PGx/biomarkers listed in Table 42.4, such as UGT1A1, EGFR, and *HLA-B*1502*, have also been reported to show ethnic differences [35,57–59]. Therefore, to promote the proper use of a drug, the clinical impacts of PGx/biomarker information should be examined on the national population of the respective country as much as possible during drug development; otherwise, the information on the label will have very little influence in changing a physician's mind in prescribing the drug in clinical practice.

42.4 CLINICAL TRIAL DESIGN AND DRUG DEVELOPMENT UTILIZING PGx/BIOMARKER

42.4.1 Designs of Clinical Trials with PGx/Biomarkers

A PGx/biomarker can be utilized in a wide range of clinical trials, such as for patient selection (i.e., inclusion or exclusion criteria, trial enrichment or stratification), assessment of molecular mechanisms of a disease, disease state or prognosis, pharmacological action of a drug, mechanism of ADRs, and dose optimization (i.e., quantitative algorithmic determination of likely dose range), and monitoring/optimizing drug efficacy/safety (i.e., indicating or predicting ADRs, detecting their onset or reversibility) [7]. To examine the clinical utility of a PGx/biomarker in drug administration, it is very important to consider how the clinical trial should be designed. Figure 42.1 shows typical designs of clinical trials using PGx/biomarkers. Other designs are also available.

Characteristics and advantages/disadvantages of each design are described in the following subsections.

42.4.1.1 PGx/Biomarker Cohort Design

In this design, subjects are randomized independently of the results of PGx/biomarker screening (Figure 42.1, top (a)). Therefore, this study design is basically used for exploratory purposes, as in the case of identification of a safety biomarker. Any imbalance in allocating the subjects with a targeted PGx/biomarker between arms of a study may cause a bias in evaluating the PGx/biomarker data. This bias may also be caused by a limited number of collected samples (convenient sample), because only a portion of the enrolled subjects may have provided consent for the analysis [60].

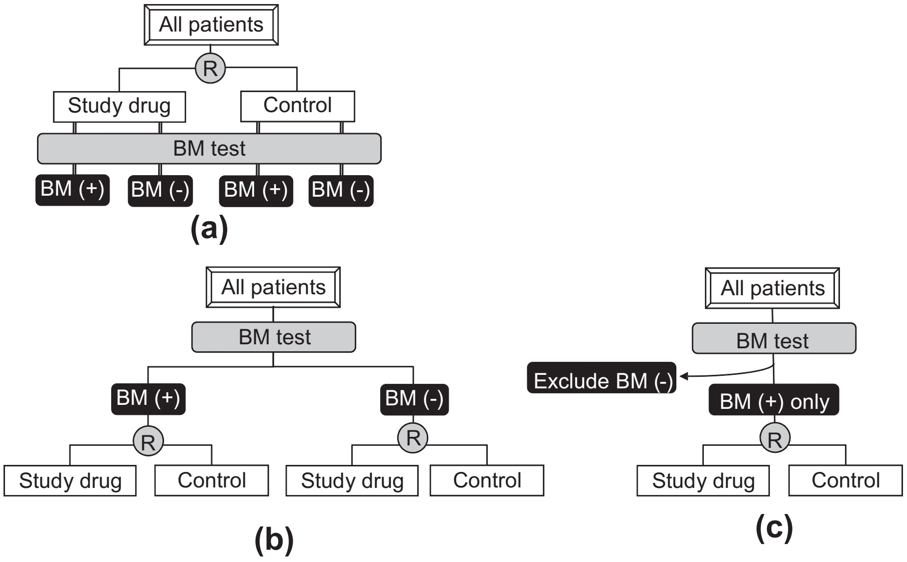

FIGURE 42.1 **Common study designs used in clinical trials utilizing PGx/biomarker.** (Top) Randomization is independent of results of PGx/BM screening. (Bottom) Randomization uses results of PGx/BM screening. R—randomization; BM (+)/(−)—biomarker positive/negative population. (a) PGx/BM cohort design; (b) PGx/BM stratified design; (c) Enriched design.

This design can be used to collect PGx/biomarker samples during a clinical trial for future analysis. It may be possible that some new scientific knowledge and/or new methodology related to PGx/biomarker, will be discovered after the clinical trial has been completed, so, it is recommended that DNA samples collected during a trial be stored properly for a certain number of years, with links to relevant clinical information, such as blood/urine drug concentration data and efficacy/safety data, so that relationships between the PGx/biomarker and drug efficacy/safety can be analyzed at a later date [12,49]. In fact, EMA, FDA, and PMDA have encouraged sample collection during clinical trials [5], and retrospective analysis-based identification of biomarkers has led to revised labeling of some drugs such as anti-cancer drugs (e.g., KRAS, EGFR) [61]. For any retrospective analysis, however, data should generally be available for all subjects (or at least for most) enrolled in a clinical trial to avoid a selection bias. A method of analysis should be predefined before conducting the retrospective analysis. Replicating the results using independent samples may help in data interpretation.

42.4.1.2 *PGx/Biomarker Stratified Design*

In this design, both biomarker test-positive and test-negative subjects are randomized based on the results of PGx/biomarker screening (Figure 42.1 bottom, (b)) [62]. This design seems to be the most rigorous in identifying the optimal target population for a drug; however, it may be difficult to apply when there are a large number of treatment arms. Sample collection for future use is also possible in this design.

42.4.1.3 *Enriched Design*

In this design, the results of PGx/biomarker screening are used for randomization as is shown in Figure 42.1, bottom, (c). The main difference is that patients without the target PGx/biomarker (PGx/biomarker (−)) are included in a stratified design but are excluded from the "enriched design" in the clinical trial. This design is typically used for a molecular-targeted drug like anti-cancer drugs [53]. Here, a prespecified cut-off value of the biomarker is used to select a subject to enroll in the study. Subjects who are likely to respond to the drug are usually selected. In some cases, subjects who have a high risk of ADR can be excluded with the help of the PGx/biomarker's cut-off value. In particular, this design is sometimes adopted when the target PGx/biomarker test negative population is expected to have a higher risk of ADR. The "enriched design," however, cannot validate the target biomarker itself, because it does not ensure that the drug is effective or safe only in PGx/biomarker test-positive subjects and the same efficacy/safety may be obtained even in PGx/biomarker test-negative subjects. Therefore, clinical impacts of excluding the target PGx/biomarker test-negative population from the trial should be considered carefully, because such an approach can deprive patients of an opportunity to receive drug therapy [3]. Sample collection for future use is also possible in this design.

As described, each design has advantages and disadvantages [3,13,63], and these should be thoroughly considered while planning a PGx/biomarker-guided trial. All data and information available at the time of the trial should be systematically collected and carefully evaluated to design appropriate clinical trials. The FDA's guidelines describe some other points to consider in designing a clinical trial with PGx/biomarkers [13,63].

42.4.2 Study Design and Development Strategy for PGx/Biomarker Analysis

42.4.2.1 PK Evaluation with PGx/Biomarkers

PGx/biomarker effects on PK have been actively studied and have been well recognized in the last decade. For example, a significant difference in PK between subjects can be explained by polymorphisms of drug-metabolizing enzymes, such as cytochrome P450 [64,65]. Thus, in general, the effects of genetic polymorphisms of the drug-metabolizing enzyme of the anticipated drug on its PK should be examined at an early stage of drug development. Although the "PGx/biomarker cohort design" can be used to examine the effects of genetic polymorphisms on PK for exploratory purposes, the PGx/biomarker stratified design is recommended when larger interindividual differences due to the drug-metabolizing enzyme's genetic polymorphism are expected.

When data from two or more studies are compared or integrated to investigate the effects of genetic factors on PK, any differences in the study designs, including inclusion/exclusion criteria, sample collection, and PGx/biomarker analysis, as well as PK measurement, should be carefully evaluated to avoid data misinterpretation. For example, it would be difficult to conclude the effects of genetic factors on PK based on data from two or more independent studies, if PK was measured using methods with different assay sensitivity or different standards for sample collection. Clinical trial site and year of a study can also affect results. More attention should be paid especially when data from different countries/regions are used for the analysis, because extrinsic factors and intrinsic factors might be significantly different between these countries/regions, which in turn may have different impacts on study results. This point should also be taken into consideration in other types of clinical trials, which are described next.

42.4.2.2 Exploratory Clinical Trials with PGx/Biomarkers

In the exploratory stage, the use of PGx/biomarkers in clinical trials is strongly encouraged. At this stage, the effects of a PGx/biomarker on drug efficacy are usually investigated because a relatively small number of patients are enrolled in the clinical trial. In addition, sometimes the effects of genetic factors on drug safety can be examined when a strong association is anticipated between a PGx/biomarker and drug safety. Results of earlier studies examining the clinical impact of a PGx/biomarker on drug efficacy/safety are very important in designing a clinical trial using this PGx/biomarker at a later stage. For example, studies on the effects of genetic factors on the dose/exposure–response relationship would provide critical information in deciding on an optimal dose for a target population. For a molecular-targeted drug such as a tyrosine kinase inhibitor in oncology, differences in efficacies between the target gene test-positive and test-negative population should be examined as early as possible during the course of drug development. Although the PGx/biomarker cohort design can be useful in establishing a possible hypothesis regarding an optimal dose or a target population, PGx/biomarker stratified design has potential to formulate more reliable hypotheses [3,13]. The enriched design can also be used in cases where a particular PGx/biomarker is expected to be clearly associated with drug efficacy or safety.

42.4.2.3 Confirmatory Clinical Trials with PGx/Biomarkers

The clinical utility of PGx/biomarkers in drug administration, based on the hypothesis established in an exploratory stage, should finally be examined in a confirmatory clinical trial. This step is crucial to the use of this PGx/biomarker in clinical practice. The PGx/biomarker stratified design can be a standard method for this purpose [62]. The enriched design can also be used if sufficient evidence was collected at the exploratory stage to enroll the target population using the PGx/biomarker, such as in the case of gefitinib administration in patients with non-small-cell lung cancer with mutated EGFR [66]. Data from a retrospective analysis may also be useful to support data interpretation.

42.4.2.4 Postapproval Clinical Trials with PGx/Biomarkers

At the time of drug approval, safety data are usually limited mainly because there were limited numbers of subjects enrolled in the clinical trials carried out before the drug was approved. Generally, an approved drug is administered to a broader population in clinical practice (after approval) than in clinical trials (before approval). Thus, rare but serious ADRs (e.g., severe skin or hepatic reactions) can be discovered and characterized after approval, when more people are taking the drug. Similarly, new PGx/biomarker-related scientific knowledge and/or a new methodology can be discovered after approval. For these reasons, the usefulness of a PGx/biomarker should be examined even in the postapproval stage. At this stage, it may be possible to find, for example, a safety risk-associated PGx/biomarker, as was reported in the case of *HLA-B*1502*, which is associated with carbamazepine-induced SJS [57], and UGT1A1, which is associated with irinotecan-induced neutropenia [67]. At this stage, retrospective analysis of stored samples can be useful in examining possible involvement of PGx/biomarkers in drug efficacy/safety. If a possibility is identified, a prospective analysis should be carried out.

42.5 FUTURE CHALLENGES

Although PGx/biomarker-guided development and administration of drugs have recently increased, there still remain many challenges with the use of PGx/biomarkers in clinical practice [3].

The first challenge is how to promote sample collection and storage for future PGx/biomarker analysis, considering that the current rate of sample collection in clinical trials is relatively low (50–69%) for most therapeutic areas [49]. A recent workshop clearly identified several ways to increase collection, including (1) international guidance on sample collection for future research, (2) additional discussion related to coding, scope, and return of results, (3) additional instruction/education for future research on PGx/biomarkers and long-term specimen storage [68]. Recent discussion on regulatory guidelines may clear the way for international harmonization [5].

The second challenge is how to increase the number of internationally qualified PGx/biomarkers. Currently, the number qualified by a single regulatory agency is limited, and the number qualified by multiple international regulatory agencies is almost none (Table 42.3). Biomarkers for nephrotoxicity in rats are probably the first ones to be qualified by all ICH regulatory agencies (EMA, FDA, and PMDA) [43]. In the era of global drug development, international qualification is absolutely necessary; it can be facilitated by submitting PGx/biomarker-related data simultaneously to the regulatory agencies of multiple countries. This may be the key to reinforcing regulatory cooperation between these international regulatory agencies with sufficient resources for establishing a novel qualification process among them.

The third challenge is about how ethnic factors influence PGx/biomarker data. There are indeed some examples where ethnic factors affect proper data evaluation. For example, the *HLA-B*1502* allele is important for predicting carbamazepine-induced SJS and TEN in Han Chinese, but not in Japanese patients [35,57,69]. Similarly, *UGT1A1*6* is clinically important when administering irinotecan as it is known to induce severe neutropenia in Japanese but not in Caucasian patients [58,70]. It is important to carefully evaluate whether the role of a biomarker in one population can be extrapolated to others with respect to ethnic factors. Examining the effects of a PGx/biomarker on drug efficacy/safety through global clinical trials is probably the best possible method of accumulating scientific evidence and evaluating how ethnic factors might influence the outcome.

The fourth challenge is how to promote co-development of companion diagnostics (CDx). Drugs that require the use of a particular diagnostic device (i.e., CDx) for ensuring balance between presumed benefits and risks have become relatively common. Although several CDxs, each specifying a target population in terms of efficacy, have been approved in oncology, such as CDxs for CCR4 and ALK [3], their numbers are still limited. To promote PGx/biomarker-guided drug administration in clinical practice, a CDx should be approved simultaneously with the drug. This concept is clearly described in the EMA, FDA, and PDMA regulatory guidelines [15,16,18]. However, synchronized development of a CDx and a drug remains a major roadblock. An early-stage close collaboration between the pharmaceutical and CDx development teams/companies may be the answer, as reported for the anti-cancer drug vemurafenib (BRAF kinase inhibitor) [71]. In the near future, establishing international CDx guidelines will be necessary to appropriately promote the co-development process at the global level.

The fifth challenge is how to provide a drug to patients who are off-target for a PGx/biomarker. The enrichment approach may be an effective way to clearly identify a drug's target population and to increase clinical trial success rates. However, a patient selection process without sufficient supporting data may lead to an inappropriate drug development strategy, in which PGx/biomarker test-negative patients would miss a chance to be treated with the drug [3]. Therefore, all available data should be carefully evaluated and the appropriateness of the strategy for enrichment should be presented to the regulatory agency for review.

In conclusion, all of the challenges just described must be overcome if PGx/biomarkers are to be properly utilized in clinical practice. As shown in Figure 42.2, they are interrelated. To better accumulate PGx/biomarker data, samples should be efficiently collected during clinical trials, as successful qualification of a biomarker depends on how much information is available. A CDx should be developed as early as possible for a qualified context of drug administration, and this context should be included in the drug label. If target patients are identified, steps should be taken to provide a drug to off-target patients. Finally, it is vital to that the challenges encountered from the early stages of drug development be discussed with a regulatory agency for the process to succeed.

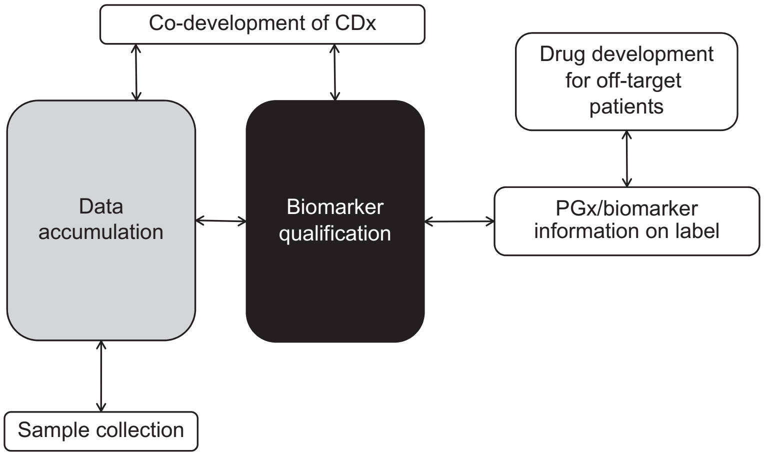

FIGURE 42.2 **Relationships among challenges for PGx/biomarker utilization in clinical practice.** Arrows indicate how each factor facilitates other factors. Every item can be not only a goal but also a means.

DISCLAIMER

GLOSSARY

Biomarker a measurable characteristic that is an indicator of normal biologic processes, pathogenic processes, and/or response to therapeutic or other interventions

Companion diagnostics an *in vitro* diagnostic device that provides information essential for the safe and effective use of a corresponding therapeutic product

Label a description of a drug product, including what it is used for, who should take it, side effects, instructions for use, and safety information

Pharmacogenetics (PGt) the study of variations in DNA sequence as related to drug response

Pharmacogenomics (PGx) the study of variations in DNA and RNA characteristics as related to drug response

Qualification a conclusion that, within the stated context of use, the results of assessment with a biomarker can be relied on to adequately reflect or forecast a biological process, response, or event, and to support use of the biomarker during new drug development, ranging from discovery through postapproval

ACRONYMS AND ABBREVIATIONS

AD	Alzheimer's disease
ADME	absorption, distribution, metabolism, and excretion
ADRs	adverse drug reactions
ALK	anaplastic lymphoma kinase
Aβ	amyloid beta
BLA	Biologics License Application
BMS	Bristol-Myers Squibb
CCR4	CC chemokine receptor 4
CDx	companion diagnostics
CHMP	Committee for Medicinal Products for Human Use
C-path CAMD	Critical path coalition against major diseases
CSF	cerebrospinal fluid
cTnI	cardiac troponins I
cTnT	cardiac troponins T
CYP	cytochrome P450
DNA	deoxyribonucleic acid
DPD	dihydropyrimidine dehydrogenase
EGFR	epidermal growth factor receptor
EMA	European Medicines Agency
FDA	Food and Drug Administration
GLP	good laboratory practice
HER2	human epidermal growth factor receptor type2
HLA	human leukocyte antigen
ICH	International Conference on Harmonization of Technical Requirements for Registration of Pharmaceuticals for Human Use
ILSI/HESI	International Life Sciences Institute/Health and Environmental Sciences Institute
IND	investigational new drug
KIM-1	kidney injury molecule-1
KRAS	Kirsten rat sarcoma 2 viral oncogene homolog
MCI	mild cognitive impairment
MHLW	Ministry of Health, Labor and Welfare
MRI	magnetic resonance image
mRNA	messenger ribonucleic acid
NDA	new drug application
PD	pharmacodynamics
PET	positron emission tomography
PgWP	Pharmacogenomics Working Party
PGx	pharmacogenomics
PK	pharmacokinetics
PMDA	Pharmaceuticals and Medical Devices Agency
POP	PMDA Omics Project
PSTC	Predictive Safety Testing Consortium
RPA-1	Renal papillary antigen-1
SJS	Stevens-Johnson syndrome
TEN	toxic epidermal necrolysis
TFF3	Trefoil factor 3

T-tau	total tau
UGT	uridine diphosphate-glucuronosyltransferase
VKORC	vitamin K epoxide reductase complex subunit 1
VXDS	voluntary exploratory data submission

43.1 OVERVIEW

This chapter provides insight into the great diversity of African populations and the implications for pharmacogenomics and stratified medicine, both for people living in Africa and for the African diaspora. Such diversity manifests itself through genetic, ethnolinguistic, and cultural differences as well as differences that arise from environmental and sociopolitical factors such as exposure to pathogens, disease burden, diet, climate, poverty, urban versus rural lifestyles, and so on.

Overwhelming archaeological and other evidence supports the thesis that Homo sapiens developed in Central-Eastern Africa about 200,000 years ago and that various migrations occurred from Africa to Europe, Asia, and the Americas 40,000–100,000 years ago [1–3]. As humans adapted to various diets, diseases, and climates, inherited traits emerged giving rise to distinct population groups with physical and physiological differences, including response to xenobiotic challenge. The greatest diversity has remained in Africa, with emigrated populations showing less diversity in proportion to the distance of migration [4,5].

Within Africa itself, various migrations took place resulting in the expansion of Bantu speakers from West-Central Africa (now Nigeria and Cameroon)—first, toward the equatorial rainforests and then into eastern and southern Africa; additionally there was migration both westward and eastward from the area that is now Sudan and migration northward of Cushitic speakers from the Ethiopian highlands to the Red Sea coast of Sudan as well as southward into Kenya and Tanzania [20] (Figure 43.1).

Early studies on the development of human diversity in Africa and elsewhere relied primarily on archaeological and linguistic evidence. With the advent of DNA sequencing, data on ethnic differences in single genes (e.g., for the lactase gene) allowed the construction of evolutionary trees

based on families of genes. The rapidity of whole-genome sequencing has allowed genomic comparison of different ethnic groups and characterization of the genetic diversity between populations. To complement this growing body of knowledge from the biological sciences, research findings of historians, linguists, economists, geographers, sociologists, and anthropologists are required to improve our understanding of human diversity and its true impact on health and, more specifically, on pharmacogenomics and stratified medicine.

43.1.1 Population Diversity and Epigenetics

The question arises as to why one might consider broad population diversity (as opposed to genetic diversity only) in relation to pharmacogenomics and stratified medicine. As human diversity is manifested in language, cultures, habitats, and so forth, and as epigenetic modifications can result from lived experiences and environmental exposure, a multidisciplinary perspective—historical, social, cultural, linguistic, political, and economic—must be assumed.

The long-standing "nature versus nurture" debate has been challenged by the recent emergence and postulated significance of "epigenetics" [6]. The effects of lived experiences (e.g., stress, famine) in one generation upon subsequent generations have been studied in great detail by behavioral and social scientists in the context of how "nurture" affects human health and behavior. It is only in the last 10 years or so that biological scientists have been able to demonstrate that such life experiences can result in inheritable epigenetic modifications of genomic DNA, thereby providing, at least in part, an explanation for the transmission of traits associated with "nurture" [7–9].

Environmental exposures have been shown to cause epigenetic change. For example, Nieminen and colleagues [10] found distinct genetic and epigenetic signatures of colorectal cancers according to ethnic origin (i.e., Egyptian and Finnish) and concluded that the possible effects of environmental exposures in carcinogenesis occur through DNA methylation. This observation should have applications in prevention, molecular diagnosis, prognosis, and treatment. The mycotoxin fumonisin B1, found in the food chain in certain countries, displays epigenetic properties, as it has been shown to induce DNA hypermethylation [11]. On this, Lock states:

> Epigeneticists now add their considerable weight to this claim that biology must be understood as situated to the same extent as are sociohistorical forces. They have thrown down the gauntlet to genetic reductionists but, for the moment, "nurture" continues to be a poor cousin—not surprising perhaps, given the challenge of demonstrating robust evidence for molecular nature/nurture links that move us beyond mere gene–environment interactions [6].

It is therefore in this context that we structure this chapter on Africa so as to demonstrate population diversity in the widest sense, in addition to including the important area of genetic diversity. The status of pharmacogenomics in Africa is summarized; this is followed by a discussion of future challenges and priorities for research.

43.2 POPULATION DIVERSITY IN AFRICA

This section attempts to provide a broad overview of the population diversity of Africa, excluding genetic diversity. In the discussion of populations, it is important to define some terms that might have different meanings when used in different contexts. In this chapter, we address race and ethnicity as being related to biological and sociological factors, respectively. Race refers to a person's physical appearance, such as skin, eye and hair color, bone/jaw structure, and so on. Thus, the major races are Caucasian, African, and Asian. Ethnicity, on the other hand, relates to sociocultural factors such as nationality, culture, ancestry, language, and beliefs. As examples, Caucasian ethnic groups can be Irish or German; Asians ethnic groups can be Chinese or Japanese; and African ethnic groups can be Bantu, Nilotics, and so forth. The depth of ethnic classification can go further into subpopulations within a country (e.g., the Chinese can be considered an ethnic group within which are subethnicities such as Han, Zhuang, and Hui). In Africa, the use of country names to denote ethnicities faces a great challenge in that the country boundaries denote political constructs of the colonial era rather than shared characteristics typical of ethnic groups.

Race and ethnicity are both associated with genealogical links in that races claim it from geographical isolation; ethnicities, from presumed shared ancestry. With population isolation barriers gone and intermarriages common, population admixture is challenging the traditional concepts of race and ethnicity. There are, however, still identifiable frameworks of race and ethnicity that are useful in understanding human population diversity, as discussed in this chapter. Race and ethnicity, however, have also been used in political and economic conflicts so that they can evoke strong reactions in people even when used in academic endeavors such as this one. We therefore replace both with the general term *population*; that is, for the African, Asian, and Caucasian races, we refer to African, Asian, and Caucasian populations. At the ethnicity level, we also refer to populations, such as Han, Hausa, and Ibo.

43.2.1 Historical Approaches

In the context of diversity, it is important to include a note on historical approaches to the study of disease and methods for its treatment and prevention. Africa has been subject to a wide range of historical events that have had an impact on disease burden both in times past and present, some of which have resulted in genetic changes both in the host and in the parasite. In his paper on historical epidemiology and infectious disease processes in Africa, Webb states:

> *The biomedical understandings of disease processes in Africa are frequently naïve, because they lack political, social, cultural, and economic historical contexts. Africanist historians can develop these historical contexts in ways that will be relevant to the practice of public health in Africa … The importance of this work in historical epidemiology extends beyond the academy. It can raise new issues to be incorporated into disease interventions. It can inform contemporary public health planners about the consequences of past interventions* [12].

This statement surely also apply to pharmacogenomics and stratified medicine.

43.2.2 Africa's Rich Cultural and Natural History

The rich cultural and natural history of Africa is presented in a UNESCO publication [13] that highlights evidence of the remains of past civilizations and their mastery of difficult terrains, as well as of the diversity of natural habitats, wildlife, and resources from desert to tropical forest to savannah. This huge variation in natural geographic regions implies that lifestyles, diet, disease burden, and so on, varies widely across the continent depending on the region inhabited. Such environmental differences are proposed to contribute to the development of ethnic diversity [14].

43.2.2.1 Linguistic Diversity

Africa has more than 2000 different native languages, with some sources claiming nearer to 3000 [15]. The languages are grouped into several major families with a continental distribution, as shown in Figure 43.1:

- Afroasiatic (Hamito-Semitic) is spoken throughout the Middle East, North Africa, the Horn of Africa, and parts of the Sahel.
- Nilo-Saharan is spoken in Sudan and Chad.
- Niger-Congo (Niger-Kordofanian) is spoken in West, Central, and Southeast Africa.
- Khoe (Khoisan) is spoken in the deserts of Namibia and Botswana.

- Austronesian is spoken in Madagascar.
- Indo-European is spoken on the southern tip of the continent and Mauritius.

The high linguistic diversity of many African countries is best illustrated by Nigeria, which has more than 500 languages [15], and one of the greatest concentrations of linguistic diversity in the world. The Niger-Congo language family, to which Nigeria belongs, has more than 1400 languages, making it the biggest language group in the world. Some of the languages in Africa with the greatest number of speakers belong to the Niger-Congo group: these include many Bantu languages (of which the best known are Ganda, Gikuya, Kongo, Lingala, Luba-Kasai, Luyia, Mbundu (Luanda), Northern Sotho, Southern Sotho, Nyanja, Rundi, Rwanda, Shona, Sindebele, Sukuma, Swahili, Tsonga, Tswana, Umbundu, Xhosa, and Zulu; Sango, of the Central Africa Republic; Akan, the largest language group in Ghana; Yoruba and Igbo, the major languages of Nigeria; Wolof, the most common language of Senegal; Fulfulde, spoken in much of West and Central Africa; and Manding, varieties of which are found in several West African countries under various names, including Bambara, the national language of Mali; and Dyula, a widespread trade language [15].

43.2.2.2 Measuring Population Diversity

One measure for determining population diversity within a particular country or region is "ethnicity." Various measures of ethnicity have been developed since the early 1960s, with the original measure based primarily on language groups. This is the atlas *Narodov Mira*, which was developed by a Soviet team of ethnographers and primarily based on language groups. The definition of ethnicity used in developing existing measurement tools is complicated and has varied among researchers. Political scientists, social scientists, and economists have used these measures to investigate the effects of ethnic diversity on political conflict, economic growth, and social outcomes.

Fearon [16] articulated the challenges of defining ethnicity, using different approaches and a variety of sources to develop his grouping system. According to Fearon, the attribution of ethnicity is ideally carried out by a country's inhabitants. Posner [17] provides a comparative description of seven different measures, including Fearon's, and developed a system of defining ethnicity for political science research based on politically relevant ethnic groupings. A number of researchers have developed multiple measures for ethnic diversity based on different criteria for membership grouping [18,19]. Clearly, it is important for a researcher to choose a measure of ethnicity that aligns with the particular hypothesis being tested [17]. Tables 43.1 and 43.2 demonstrate the ethnic diversity of Africa based on Fearon's 2003 data [16].

Fearon's method of grouping was used in his measurement of indices for ethnic and cultural diversity. The most commonly used measure of aggregate ethnic diversity is ethnic fractionalization, defined as the probability that two individuals selected at random from a country will be from different ethnic groups. If the groups in one country speak

TABLE 43.1 Descriptive Statistics on Ethnic Groups Larger than 1% of Country Population by Region[a]

Region	Countries (n)	Ethnic Groups (n)	Ethnic Groups (% of World)	CF[b]	EF[b]

Source: Modified from Fearon [16].

structurally unrelated languages, their cultural fractionalization (CF) index will be the same as their ethnic fractionalization (EF). The more similar the languages spoken by the different ethnic groups, the more the related cultural measure will be reduced below the value of EF for that country [16].

Using a global database, Fearon found 822 ethnic groups worldwide, 315 of them originating in Africa. Not only does Africa demonstrate more diversity than other regions of the world, but the extent of its diversity varies dramatically from country to country (see Table 43.2). An important point to note in considering diversity per country is that most African country boundaries are political constructs and many ethnic groups overlap national borders.

The ethnolinguistic data clearly demonstrate that greater ethnic diversity exists in Africa compared to the rest of the world and is consistent with the greater diversity of African populations as demonstrated in genetic studies [20,21]. These data have relevance for past and future studies of pharmacogenetics and pharmacogenomics, as there is a requirement to define and align ethnicity with genetic data.

43.2.2.3 *Diversity in Demographic, Social, Economic, and Health-Related Indicators*

Africa as a continent displays considerable diversity in many different indicators; this is evident from statistical data available from the World Health Organisation (WHO), the UN Department of Economic and Social Affairs (UNESA), the World Bank, the African Development Bank, and other sources. It is apparent that for the African continent "no one size fits all." This will be of importance to the stratified medicine of the future. In any research project or health intervention in an African country, the social, economic, and cultural determinants of health each must be considered. We have chosen to illustrate African diversity using the socioeconomic and health indicators in the following subsections.

Urban versus Rural

Data from the UNESA show the urban percentage of populations from all regions of the world for 2011 with estimates for 2030 [22]. As a region, Africa exhibits the greatest diversity, with an urban percentage of the populations ranging from less than 20% to greater than 80%. This clearly has implications for diet, environmental pollutant exposure, life style, and access to education and health services.

Environmental Health

Several measures are classified among environmental heath indicators (e.g., alcohol and tobacco consumption, access to sanitation and clean water, indoor and outdoor pollution). These indicators show great differences between Africa and other regions as well as differences between African countries. For example, WHO data [23] show that African countries have a marked variation in the percentage of their populations with access to clean water (30–99%) and that the continent differs markedly from most of the rest of the world in this respect. From a health perspective, lack of access to clean water increases the population risk of waterborne diseases.

Life Expectancy and Age Distribution

Life expectancy has an impact on the proportions of different age groups in a population. Africa shows the greatest diversity in this regard, with life expectancy in some countries at 47–55 years of age and others greater than 70 years. Other regions in the world are more uniform in terms of life expectancy, which averages around 70–80 [22,23]. In planning for stratified medicine in the future, different regions of the world will have to take into account the age proportions in their populations. Burden of disease and ensuing healthcare needs vary considerably depending on the profile of the different age groups. In the future, while most of the world will have to cater to a large extent to the health needs of those over 60 years of age, African countries will likely be more diverse in this regard [24].

Burden of Disease

Researchers, governments, and the pharmaceutical industry must take note of the burden of disease and how it changes over time when planning future research or health policy interventions. For future pharmacogenomics studies and for progress toward stratified medicine, decisions have to be made with respect to prioritizing diseases and standardizing treatment regimens. In this context, it is useful to note the most recently available comprehensive health-related statistics compiled by WHO by region and by country [25,26]. Examples of the WHO data are shown in Tables 43.3–43.5.

What is interesting about the WHO data in Table 43.3 is that Africa has the highest mortality rates (30–70 age group) for cardiovascular disease and diabetes, and that the mortality rates for communicable and noncommunicable diseases (NCDs) are more or less equal. Cancer, cardiovascular disease, and diabetes have been considered diseases of the developed world, but figures show that attention to them is also required in Africa. The implications of these diseases are that the drugs for treatment of NCDs in Africans should not be neglected. Mortality figures suggest successful

TABLE 43.3 Age-Standardized Mortality Rates by Cause for 2008

Region	Noncommunicable Disease	Communicable Disease	Cancer[a]	Cardiovascular Disease/Diabetes[a]	Chronic Respiratory Conditions[a]

treatment for these diseases in developed countries and little to no treatment in many parts of Africa. However, a degree of underreporting in many countries is likely.

Table 43.5 shows recent mortality data for HIV/AIDS, malaria, and tuberculosis (TB) for the major regions of the world. These diseases remain major problems in many African countries. In 2011, more than 20 million cases of malaria were reported in the African region. [26] Data for HIV/AIDS, malaria, cardiovascular disease, diabetes, and other causes of death indicate a wide diversity in prevalence and mortality between African countries. For example, 2011 data for HIV prevalence vary from <1% in Algeria to >25% in Swaziland. Death in 2010 due to malaria also shows great variation across African countries, with some reporting less than 1 death per 100,000 population and others reporting more than 150 per 100,000.

43.2.3 Population Diversity and Stratified Medicine

Population-based differences in disease susceptibilities and drug response were already observed before the era of genetics/genomics. The practice of stratified medicine therefore precedes pharmacogenetics/genomics. There has

been use of drugs based on patient race/ethnicity, but it is surrounded by serious controversy. With respect to people of African origin, the first example of this practice was in the United States when BiDil, a medication for congestive heart failure, was licensed specifically for use in American patients who self-identified as black [28]. Early studies had shown that African American patients with congestive heart failure generally responded less effectively to traditional treatments than did white patients with similar conditions [29]. Some populations have been associated with higher susceptibilities to some diseases; for example, Caucasians have a higher risk for coronary artery disease compared to African Americans and West Africans [30], while the opposite is true for hypertension [31].

43.3 POPULATION GENETICS, DIVERSITY, ANCESTRY, AND ADMIXTURE

Given the definition of population as encompassing race and ethnicity, specialist scientists have come up with further definitions; geneticists define it as a local group of people sharing a common gene pool and anthropologists define it as a group of people sharing a common language. In-depth discussion of these definitions is beyond the scope of this chapter; however, many studies observe an interesting overlap in the differently defined populations, which is not surprising given their shared geographical ancestry and genealogical relationships. The relevance of an understanding of Africa's population genetics and its diversity and admixtures lies in the potential use of such knowledge in addressing healthcare issues on the continent.

43.3.1 Genetic Variation and Diversity in African Populations

Genetic diversity, the level of biodiversity, refers to the total number of genetic characteristics in the genetic makeup of a species. It is distinguished from genetic variability, which describes the tendency of genetic characteristics to vary both within and among populations. Genetic diversity serves as a way for populations to adapt to changing environments. With more variation, it is more likely that some individuals will possess variant alleles that are suited for the environment. Those individuals are more likely to survive to produce offspring who bear that allele.

The determination of genetic diversity is based on several hypotheses and theories. These include the *neutral theory of evolution*, which proposes that diversity is the result of the accumulation of neutral substitutions; and the *diversifying selection theory*, which proposes that two subpopulations of a species that live in different environments select for different alleles at a particular locus. This may occur, for instance, if a species has a large range relative to the mobility of individuals within it. The *frequency-dependent selection theory* proposes that as alleles become more common, they become more vulnerable. This occurs in host–pathogen interactions, where a high frequency of a defensive allele in the host means that it is more likely that a pathogen will spread if it is able to overcome that allele [20].

The nature and importance of *human genetic variation*, on the other hand, address the differences between individuals and populations due to allelic variations. The allelic variations between individuals are a result of the exchange of genetic material during meiosis and various mutational events. Alleles occur at different frequencies in different human populations, with populations that are more geographically and ancestrally remote tending to differ more.

Genetic variation between populations is driven by the *natural selection* and *neutrality* of most mutations. Natural selection may confer an adaptive advantage to individuals in a specific environment if an allele provides a competitive advantage. Alleles under selection are likely to occur only in those geographic regions where they confer an advantage. The neutrality of most mutations encompasses the fact that they do not appear to have any selective effect on the organism one way or the other. In this case, the main cause of population differences is *genetic drift*, which is the effect of random changes in the gene pool. In humans, founder effect and past small population size (increasing the likelihood of genetic drift) may have an important influence on neutral differences between populations.

Based on these premises about population genetics, numerous studies have been conducted in populations from around the world, including those in Africa. Our overview of these starts by looking at the results of some of the latest major genetic studies done with African populations and makes reference to older studies that made similar findings. Emerging detailed data from genome-wide genotyping and whole-genome sequencing studies are highlighted.

The most comprehensive study of African populations so far, with respect to both the number of African and non-African populations studied and the genetic markers investigated, is that of Tishkoff et al. [5]. In this landmark work, the investigators conducted genetic analysis on 121 African populations, 4 African American populations, and 60 non-African populations for patterns of variation in 1327 nuclear microsatellite and insertion/deletion (ID) markers; this was the greatest number of markers used before the application of whole-genome microChip genotyping tools for the study of population structure and diversity.

43.3.2 High Genetic Diversity in African Populations

Genetic diversity was estimated by two methods [5], one based on the variance of microsatellite allele length (i.e., the microsatellite mutation rate) and the other based on heterozygosity (i.e., the proportion of individuals

heterozygous at the loci studied). Using both measures, diversity was found to be high in African populations and higher than that found in European/Middle Eastern, Indian, East Asian, Oceanian, and Native American populations [5]. Genetic diversity also tended to decrease in proportion to the distance of a population from Africa, supporting what is known as the out-of-Africa model of human migration, in which serial founder effects are associated with reduced heterozygosity.

Further analysis of genetic diversity with respect to microsatellite variance and heterozygosity showed significant correlation with linguistic, geographical, and subsistence classifications. The hunter-gatherer populations (e.g., Pygmies, Bakola Pygmies, and San) were observed to have the highest genetic diversity. Phylogenetic trees constructed from genetic distances between populations also showed clustering by major geographic regions, both on a global scale and within Africa. These correlations support models of human population structure based on language classifications, archeological findings, geographical ocation, and livelihood. The genetic studies, however, applied both molecular and quantitative measures to these population structures.

43.3.2.1 Genetic Structure of African Populations

The population structure in Tishkoff's study [5] was explored using principal component analysis (PCA) and a Bayesian model-based approach with STRUCTURE software. Using STRUCTURE, the study inferred 14 population clusters (K1–K14). The African samples clustered primarily by geographical region and to a lesser extent by linguistic affiliation (Table 43.6).

The PCA of global populations revealed 72 significant components (PC1–72). These results tally with those obtained using STRUCTURE in that the first component, PC1 (accounting for 19.5% of the extracted variation) distinguished African and non-African populations. The admixture populations—African Americans and South African Cape Coloreds—clustered between the African and non-African population along PC1. Other PCs differentiated populations as indicated in Table 43.7. The PCA data can be easily visualized using the PCA plots in Figure 43.2(a,b).

The work by Tishkoff and colleagues [5] used 1327 nuclear microsatellite and ID markers to infer population structure and clustering. In 2008, we established a Biobank and Pharmacogenetics Database for African populations encompassing 10 ethnic groups from Kenya, Nigeria, Tanzania, and Zimbabwe [33]. Using the Illumina beadchips (www.illumina.com) and the genotype information of 364,648 SNPs, Maimbo and coworkers [34] characterized 467 unrelated individuals from these groups (Kenya: Maasai, Luo, Kikuyu, and a mixed population; Nigeria: Yoruba, Ibo, and Hausa; Tanzania: mixed populations; and Zimbabwe: Shona and San). Data on other African and non-African populations were taken from the HapMap project (www.hapmap.org/).

With PCA, we can discern genetic differentiation among all identified populations (Figure 43.3). The African populations were clearly distinguishable from Indian, Mexican, and Asian (Japanese and Chinese) populations and from those with European ancestry. In addition, African populations showed clustering patterns similar to those for the Yoruba (YRI), Luhya (LWK), and Maasai (MKK) in the HapMap project, compared with the other populations (Figure 43.3).

Population structure between the African ethnic groups was examined using FRAPPE analysis, which uses a maximum likelihood method to infer the genetic ancestry of each individual. A total of 98,196 SNPs were assessed by FRAPPE. The results were consistent with the those obtained by PCA (Figure 43.3(b)). At K = 2 up to K = 7, the data showed the same number of clusters as were observed in PCA, coinciding with the ancestral populations non-Bantu (Nigerian Yoruba, Ibo, and Nigerian Yoruba from HapMap); Bantu (Zimbabwean Shona and Tanzanian mixed

populations), Afro-Asiatic (Nigerian Hausa), Khoisan (Zimbabwean San), and Nilotes (Kenyan Luo, Luhya, Maasai Kikuyu, and HapMap Maasai).

The Luhya, who have been reported as belonging to the Bantu (www.ethnologue.com/), were clearly clustered with the Nilotes, supporting the PCA data presented in this study (see Figure 43.3). Analysis at K = 5 revealed additional substructures in the Kenyan ethnic groups with Nilotic ancestral origin, dividing the group into three main clusters that are also similar to those observed in PCA. Bantu and non-Bantu populations were clearly differentiated up to K = 11, which result is similar to those reported by Bryc et al. [35].

F-statistics (F_{ST}) provides a measure of genetic structure. We have used average F_{ST} as a measure of genetic diversity to evaluate differences between populations calculated over all the autosomes (Table 43.8). The genetic diversities between and among African populations are generally larger than those observed between and among the Asian, Mexican,

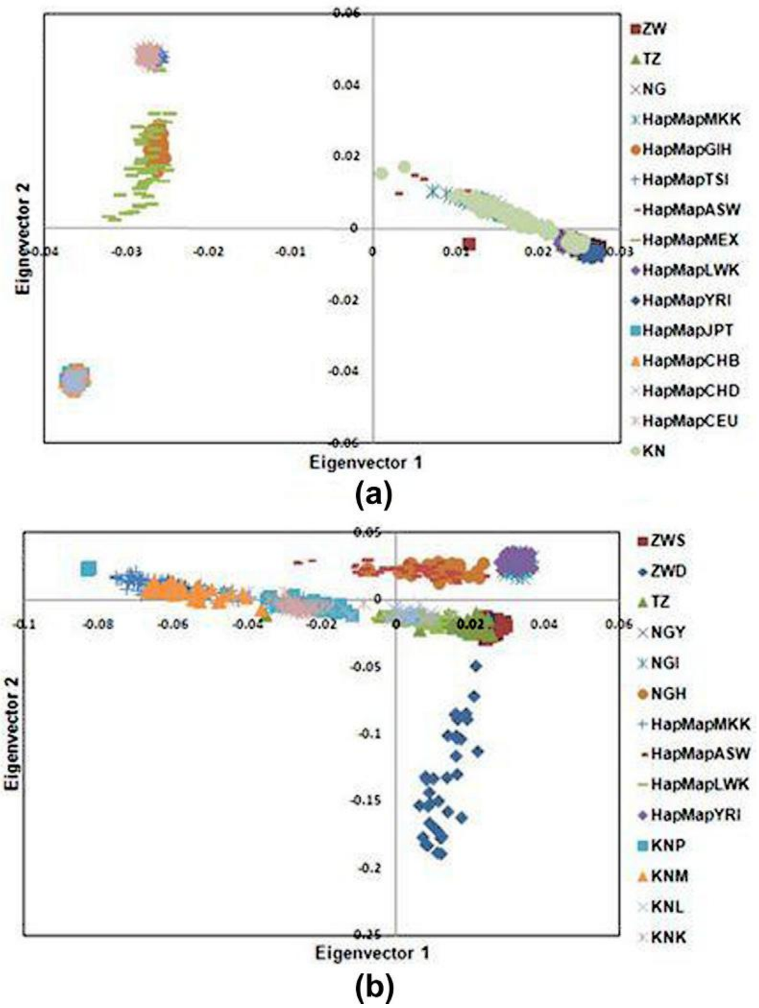

FIGURE 43.3 **PCA of world populations.** (a) Assemblage of African Biobank populations (Zimbabwe, Tanzania, Nigeria, Kenya) in relation to populations in the HapMap European (HapMap TIS, HapMap CEU), Mexican (HapMap MEX), Indian (HapMap GIH), Asians—Chinese (HapMap CHB, HapMap CHD) and Japanese (HapMap JPT), Kenya Luhya (HapMap LWK), Kenya Maasai (HapMap MKK), and Nigeria Yoruba (HapMap YRI) based on the two most informative principle components. (b) Using the two eigenvectors, assemblage of African HapMap populations: HapMap YRI, HapMap MKK, and HapMap LWK; African Biobank ethnic groups: Zimbabwe San (ZWD), Zimbabwe Shona (ZWS), Kenya Kikuyu (KNK), Luo (KNL), Maasai (KNM); Kenya mixed groups (KNP), Nigeria Ibo (NGI), Yoruba (NGY), Hausa (NGH); and mixed ethnic groups from Tanzania (TZ). *Source: Maimbo et al., unpublished data* [34].

Indian, and European populations. A low F_{ST} of 0.0393 was observed between the mixed Kenyans and individuals of West European ancestry, thus confirming the large genetic distance between these populations. Again average F_{ST} for individuals of African ancestry in the Southwest United States (ASW) from the HapMap data were as expected, showing that they are more similar to other African populations than to European and Asian populations. These data indicate that results from F_{ST} and PCA analysis are in agreement and agree with the geographical background of the populations under consideration (Figure 43.3(a) and Table 43.8).

43.3.2.2 *The Out-of-Africa Population Origin Model*

Most of the genetic data described so far point to human origin in Africa. Ancestral Africans maintained a large and subdivided population and experienced complex patterns of population expansion, contraction, migration, and admixture during their evolutionary history. The bottleneck associated with the founding of non-African populations (50–100 KYA) resulted in lower levels of genetic diversity, an increase in linkage disequilibrium (LD), and more similar LD patterns. Figure 43.4 schematically indicates the proposed out-of-Africa model, according to

which, anatomically modern humans evolved in Africa around 200 KYA, migrated to Euroasia within the last 40–80 KYA, and then migrated to the Americas within the last 15–30 KYA.

43.3.2.3 African Populations' Admixture Within and Outside of Africa

The history of Africa has been characterized by both ancient and recent events that have resulted in population admixtures. Some of these are visually easy to discern, as in populations resulting from the mixture of African and non-African populations; some are not visible, however, and require genetic analysis to uncover. African Americans and South African Cape Mixed Coloreds represent established admixture populations, whereas recent global population movements are giving birth to more complex admixture patterns.

The slave trade of the eighteenth century (1711–1800) is estimated to have resulted in the shipment of more than 40,000 people from the West African coast (Senegal to Cameroon) [36]. In the study carried out by Tishkoff and colleagues [5], African Americans from Chicago, Baltimore, Pittsburgh, and North Carolina were found to have substantial ancestry from the African Niger-Kordofanian and from Europeans. European and African ancestry varies considerably in African Americans, as later shown in detail by Bryc and coworkers, [35] who analyzed African Americans for genomic admixture by PCA using the Affymetrics GeneChip 500 K, and showed European ancestry to be on average 18.5% but with very large interindividual variation. The X-chromosome showed elevated levels of African ancestry, consistent with a sex-biased pattern of gene flow, with an excess of European male and African female ancestry. Levels of African and European genetic admixture have also been observed in genes coding for drug-metabolizing enzymes.

The Cape Mixed Ancestry population of South Africa showed the highest level of intercontinental admixture of any global population, with nearly equal high levels of Southern African Khoisan (SAK), Niger-Kordofanian, Indian, and European ancestry. This level of admixture has been shown to have important implications in the variability of genes responsible for drug disposition.

43.3.2.4 Dietary Factors in Population Diversity and Evolution

Natural selection and random genetic drift are two factors that may affect allele frequency in a population. Both may lead to the elimination or the preferential selection of a particular allele. Evolution of the *LCT* gene in world populations, and especially in Africans, has been well documented [37]. This gene is the determinant of the trait commonly called lactase persistence/nonpersistence, depending on whether lactase activity continues from childhood into adulthood.

Populations in various parts of Africa began domesticating animals as a source of food and for ploughing more than 7500–9000 years ago in southern Egypt [38,39]. The foundation of the selection based on *LCT* variation is that individuals raised in areas where dairying is commonly practiced maintain lactase activity into adulthood while individuals in areas where there is less dairying become lactase nonpersistent as adults. Tishkoff and colleagues [37] looked at the convergent adaptation of human lactase persistence in Africa and Europe and found that the frequency of lactase persistence was lowest in the Khoisan-speaking Sandawe hunter-gatherer population from Tanzania (26%).

In our genome-wide genotyping study [34], among the most highly differentiated SNPs, rs12472293, rs1050115, and rs961360 were found in the surrounding area (within 250 kb) of an LD block containing *LCT* and the *minichromosome maintenance gene 6* (*MCM6*). We observed that the Kenya Kikuyu (KNK) and the Nigeria Hausa (NGH) maintain minor allele frequencies (MAFs) for all three SNPs in the *LCT* gene at ~30%. On the other hand, the MAFs in the San population were observed to be less than 20%.

Genetic variation has also been shown to occur in genes coding for proteins important in disease susceptibility. Such variation has been associated with selection of certain genotypes that confer resistance to some infections. In Africa, important susceptibility and/or resistance genes have been documented for HIV/AIDS, tuberculosis, and malaria.

The next section focuses on pharmacogenomics, which is the study of genetic variation in genes that influence drug disposition and efficacy, and its implications for stratified medicine.

43.4 PHARMACOGENOMICS IN AFRICA

Pharmacogenomics refers to the study of total genetic variation in an individual that affects drug response. Although sometimes pharmacogenomics is used interchangeably with pharmacogenetics, the latter refers to studies on a specific gene or a few genes that are known to be rate-limiting in the metabolism of a particular chemical or drug. Many studies to date have been of a pharmacogenetic nature, focusing on genes involved in the pharmacokinetics (absorption, distribution, metabolism, and excretion) and the pharmacodynamics (mechanisms of action) of drugs [40,41]. Post-human genome sequencing has seen an exponential increase in high-throughput genomic technologies that have enabled mass identification of pharmacogenes at a faster pace and less expensively. These technologies have included RNA expression arrays, genome-wide association studies (GWAS) and targeted whole-exome or whole-genome sequencing.

Such advances have enabled evaluation of genes showing significant changes in expression as well as identification of single-nucleotide polymorphism (SNP) profiles for patients with different drug response patterns. The myriad ongoing studies of variation in the human genome have seen the curation of gene variations associated with drug response into The Pharmacogenomics Knowledge Base (PharmGKB, www.pharmgkb.org). This database was developed by the US PharmacoGenetics Research Network (PGRN) to aid researchers in investigating how genetic variation affects drug response [42]. However, pharmacogenomic determinants of drug response differ between as well as within populations. Africa remains understudied with respect to genomic variation. This section evaluates the pharmacogenomics studies that have been carried out among African populations.

Before the sequencing of the human genome was completed (pre-2000), pharmacogenomic studies in African populations were largely focused on candidate SNPs or candidate gene analysis, replicating earlier reports on either Caucasian or Asian populations. There was lack of appreciation of the inherent qualitative and quantitative differences in genetic variants between different populations to the extent that African populations were treated as homogenous, with data observed in one ethnic group often extrapolated to represent all African groups.

Most current drug discovery and development are carried out on a genetic backbone of either Caucasian or Asian populations, when a new drug is prescribed for African populations, it may possibly be the first time it is exposed to some of Africa's unique genetic variations. This may result in unexpected ADRs. For example, abacavir, a nucleoside reverse transcriptase inhibitor (NRTI) used in the treatment of HIV-1, results in hypersensitivity in nearly 8% of patients carrying the *HLA-B*5701* allele. This variant is rare in African populations, however, and relatively high in Indian populations (up to 20%), which shows that genetic testing for this HLA variant across all world populations may not be useful [43].

In these early stages of the post–genome sequencing era, publications on pharmacogenomics with an African connection have mostly reported on candidate genes or targeted gene domain sequencing, including both nuclear and mitochondrial genomes [44–53].

43.4.1 Pharmacogenetic Diversity in African Populations

The genetic diversity of African populations has been well demonstrated, as described in Section 43.3, through the use of various genetic markers, including genome-wide genotyping, microarrays for more than 500 K SNPs, microsatellite markers, and mitochondrial DNA. We turn now to the pharmacogenetic diversity that exists between Africa and the rest of the world, as well as the diversity that exists between African populations themselves.

Studies of genes encoding drug-metabolizing enzymes (DMEs), such as the cytochrome P450 (CYP450) and glutathione S-transferase superfamilies, have identified variations that affect the use and efficacy of therapeutic drugs. CYP enzymes are responsible for the phase 1 hepatic and intestinal metabolism of a wide spectrum of endogenous and xenobiotic compounds. The most clinically relevant CYP enzymes are CYP1A2, CYP2B6, CYP2C8, CYP2C9, CYP2C19, CYP2D6, CYP3A4, and CYP3A5, and they are thought to metabolize more than 90% of all therapeutic drugs [54–56]. CYPs metabolize a broad spectrum of substrates; thus, functional variation in their genes is associated with individual and population differences that have pharmacogenomics relevance, especially with respect to adverse drug events (ADEs).

Early studies of drug-handling variation in African and other populations were of a phenotyping nature, especially for CYP2D6, CYP2C19, and NAT2 activities. CYP2D6 was the most studied enzyme, using phenotyping probe drugs (e.g., debrisoquine, dextromethorphan, metoprolol, codeine, and sparteine), while CYP2C19 and NAT2 were phenotyped using mephenytoin and caffeine, respectively. Metabolic ratios—parent drug conc/metabolite(s)—were used, and cut-off points were designated (antimodes obtained from probit analysis of population metabolic ratio data) for classifying individuals broadly into poor and extensive metabolizers (PM and EM) or fast and slow acetylators.

Later studies characterized the genetic basis for the phenotypes and launched numerous studies in different populations linking phenotype with genotype. PMs are usually homozygous or heterozygous for null alleles, whereas EMs comprise a wide spectrum of individuals including normal allele homozygotes, heterozygotes with at least one functional allele regardless of level of activity, and homo- or heterozygotes of reduced functional activity. Recently, therapeutic (dose) recommendations were published [57] for gene-drug combinations comprising 53 drugs and 11 genes. For example, for doxepin, it is recommended that CYP2D6 PMs receive 60% reduced dosage, while ultrarapid metabolisers (UM) should receive a 100% dose escalation.

Table 43.9 and Figure 43.5 provide a comprehensive analysis of a selected number of SNPs in genes coding for drug-metabolizing enzymes in many African and non-African populations. PCA analysis results clearly show the clustering of the major world populations—Asians, Caucasians, and Africans—in the first two PCs (PC1 and PC2; Figure 43.5). This is consistent with the population clustering found by Maimbo et al. [34] using markers, shown in Figures 43.2 and 43.3.

An excellent review on the phenotype and genotype of CYP polymorphisms in African populations has been written by Alessandrini and coworkers [58]. In it the authors demonstrate the genetic diversity of CYP450 alleles among the various African populations that can have clinical implications. This further supports previous work by Matimba and colleagues [33] who conducted extensive population-genotyping studies with African populations.

The variability in genes important for drug response has significant implications for the safe and efficacious use of drugs, and it necessitates the inclusion of this genetic information in the discovery and development of new chemical entities for treatment of disease. Such knowledge can also inform and guide the design of clinical studies that may produce population- and regional-specific product labeling.

Although the burden of infectious and parasitic diseases is great in African populations (e.g., HIV/AIDS, TB, and malaria), early studies in pharmacogenetics among Africans focused mostly on genes whose enzymes are involved in the metabolism of drugs used in noncommunicable diseases. For example, studies have been carried out on CYP2D6 and NAT2, the relevance of which is mostly for antidepressants, antipsychotics, and anticancer drugs, respectively. Despite the weakness in early pharmacogenetics studies in African populations, a substantial amount of information has begun to accumulate on the genetic diversity of Africans, especially with respect to genes of pharmacogenetic importance. Further fine genetic differences between ethnic groups are being revealed as more populations are studied [59,60].

There is much more pharmacogenetic data on CYP2D6 with respect to Africans and other populations than any other pharmacogene because of its involvement in the metabolism of commonly used drugs, most of which have narrow therapeutic indices (e.g., antidepressants and antipsychotics). In populations of European descent, phenotyping and genotyping established the main CYP2D6 genetic variants that can explain the CYP2D6 phenotype; these include *CYP2D6*2*, **3*, **4*, and **5*. These variants constitute genotypes that result in good correlations with phenotypes and are naturally replicated in other populations, including African populations.

Pioneering work in African populations on the pharmacogenetics of CYP2D6 and CYP2C19 was carried out among Zimbabweans [61–65], Ghanaians [44,66], Tanzanians [67,68], Ethiopians [69], Zambians [70,71], and South African Mixed Coloreds and Xhosa populations [72–74]. New variants were discovered and characterized (e.g., *CYP2D6*17* [63]) and their functional effects on drug metabolism were subsequently characterized [75,76]. In the study of CYP2D6*17 function in Tanzanians, who were genotyped and phenotyped for CYP2D6, it was observed that all carriers of the *CYP2D6*5/*17* genotype are EMs with codeine yet are all PMs with respect to debrisoquine and dextromethorphan [75]. From this and other studies, it became obvious that classification of people into EM, UM, and PM with respect to CYP2D6 in African populations is probe drug–dependent. In addition, frequencies of each variant in different populations were shown to differ; for example, among Ethiopians, *CYP2D6 *2N* is the most common allele instead of *CYP2D6*6*, as in Caucasians [69].

43.4.1.1 *Variation in Pharmacogenetically Relevant Genes in African Populations*

In the following subsections, we discuss some very important pharmacogenes (VIPs)—*CYP3A5*, *CYP2C9*, *VKORC1*, *CYP2B6*, *NAT-2*, and *CYP2D6*—and their function in the metabolism of drugs relevant in Africa.

CYP3A5

CYP3A5 variability in protein expression is largely attributed to four alleles: *CYP3A5*1*, *CYP3A5*3*, *CYP3A5*6*, and *CYP3A5*7*, of which only *CYP3A5*1* is associated with CYP3A5 expression; the other three are nonexpressors. The *CYP3A5*3* allele varies in frequency between different populations, from as low as 4% in Africans to as high as 94% in Caucasians [56]. The frequency of the *CYP3A5*3/*3* homozygous genotype, which is associated with null CYP3A5 activity, differs among African populations, from as low as 0 to as high as 53%, while there are differences between ethnic groups in the same country—for example, among Cameroonian ethnic groups, the homozygous *CYP3A5*3/*3* genotype varies from 0 to 17% [56].

There are also qualitative differences when African populations are compared to other world populations. The *CYP3A5*6* and *CYP3A5*7* alleles are observed almost exclusively in individuals with recent African ancestry. The significance of the distribution of the various *CYP3A5* allelic variants seems to point to environmental influence. For example, Thompson and colleagues [77] reported that elevated *CYP3A5*3* frequencies tended to be positively correlated with increased geographic distance from the equator.

Bains and coworkers [56] reviewed evidence suggesting a strong positive correlation between latitude and functionally important variants of genes implicated in salt-sensitive hypertension. *CYP3A5* is involved in the metabolism of renal cortisol to 6-β-hydroxycortisol, which is a key regulator of renal sodium transport, and immune responses that cause inflammation; thus, *CYP3A5*1* provides a selective advantage in equatorial populations because of the role of CYP3A5 in salt retention and the reabsorption of water. On the other hand, it is detrimental to carry the *CYP3A5*3* allele in the same region. This is supported by the generally low frequencies of homozygous *CYP3A5*3/*3* in African populations around the equator—Ghana (up to 0.04), Senegal (up to 0.09), Malawi (up to 0.05), Nigeria (up to 0.02)—when compared to populations far from the equator—Ethiopia (up to 0.53) and most European populations (from 0.84 up to 0.90).

The frequency of *CYP3A5*3* in world populations is shown in Figure 43.6, which was taken from Bains and coworkers [56]. The geographical distribution of CYP3A5 variants shown has pharmacogenomic relevance for African populations because CYP3A5 is involved in the metabolism of drugs used to treat the three most common infectious diseases: malaria (artemether, lumefantrine, mefloquine, primaquine, chloroquine), HIV/AIDS (efavirenz, saquinavir, maraviroc, indinavir, nelfinavir, ritonavir, lopinavir), and tuberculosis (rifampicin). In a study among Ugandans [78], coadministration of artemether/lumefantrine with efavirenz was associated with reduced artemether levels.

CYP2B6 and Efavirenz Pharmacogenetics

The availability of ARV drugs has transformed HIV/AIDS from a "death sentence" to a chronic disorder. However, this chronic nature implies that HIV/AIDS patients are required to take medications for the rest of their lives. Most, if not all, of the available ARV drugs were developed in clinical trials that did not include African populations, and some have been shown to be unsuitable and lead to ADRs in a proportion of African patients [79]. Certain of these ADRs are serious and have led to patient noncompliance. ARV noncompliance is associated with development of virus resistance and the need to move patients to very expensive second-line ARV regimens. Most ARV drugs are substrates of at least one of the following CYPs: 1A1, 1A2, 1B1, 2A6, 2B6 2C8, 2C9, 2C19, 2D6, 2E1, 3A4, and 3A5; thus, they are subject to interpatient variability in plasma levels due to polymorphisms in genes coding for these enzymes. The combined antiretroviral drug therapy is commonly referred to as highly active antiretroviral therapy (HAART).

Efavirenz (EFV) forms the backbone of first- and second-line HAART regimens. EFV is primarily metabolized by CYP2B6 and to a minor extent by CYP1A2, CYP2A6, and CYP3A5 [80]. EFV metabolism by CYP2B6 leads to 8-hydroxy-EFV (8-OH-EFV), which accounts for 92% of the metabolic pathway, while some minor metabolites are produced through other pathways. There is high interindividual variability in plasma EFV levels after drug administration at the usual dosage regimen of 600 mg/day. Above-normal levels of EFV are associated with adverse effects such as neuropsychiatric manifestations. The SNP 516G>T is associated with diminished activity of the CYP2B6 isoenzyme, increased plasma EFV concentrations, and increased incidence of EFV-associated neuropsychological toxicity.

The preferable mid-dosing plasma level of EFV is 1–4 μg/ml to allow for optimized antiretroviral potency and to minimize the risk of toxicity. HIV-1 patients who receive standard doses and have a plasma EFV concentration of <1 μg/ml appear to have a higher risk for virological failure and emergence of selective drug resistance, while those with high plasma EFV concentrations of >4 μg/ml may experience adverse CNS effects more frequently.

Gounden et al. [81] found a correlation between *CYP2B6* 516T/T genotype, EFV concentrations, and early neuropsychiatric side effects. Several studies have confirmed these findings in African populations from Zimbabwe [82], Uganda [53], South Africa [49], and among

FIGURE 43.6 **Distribution of the five inferred CYP3A5 haplotypes for some African populations.** Genotyping was performed in 2245 individuals from 32 geographically and ethnically diverse African populations for common clinically relevant CYP3A5 alleles; also genotyped were an additional non-African 293 individuals from Europe and the Arabian Peninsula. The size of each circle is proportional to the number of individuals sampled from a given population. The allele combinations at all three loci are given in the key. The alleles in brackets define the inferred haplotype. The lowest *CYP3A5*3* frequencies are found in Sub-Saharan Africa, although frequencies are higher in East Africa than in other populations sampled from the continent. *Source: Reprinted with permission from BMC Genetics: From Bains* [56].

Tanzanians [47]. Moreover, other studies have established that *CYP2B6* T983C increases the predictive capability of the *CYP2B6* G516T SNP for EFV pharmacokinetics [49,83]. Associations between increased plasma EFV exposure and *CYP2B6* 516G>T and 983T>C have been consistent across multiple studies and populations, moving us closer to the possible design of a pharmacogenomics diagnostic tool to aid in EFV-dosing decisions [49]. *CYP2B6*6* is more frequent in African populations compared to Caucasians and Asian populations (Table 43.9).

Studies to determine EFV dosing in Caucasians arrived at a dose of 600 mg/day. Population pharmacokinetic studies in African populations (Tanzania, Ethiopia, Zimbabwe, South Africa) showed that more than 50% of patients have EFV levels above the minimum safe level of 4 μg/ml. Pharmacometric modeling indicates a need to reduce the

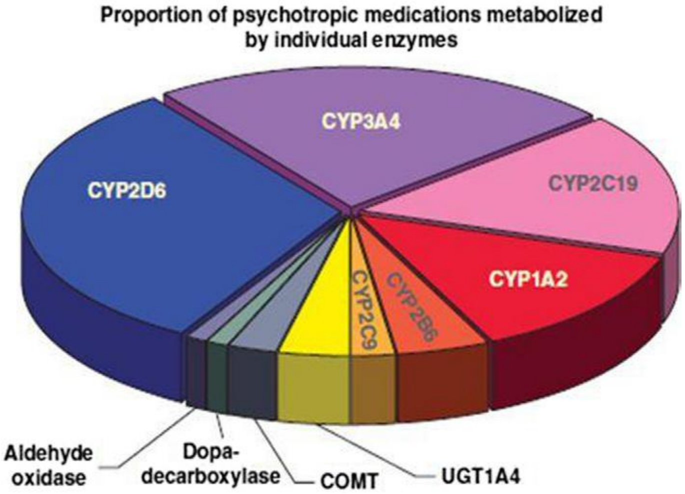

FIGURE 43.7 **Proportion of psychotropic medications metabolized by individual enzymes.** *Source: Reprinted with permission from Nature Publishing Group, Mol Psychiatry: From Stingl et al.* [84].

dose of EFV in a significant number of African patients to as low as 200 mg [79]. The modeling shows that patients homozygous for the *CYP2B6*6* require 200 mg, while women heterozygous for *CYP2B6*6* and weighing below 62 kg require 400 mg [79]. Studies in patients in South Africa also demonstrated that it is possible to predict patients likely to have high plasma concentrations based on the *CYP2B6*6* genotype [49]. While *CYP2B6*6* and some biometric measures explain about 22% of elevated EFV plasma concentrations [79], *CYP2B6*6*'s use as a biomarker for CNS ADRs still needs further investigation.

CYP2D6 and the Metabolism of Antidepressants and Antipsychotics

One of the most studied pharmacogenes, *CYP2D6*, has resulted in the development of genotyping kits such as the amplichip CYP450 by Roche, which is used to categorize CYP2D6 phenotypic activity based on CYP2D6 genotypes. These genotypes are computed from nearly 100 allelic variants that have been reported to date. With respect to CYP2D6, individuals are categorized as ultrarapid, extensive, intermediate, and poor metabolizers. As mentioned earlier, CYP2D6 phenotypes and genotypes show both qualitative and quantitative differences in world populations, including different activity levels for drugs that need CYP2D6 activation. Some of the substrates of CYP2D6 include the following: tamoxifen, sertraline, imipramine (Tofranil), doxepin (Adapin, Silenor, Sinequan), maprotiline (Deprilept, Ludiomil, Psymion), trimipramine (Surmontil), desipramine (Noraprim), nortriptyline (Aventyl, Pamelor), clomipramine (Anafranil), paroxetine (Paxil), venlafaxine (Effexor), amitriptyline (Elavil), mianserin, Trazodone (Desyrel), bupropion (Wellbutrin), nefazodone (Serzone), citalopram (Celexa) and sertraline (Zoloft); and antipsychotics: perphenazine (Trilafon), thioridazine (Mellaril), olanzapine (Zyprexa), zuclopenthixol (Cisordinol, Clopixol, Acuphase), aripiprazole (Abilify), flupentixol (Depixol, Fluanxol), haloperidol (Haldol), perazine (Taxilan), risperidone (Risperdal), and pimozide (Orap) [41].

Most drugs are metabolized by more than one enzyme, however, and Figure 43.7 illustrates this for psychotropic drugs generally. In addition to genetic polymorphisms, several inhibitors also compromise the effectiveness of substrate drugs by reducing CYP2D6's activity to varying extents. As an example of a CYP2D6 substrate, tamoxifen, prescribed for the treatment of estrogen receptor–positive breast cancer, is converted by CYP2D6 to endoxifen, the active metabolite. With CYP2D6 PM status in world populations ranging from 0.5% to nearly 10%, there are differences in the effectiveness of tamoxifen interindividually and between different populations. Besides CYP2D6 variations, there are genes whose expressed enzymes participate in tamoxifen metabolic and elimination pathways (e.g., CYP3A4, CYP3A5, SULT1A1, and UGT2B15); these need to be taken into account when designing a tamoxifen pharmacogenomic testing tool.

Hicks and colleagues [85] published "Clinical Pharmacogenetics Implementation Consortium Guideline for *CYP2D6* and *CYP2C19* Genotypes and Dosing of Tricyclic Antidepressants" to guide clinicians in the use of these drugs in Caucasians. These guidelines clearly do not address the case for African populations for whom African-specific variants for diminished CYP2D6 enzyme activity have been discovered—for example, *CYP2D6*17* [64] and *CYP2D6*29* [86]. No clinical studies have been performed to evaluate these variants' likely effects in patients on CYP2D6 substrate drugs, although Masimirembwa and Hasler [59] made postulations on their possible effect.

CYP2C9 and VKCOR1 the Disposition of Warfarin

Warfarin, a drug used for the long-term treatment and prevention of thromboembolic events, exhibits a narrow therapeutic window and shows substantial interpatient dose variability. It is one of the most used anticoagulants in the world. It is very difficult to determine the appropriate warfarin dose; thus, in the first few days of treatment, this drug is associated with one of the highest rates of ADEs. It is estimated that 20% of patients started on warfarin are hospitalized for ADEs during the first 6 months of treatment. The S-warfarin isomer, which is the more potent, is metabolized principally by *CYP2C9*; thus, its polymorphic variation affects the relative levels of circulating warfarin and other drugs [87].

Many allelic variants have been reported for *CYP2C9*, with *CYP2C9*2* and **3* being the most common low-activity alleles. Individuals homozygous for either *CYP2C9*2* and *3 or heterozygotes carrying only nonfunctional alleles, clear S-warfarin at a rate that is 90% lower than those with the *CYP2C9*1/*1* genotype. There are differences in the frequencies of these variants, as 8% of Caucasians have been shown to carry at least one copy of the *CYP2C9*2* variants compared to 1% among African Americans, and the allele is rare in Asians. The frequency of *CYP2C9*3* shows a similar distribution, except that it is found in about 3% of Asians [88,89]. Prior pharmacogenomics testing for CYP2C9 variants, coupled with dosage adjustments in Caucasians, reportedly result in a 30% reduction in hospitalizations [90].

In addition to CYP2C9, the warfarin target VKOR is an important determinant of warfarin response because its gene also exhibits genetic polymorphism. The anticoagulant effects of warfarin are exerted through decreased synthesis of vitamin K–dependent clotting factors by inhibiting the *VKORC1* C1 subunit. A mutation (G>A) in the promoter of the *VKCOR1* gene results in individuals presenting with a genotype (AA) needing 50% lower warfarin doses to exert the same effect. Taken together, variation in CYP2C9 (~15%) and VKORC1 (~25%) accounts for nearly 40% of the interindividual variability in warfarin dose requirements among Caucasians [88].

The contribution of each gene differs in different populations as well. However, similar to CYP2D6, the frequency of the homozygous AA, heterozygous AG, and homozygous GG genotype differs in different populations—14%, 47%, and 39% among Caucasians; 82%, 18%, and 0.35% among Asians, and poorly characterized among Africans. This has huge implications for warfarin response in these populations. Other genes, such as CYP4F2 and gamma-glutamyl carboxylase, have also been shown to influence warfarin dose requirements, yet there are no data on their contribution [88,91]. Many algorithms have been developed for warfarin dosing, but very few are applicable to African populations because of lack of information.

In the clinical use of warfarin, based on international normalized ratios (INR) between 2.0 and 3.0, studies show that Asian Americans require low weekly doses of 24 mg/week, followed by Caucasians and Hispanics at 36 and 31 mg/week, respectively. African Americans require the highest dose—an average of 43 mg/week [92]. Therefore, African American ancestry has been used as a predictor of high warfarin dosage [93]. Pharmacogenetic studies based on *CYP2C9* and *VKCORI* are shedding light on these clinical observations of variation in different population groups. In particular, the fact that the *CYP2C9*2* and **3* alleles occur at very low frequencies in African populations [33] means that the FDA-approved pharmacogenetic diagnostic kit for them is of little value to African populations.

N-Acetyl Transferase-2 (NAT-2) in the Disposition of Isoniazid

The variability of isoniazid disposition was one of the first to be characterized and continues to be of great importance to the people of Africa. This is because isoniazid is one of the key components of the cocktail of drugs used to treat tuberculosis. Genetic polymorphism studies led to the discovery of variants that explain rapid acetylator (RA) and slow acetylator (SA) status, which have subsequently been studied in African populations [94]. Pharmacometric modeling of isoniazid clearance in Caucasian SAs and RAs shows that the currently used standard dose can be doubled in RA and halved in SA to achieve the same safe and efficacious levels in blood [95].

In the intention-to-treat (ITT) analysis, isoniazid drug-induced liver injury (INH-DILI) occurred in 78% of SAs in the standard (STD) treatment group, while no SA in the PGx-guided group experienced either INH-DILI or early treatment failure. Among RAs, early treatment failure had a significantly lower incidence rate in the PGx group than in the STD group (15.0% vs. 38%). Thus, the NAT-2 genotype-guided regimen resulted in much lower incidence of unfavorable events, INH-DILI, or early treatment failure than the conventional standard regimen [96]. These studies are relevant to African populations for whom the SA phenotype has been shown to exceed 50%, who carry the heaviest burden of TB infections in the world, and are likely to be treated with NAT-2 drug substrates.

43.5 FUTURE PERSPECTIVES

43.5.1 Epigenetics

Even in well-studied Caucasian populations, after taking into account most of the known genetic variation in DME genes, there has always been a gap between genotype-predicted phenotypes and those determined by *in vivo* probe drugs—specifically, inadequate correlation between genotypes and variation in plasma drug levels. As described by Gomez and Ingelman-Sundberg:

Epigenetics describes the changes that do not involve any alteration in DNA sequence and include covalent modifications of DNA and histones, DNA packaging around nucleosomes, chromatin folding and attachment to the nuclear matrix, and regulatory non-coding RNAs, e.g., microRNAs (miRNAs) [97].

Thus, many early observations of environmental effects can now be explained by epigenetics. There are several processes involved in epigenetics, but the most common are DNA methylation and microRNA regulation. For example, methylation in DME promoter regions is associated with reduced expression of the respective genes, while the presence or absence of microRNA target sequences in the 3′UTR region of DME genes results in differential regulation of the same genes [97,98].

In terms of ongoing research, epigenetics has opened up a huge area of interest for many biological disciplines including pharmacogenetics. In addition to traditional pharmacogenetics, which focuses on variation in exon/introns, a new discipline, pharmacoepigenetics, looks at other mechanism to explain interindividual drug response variations. Many of the genes encoding DMEs, drug transporters, transcription factors, drug targets, and nuclear receptors are regulated at the epigenetic as well as the pharmacogenetic level. Studies are now looking at the role of microRNAs (miRNAs) in terms of variation in their coding sequences (mirSNP) and regulatory target sequences. All of this variation affects plasma drug levels and is important in establishing pharmacogenomics algorithms for drug response. DNA methylation has been demonstrated or predicted in the following clinically relevant CYPs, CYP2C19, CYP2D6, and CYP3A4/5. Many studies have reported DNA methylation in GSTs, especially the glutathione-S-transferase P1 (GSTP1) that has been found to be differentially methylated in different tumors. These observations in DMEs are also being reported in nuclear receptors, which are vital in the transcription control of genes encoding drug transporters and enzymes.

Thus, pharmacogenomics knowledge cannot be complete without incorporating effects associated with epigenetic changes, such as DNA methylation and noncoding regulatory RNAs, including microRNAs. For example, a study by Turrin and coworkers [99] reported an inverse correlation between miR212, 328, and ABCG2 (a transporter) gene expression, indicating that variations in miRNAs that regulate genes for drug-metabolizing enzymes, transporters, and targets may give rise to variations in drug response. An appreciable number of chemical entities that affect the genome's DNA methylation landscape are now being used in clinical practice; however, the challenge here is overcoming their lack of specificity. As yet no studies in African populations have reported on the role of epigenetics in drug response, but there is evidence from functional studies that it does have a role to play.

43.5.2 From Pharmacogenetics to Pharmacogenomics: Where Does Africa Feature?

Current advances in genomics research and in related technologies make it possible to translate research results into potential health benefits through pharmacogenomics, ultimately leading to stratified medicine and personalized therapy. SNP functional data are being curated in the encyclopedia of DNA elements (ENCODE), which will aid in the description of functions for most SNPs in the human genome, and thus further our understanding of drug response. Individualization of drug therapy based on genetic make-up is a desirable paradigm, especially for the treatment of diseases with drugs that (1) exhibit narrow therapeutic windows, (2) may raise toxicity above certain levels, or (3) lower therapeutic failure below certain levels (e.g., low levels of ARVs that may promote virus resistance). Currently, antiretroviral and anticancer drugs are administered at maximally tolerated doses as defined for particular populations. Inevitably, up to 30% of patients are thought to present with ADEs, some of them fatal.

Pharmacogenomics can improve prediction of individuals likely to be at greater risk of drug-induced ADEs [100]. However, clinical data on African populations are lacking. For this reason, in addition to embracing pharmacogenomics, epidemiological research should include the mapping of disease and ADE/ADR determinants.

Based mostly on studies on European populations, several pharmacogenetics prognostic tools have been developed or are projected to be developed by 2020 [101]. Some of them have been recommended by the FDA, including the ampliChip CYP450 by Roche, the DMET chip by Affymetrix, and TheraGuide 5-FU by Myriad Genetics. These tools predict either efficacy or toxicity, and most of them at present remain largely irrelevant to African populations because they are not premised on African-specific genetic variants. A recent study evaluated the ampliChip CYP450 tests designed by Roche and reported poor sensitivity when used in a black South African cohort [74]. In general, African populations are likely to benefit more from denser genetic testing tools because of their small LD blocks compared to other world populations. As can be seen, understanding the pharmacogenomic determinants of drug response and toxicity is critical.

Despite considerable advances in our understanding of human genetic architecture, the genetic underpinning of complex disorders remains elusive. On the basis of our current understanding of neurobiology, numerous candidate genes have been implicated in the etiology of and response to treatment of addiction. Genome-wide association studies

(GWASs) have identified other novel targets. However, study replication is often lacking, which complicates interpretation. The situation is expected to improve as issues such as phenotypic characterization, the apparent "missing heritability," the identification of functional variants, and possible gene–environment (G-E) interactions are resolved.

It has become apparent that genetic diversity and heterogeneity in African populations call for comprehensive genomic, including pharmacogenomic, research in as many African populations as possible. Three initiatives, the Malariagen Project (www.malariagen.net), 1000 Genomes (www.1000genomes.org), and H3Africa (www.h3africa.org), are at the forefront of research on African populations. For example, 1000 Genomes is making available a plethora of data from previously uncharacterized population groups. However, the boldest initiative is the Human Heredity and Health for Africa (H3Africa) project.

43.5.3 Catalyzing Genomics Research in Africa: Human Heredity and Health

Human Heredity and Health for Africa (H3Africa) is an initiative born out of the partnership of the Africa Society for Human Genetics (AfSHG), the Wellcome Trust (United Kingdom), and the National Institutes of Health (NIH). Its goal is to redress the disproportionate lack of genomics research in Africa that developed after WHO identified genomics as one of the critical drivers in improving human health. Africa is faced with the quadruple burden of infectious disease, HIV/AIDS, malaria, and TB, as well as the rapid rise in noncommunicable diseases. According to an H3Africa white paper: "Differences in disease prevalence between African countries, geographic regions within a country, and ethnic groups in the same geographic region are the result of a combination of human genomic and environmental factors." Thus, H3Africa seeks to use recent technology advances to strengthen African research in order to identify genetic variations associated with disease susceptibility, pathogenesis, and treatment response. It is leveraging funding from the Wellcome Trust and NIH to promote African genomics research.

Already, several groups have been identified for genomics research funding (see www.h3africa.org). The inclusion of African populations in this global research agenda is of obvious research and practical importance because African populations harbor the greatest genetic diversity, from which all other world populations originated. Thus, genomic research among Africans is likely to lead to new discoveries and advances that can contribute to improved global health. Pharmacogenomics is an important component of the H3Africa initiative, with the expectation that African populations will benefit considerably from pharmacogenomics findings that are likely to reduce ADEs, which are estimated to cost billions of dollars annually.

With the focus of H3Africa on characterizing diversity within indigenous African populations, it is hoped that the availability of data from genomics studies will tell us how genomic variation affects individual and population differences in response to drugs. Studies of genetic variation patterns in African populations are crucial to our understanding of how genes affect phenotypic variation, including disease predisposition and response to treatment.

43.6 CONCLUSIONS

Many more pharmacogenetic and clinical studies are needed to define and characterize the great genetic diversity of African populations with respect to drug efficacy and safety. Pharmacogenomic tools need to be developed to suit the variations seen in African populations to better define dose regimens.

Although pharmacogenomics profiles of drug response and tolerability have been an important area of research in personalized medicine, a huge effort must be exerted toward clinical validation of the myriad of pharmacogenomics tests that will soon be available. Clinical validity will only become possible once we understand and take into account SNPs, copy number variants, noncoding RNA in gene regulation, gene–gene and gene–environmental interactions, and epigenetic modifications.

For the effective translation of pharmacogenomics research, healthcare practitioners should be familiar with genetic determinants of drug response and willing to catalyze the transition of knowledge from bench to bedside and vice versa. Thus, the research and clinical capacities of African researchers and physicians should be strengthened through pharmacogenomics training so that this knowledge can be integrated into medical practice and eventually lead to personalized medicine.

KEY CONCEPTS

- Population diversity manifests itself through genetic, ethnolinguistic and cultural differences as well as differences arising from environmental and sociopolitical factors such as exposure to pathogens, disease burden, diet, climate, poverty, urban versus rural lifestyle, and so on.
- African populations exhibit greater diversity than do populations from Europe, Asia, and the Americas.
- Measurement of population diversity is complicated and may be based on ethnolinguistic–cultural factors or on genetic factors. One nongenetic measure is a country's ethnic fractionalization (EF), defined as the probability that two individuals selected at random from a country will be from different ethnic groups.

- Population structure and genetic diversity have been determined by various approaches, including rates of microsatellite mutation, heterozygosity, linkage disequilibrium, and F-statistics. All of these have led to a detailed understanding of population clusters in Africa and of the extent of their differences, and to the postulation of their migrations both within the continent and out of Africa to Europe, Asia, and the Americas.
- Genetic variation in African populations has arisen from human interaction with various environmental factors, including disease. Genetic and genomics studies have now identified biomarkers for disease susceptibility and/or resistance that influence the practice of medicine. A degree of variation has been postulated to have derived from human interaction with plant life; this so-called animal–plant warfare has resulted in the evolution of xenobiotic-metabolizing enzymes in humans, which are thought to protect humans from plant-derived chemical insults.
- The discovery of genetic polymorphisms in xenobiotic-metabolizing enzymes gave rise to the study of pharmacogenetics. These enzymes have been demonstrated to be largely responsible for the metabolism and disposition of most therapeutics used in disease prevention and treatment.
- The population diversity demonstrated for genes and noncoding regions is also observed for genes encoding drug-metabolizing enzymes and drug transporters. Over decades of phenotype and genotype studies, many clinically important pharmacogenetic variations have been discovered and characterized, such that there are now a number of FDA-approved pharmacogenetic tests and a number of drug labels now bearing information on pharmacogenetics.
- Pharmacogenetic studies in African populations are on the increase and are already demonstrating continental diversity that has relevance in stratified medicine for both indigenous and diaspora Africans. While generalizations in Caucasian populations on the clinical utility of pharmacogenetic traits and tests are possible, they are likely to be difficult with African populations given Africa's demonstrated continental diversity.
- To date, clinical applications of pharmacogenetics have focused mainly on diseases prevalent in Caucasian and Asian populations. In Africa, these applications must be extended to the treatment of numerous viral, bacterial, protozoal, and helminthic diseases.
- Epigenetic changes may show diversity across populations depending on life experiences, and this diversity may have implications for pharmacogenomics and stratified medicine. Given the diverse cultures, diets, disease prevalence, and environments within the African continent, epigenetic studies are likely to produce interesting results.

ACKNOWLEDGMENTS

Funding for this work was from the European and Developing countries Clinical Trial Partnership (EDCTP) and the International Science Program (ISP) for CM and JAH and from the Medical Research Council (MRC) of South Africa, National Research Foundation (NRF), and University of Cape Town for CD. CM is an EDCTP Senior Clinical Research Fellow. We thank the technical staff of the Laboratory for Genotyping Development at RIKEN Center for Genomic Medicine, for genome-wide SNP genotyping in the unpublished work by Maimbo and colleagues [34]. This work was conducted as a part of the Biobanking and Pharmacogenetics project at AiBST, which was supported by EDCTP (European Union) and IPICS (Sweden).

GLOSSARY

Ethnic fractionalization (EF) the probability that two individuals selected at random from a country will be from different ethnic groups

F-statistics (F_{ST}) the proportion of the total genetic variance contained in a subpopulation (subscript S) relative to the total genetic variance (subscript T). Values can range from 0 to 1. High F_{ST} implies a considerable degree of differentiation among populations. F_{IS} (inbreeding coefficient) is the proportion of the variance in the subpopulation contained in an individual. High F_{IS} implies a high degree of inbreeding

Linkage disequilibrium (LD) the tendency for two alleles to be present on the same chromosome (positive LD) or not to move together (negative LD). As a result, specific alleles at two different loci are found together more or less than expected by chance. The same situation may exist for more than two alleles. LD magnitude is expressed as the delta (D) value and corresponds to the difference between the expected and the observed haplotype frequency. It can have positive or negative values and is decreased by recombination, so it decreases every generation of random mating unless some process opposes the approach to linkage equilibrium. Permanent LD may result from natural selection if some gametic combinations result in higher fitness than other combinations

ACRONYMS AND ABBREVIATIONS

ADE	adverse drug event
ADR	adverse drug reaction
AfSHG	African Society for Human Genetics
EF	ethnic fractionalization
EM	extensive metabolizer
ENCODE	Encyclopedia of DNA Elements
CF	cultural fractionalization
CYP	cytochrome P-450
EFV	efavirenz
FDA	Food and Drug Administration
5-FU	5 fluorouracil
GWAS	genome-wide association study
HAART	highly active antiretroviral therapy
H3Africa	Human Heredity and Health for Africa project
INH-DILI	isoniazid drug induced liver injury
LD	linkage disequilibrium
NAT-2	(v) N-Acetyl Transferase-2
NIH	National Institutes of Health
NRTI	nucleoside reverse transcriptase inhibitor

PM	poor metabolizer
PCA	principal component Analysis
SNP	single-nucleotide polymorphism
TB	tuberculosis
UM	ultrarapid metabolizer
VKORC1	vitamin K 2,3-epoxide reductase C1 subunit

44.1 OVERVIEW

Pharmacogenetic and pharmacogenomic studies have established the importance of polymorphic drug-metabolizing enzymes, receptors, transporters, and ion channels in the differential response of patients to drugs. Among these target genes, cytochrome P450 has become the most important subject of extensive studies concerning individual variation in drug metabolism and disposition. The association between decreased drug clearance and the activity of several kinds of CYP enzymes, the inherited nature of the functional deficiency in drug-related genes, and their frequencies and clinical importance were evaluated extensively [1]. During the past ten years, the genetic polymorphisms of transporters and receptors have been increasingly studied at the protein and gene level. It has gradually been demonstrated that genetic differences in ion channels reflect differences in the distribution of polymorphic traits, such as disease susceptibility and drug efficacy or tolerability, which has become a rising field of study on pharmacogenetics and pharmacogenomics research.

In this chapter, we mainly summarize studies with Chinese populations on the individual variations in drug disposition and response mediated by drug-metabolizing enzymes, drug receptors, drug transporters, and ion channels, as well as the role of genotype on herb–drug interactions and translational medicine.

44.2 PHARMACOGENOMICS OF DRUG-METABOLIZING ENZYMES IN CHINESE POPULATIONS

44.2.1 CYP2C19

The genetic polymorphism of CYP2C19 has been elucidated in several different studies of the Chinese population

Handbook of Pharmacogenomics and Stratified Medicine. http://dx.doi.org/10.1016/B978-0-12-386882-4.00044-X

TABLE 44.1 CYP2C19 Allele Frequencies in Chinese Subjects

	Han (n = 202)	Dong (n = 148)	Dai (n = 386)	Bai (n = 404)
*CYP2C19*1*	0.559 (113)	0.541 (80)	0.666* (257)	0.688* (278)
*CYP2C19*2*	0.336 (74)	0.399 (59)	0.303 (117)	0.257* (104)
*CYP2C19*3*	0.074 (15)	0.060 (9)	0.031* (12)	0.052 (21)
*CYP2C19*5*	–	–	–	0.0025 (1)

since the 1990s. The two defective alleles were found together, first in poor metabolizers (PMs) of the Chinese Dong nationality, and accounted for 100% of the PM alleles. CYP2C19*2 and CYP2C19*3 represent 86.8% and 13.2% of the mutant alleles in this ethnic group, respectively. Similar results were then defined in the Chinese Han majority (83.2% and l6.8%, respectively) and Chinese Bai minority (82.5% and l6.7%, respectively) [2].

In a group of Han subjects (n = 101), 19.8% were classified as PMs phenotypically and 100% of these phenotypes could be explained by CYP2C19*2 and CYP2C19*3. Several other studies carried out by Shimada et al. and Qin et al. confirmed that CYP2C19*2 accounts for most mutant CYP2C19 alleles in Han subjects, and that CYP2C19*3 can partially explain these mutant alleles in Chinese Bai subjects; 27 of 202 (13.4%) were classified as PMs phenotypically, and only one appeared to be an outlier. The outlier was finally found to be a heterozygote with a CYP2C19*2 and a new mutant allele consisting of a C→T mutant allele at bp 1297 in exon 9. This mutation, which is designated as CYP2C19*5, results in the substitution of Arg433→Trp433 in the heme-binding region and may produce an inactive protein [3].

It has also been determined that CYP2C19*2 and CYP2C19*3 account for all mutant alleles in the Chinese Dai minority (90.7% and 9.3%, respectively). It was noticed that other rare mutations of CYP2C19 found in Caucasian populations—including CYP2C19*6, CYP2C19*7, and CYP2C19*8—were not detected in the Chinese population. The CYP2C19 allele frequencies in these ethnic groups are presented in Table 44.1, in which significant differences in frequencies are clearly shown.

It has been found that there is a large ethnic difference in the amount of CYP2C19 protein in microsomes. The amount of CYP2C19 in microsomes from Japanese and Caucasians is 0.8% and 1.4% of total CYP450, respectively. Moreover, the amount of CYP2C19 in microsomes is highest in individuals who are homozygous for the normal gene (CYP2C19*1/*1), and lowest in those homozygous for the mutation gene (CYP2C19*2/*2 or CYP2C19*3/*3) compared with heterozygous (CYP2C19*1/*2 and CYP2C19*l/*3). Studies that investigated the relationship of gene dose and the ratio of S- and R-mephenytoin in Chinese Han, Dong, Dai, and Bai subjects showed that heterozygous extensive metabolizers (CYP2C19*1/*2 and CYP2C19*1/*3) had significantly higher S/R ratios compared with homozygous wild-type extensive metabolizers (CYP2C19*1/*1). This clearly indicated that gene dosage has an affect on mephenytoin metabolism.

The gene dosage effect of CYP2C19 could influence the metabolism of its substrates. Diazepam is one of the most commonly prescribed sedative drugs for the treatment of anxiety, convulsions, and muscle spasms. N-demethylation is the major metabolic pathway of diazepam in vivo at therapeutic doses. There is evidence that in white and Korean populations the metabolism of both diazepam and its N-demethylated metabolite, desmethyldiazepam, cosegregates with the S-mephenytoin hydroxylation polymorphism; however, the data from studies of the Chinese population conflict with the findings from studies of white and Korean populations. It has been suggested that this discrepancy might be related to the proportion of heterozygotes in Chinese versus Caucasian extensive metabolizers (EMs).

Our studies have shown that the presence of mutations of the CYP2C19 gene cosegregates with the impaired metabolism of diazepam among Chinese subjects in a manner suggesting a gene–dosage effect. A significant difference in the half-lives (t1/2) existed between the heterozygous EMs (CYP2C19*1/*2) and homozygous EMs (CYP2C19*1*1). The slowest mean clearance of diazepam was seen in the CYP2C19*2/*2 subjects, and the fastest in the CYP2C19*1/*1 subjects, with the CYP2C19*1/CYP2C19*2 heterozygotes having an intermediate value. Figure 44.1 shows the demographic characteristics and pharmacokinetic parameters of oral diazepam in healthy Han Chinese subjects with different CYP2C19 genotypes. There were significant intergenotypic differences in the plasma half-lives of diazepam and its active metabolite demethyldiazepam between the different genotypic groups, with the subjects homozygous for the allele m1 (CYP2C19*2/*2) having the longest t1/2 and the wild-type (WT) homozygotes (CYP2C19*1/*1) having the shortest t1/2 for both compounds.

As expected, the slowest mean clearance of diazepam existed in the subjects with CYP2C19*2/*2, and the fastest was observed in the WT/WT subjects. As hypothesized, the heterozygotes (CYP2C19*1/*2) had intermediate values of systemic clearance and elimination half-life. This study was the first definitive evidence that the gene–dosage of CYP2C19 can markedly affect the metabolism and disposition of diazepam and desmethyldiazepam in humans [4].

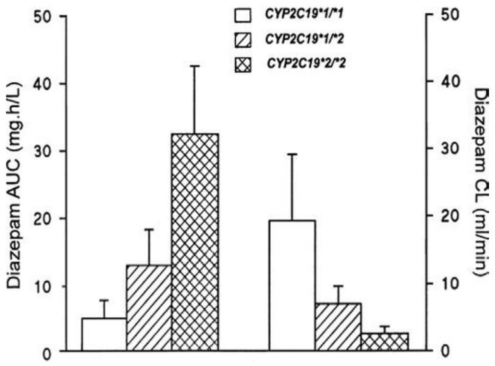

FIGURE 44.1 Effect of CYP2C19 gene dosage on diazepam pharmacokinetic parameters.

44.2.2 CYP2D6

Chinese individuals have greater sensitivity than Caucasians to the effects of propranolol on heart rate and blood pressure. Decreased protein binding and increased sensitivity to plasma renin activity suppression in Chinese can only partially explain their increased sensitivity to propranolol. CYP2D6 is one of the most important drug-metabolizing enzymes in the human liver, which is mainly responsible for propranolol clearance. About 71% of CYP2D6 alleles code for normal enzyme in Caucasians, while 26% is a nonfunctional enzyme mainly prescribed as CYP2D6*4 (15.6%), CYP2D6*5 (6.9%), and CYP2D6*3 (1.6%). Except for CYP2D6*5, which exhibits a similar frequency in Caucasians, Japanese, and Chinese, the other functionally defective alleles of CYP2D6 are very rare in Chinese. However, Chinese metabolize CYP2D6-mediated drugs more slowly than Caucasians, which may due predominantly to high frequencies of variants of 2D6*10—a reduced function allele.

The frequency of mutant allele CYP2D6*10 that encodes a reduced activity of the enzyme is even higher than that of CYP2D6*1 (50% vs. 26.9%), resulting in a higher prevalence of this allelic variant among Chinese patients. Thus, the average activity value of CYP2D6 is lower in Chinese than in other racial populations whose frequencies of the CYP2D6*10 allele are remarkably lower. Therefore, Chinese subjects exhibit a relatively lower metabolizing activity of CYP2D6 on average and may be more sensitive than Caucasians to the effect of CYP2D6 substrates (e.g., propranolol, metoprolol, timolol).

44.2.3 CYP3A

Human cytochrome P450 3A evolved to catalyze the metabolism of numerous common therapy drugs and endogenous molecules. Members of the CYP3A family make up the majority of those expressed in human liver and intestine, and there are marked interindividual differences in their protein expression and activity. The activity of the CYP3A enzyme in the Chinese is highly variable, exceeding 14-fold, and contributes greatly to variation in oral bioavailability and systemic clearance of CYP3A substrates. The genetic factors play an important role in the interindividual variability in CYP3A activity.

Detection of CYP3A5 and CYP3A4 variant alleles and knowledge about their allelic frequency in specific ethnic groups are important in determining individualized drug dosing and improved therapeutics. In a group of 302 unrelated Chinese healthy volunteers, the frequency of the CYP3A5*3 and CYP3A4*18 variant allele were 77.8% and 1%, respectively [5]. The CYP3A4*18 and CYP3A5*3 allelic frequencies are similar to those reported previously for Chinese residents in Taiwan. The frequency of the CYP3A5*3 allele in that population is similar to that in the Japanese but lower than Caucasians. Meanwhile, approximate 62% of the Chinese population carrying the CYP3A5*3/*3 genotype may appear not to express CYP3A5 protein and exhibit a lower total expression of CYP3A.

The calcineurin inhibitor, cyclosporine, is widely used to prevent allograft rejection after solid organ transplantation. It has a narrow therapeutic index and shows considerable interindividual differences in its pharmacokinetics. Interindividual differences in the activity and expression of the metabolizing enzymes cytochrome P450 (CYP) 3A4 and 3A5 contribute considerably to cyclosporine pharmacokinetics. The median cyclosporine dose-adjusted (C0) in CYP3A5*1/*1 genotype subjects was 14.8 ng/mL per mg/kg; in CYP3A5*1/*3 patients ($n = 34$), it was 23.7 ng/mL per mg/kg; for CYP3A5*3/*3 patients ($n = 66$), it was 26.4 ng/mL per mg/kg ($p = 0.012$). Accordingly, cyclosporine dose-adjusted C0 was larger in Chinese CYP3A5 nonexpressors than expressors in the first week after renal transplantation.

The present study shows that genetic polymorphism in CYP3A5 is responsible for the large interindividual variability of cyclosporine pharmacokinetics during the early phase after renal transplantation in Chinese patients. Those with the CYP3A5*3 variant genotype require a low dose of cyclosporine to reach target levels compared with those with the CYP3A5*1 allele.

44.2.4 Histamine N-Methyltransferase

Histamine N-methyltransferase (HNMT) plays an important role in the metabolism of histamine—a biogenic amine that has many physiologic and pathological roles in human tissues. A total of 11 single nucleotide polymorphisms (SNPs) were identified in 192 unrelated healthy Chinese adults, among which six SNPs had variant allele frequencies greater than 5% (Figure 44.2). Of the six common SNPs, three (21637T>C, 2463T>C, and 2411 C>T) were located in 5′-FR, one (314C>T) in coding exons, and two (939A>G and 1097A>T) in the 3′-untranslated region (3′-UTR). Most of these common SNPs were in linkage disequilibrium.

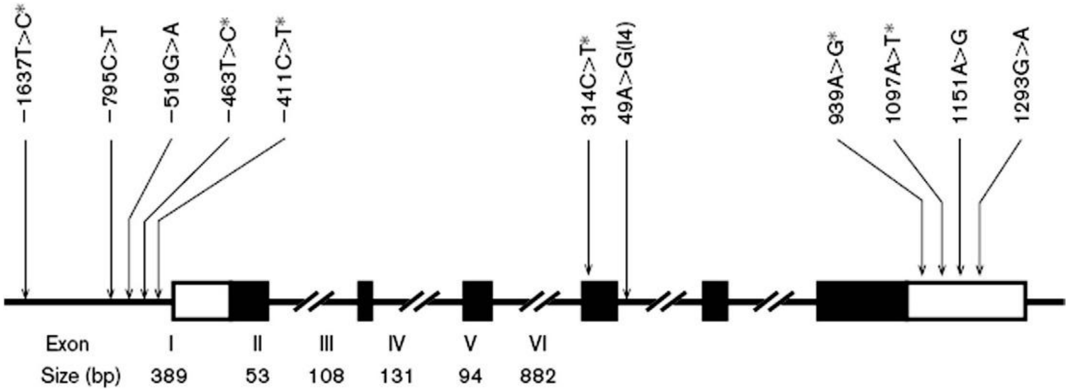

FIGURE 44.2 **Human HNMT structure and polymorphisms in Chinese subjects.** Exons are represented as rectangles: black rectangles—encoding; white—UTR sequences. SNP positions are indicated by arrows; common SNP, by an asterisk. The polymerase chain reaction product sizes corresponding to segments of HNMT are also shown.

Genotype–phenotype correlation analyses were performed for those common SNPs in 5′-FR and 3′-UTR. In males, no significant association was found between HNMT activity and these noncoding SNPs. However, in females, the 21637T>C or 2463T>C tended to be associated with decreased HNMT activity, whereas the 939A>G or 1097A>T appeared to be correlated with increased enzymatic activity. HNMT polymorphisms differ considerably between Chinese and American Caucasians.

The common SNPs in 5′-FR (21637T>C and 2463T>C) and 3′-UTR (939A>G and 1097A>T) might conditionally regulate the activity of HNMT, or it might be genetically linked to unknown mutation(s) underlying the HNMT phenotypic variance. The C314T missense mutation (Thr105Ile) in the HNMT gene has been identified as representing a common functional polymorphism in Caucasians, whereas an A595G (Ile199Val) variant has been reported in one HNMT cDNA from a Japanese subject. The point mutations C314T and A595G within HNMT were both detected in 352 unrelated Chinese Han subjects. None of these subjects contained the A595G mutation, whereas 40 (11.6%) heterozygotes and 1 (0.3%) homozygote for the variant T314 allele were detected.

The frequency of the variant T314 allele in this Chinese population was 0.060 (95% CI: 0.042–0.078), no different from Japanese but significantly lower than American Caucasians. The C314T mutation represents a common functional genetic polymorphism in the Chinese Han population with a variant T314 allele frequency similar to Japanese but lower than American Caucasians, whereas the A595G mutation does not appear to exist in this population [6,7].

We investigated the polymorphisms in the HNMT gene in Chinese to assess their relationship with HNMT activity. HNMT polymorphisms were screened in 192 unrelated subjects by direct sequencing with purified polymerase chain reaction products comprising all six exons, plus splice junctions, as well as approximately 2 kb of the 5-flanking region (5-FR). Erythrocyte HNMT activity was measured by radiochemical microassay. A total of 11 single nucleotide polymorphisms (SNPs) were identified, among which six SNPs had variant allele frequencies greater than 5%. Of the six common SNPs, three (1637T>C, −463T>C, and −411C>T) were located in 5′-FR, one (314C>T) in coding exons, and two (939A>G and 1097A>T) in the 3′-untranslated region (3′-UTR). In females, the −1637T>C or −463T>C tended to be associated with decreased HNMT activity, whereas the 939A>G or 1097A>T appeared to be correlated with increased enzymatic activity. The common SNPs in 5′-FR (−1637T>C and −463T>C) and 3′-UTR (939A>G and 1097A>T) of HNMT might conditionally regulate the activity of HNMT in a Chinese population with a gender difference.

44.3 PHARMACOGENOMICS OF DRUG TRANSPORTERS IN CHINESE POPULATIONS

44.3.1 ABCC1

Multidrug resistance-associated protein 1 (MRP1/ABCC1) has been shown to cause multidrug resistance in model cell lines and in clinical settings. We explored the distribution frequencies of four common single nucleotide polymorphisms of MRP1/ABCC1—Cys43Ser (128G>C), Thr73Ile (218C>T), Arg723Gln (2168G>A), and Arg1058Gln (3173G>A)—in a mainland Chinese population and investigated whether these SNPs affect the expression and function of MRP1/ABCC1. The four candidate SNPs were recreated by site-directed mutagenesis and tested for their effect on MRP1/ABCC1 expression and multidrug resistance (MDR) function in stable transfected HEK293 and CHO-K1 cell lines. Real-time PCR, Western blot, and confocal microscopy were used to determine mRNA, protein expression, and protein trafficking. Last, the effect of mutations on MRP1/ABCC1-mediate drug resistance was determined using a methyl thiazolyl tetrazolium assay.

We found the allelic frequencies of Cys43Ser (128G>C), Thr73Ile (218C>T), Arg723Gln (2168G>A), and Arg1058Gln (3173G>A) in mainland Chinese were 0.5, 1.4, 5.8, and 0.5%, respectively. Among them, the Arg723Gln mutation significantly reduced MRP1/ABCC1-mediated resistance to daunorubicin, doxorubicin, etoposide, vinblastine, and vincristine. The Thr73Ile mutation reduced resistance to methotrexate and etoposide, whereas the Arg1058Gln mutation increased the response of two anthracycline drugs and etoposide in HEK293 and CHO-K1 cells as well as vinblastine and methotrexate in CHO-K1 cells (Figures 44.3 and 44.4) [8].

We subsequently investigated the clinical application of this polymorphism with lung cancer susceptibility and chemotherapy response in a Chinese population. A total of 77 lung cancer patients and 71 cancer-free controls were enrolled in the study. Individuals carrying the 723Gln (A) allele have a 3.4-fold increased risk—adjusted odds ratio (OR) 3.42; $p = 0.013$—of lung cancer compared with wild-type individuals. Further, stratified analysis indicated that older individuals (>50 years) carrying the 723Gln (A) allele have the highest susceptibility to lung cancer (adjusted OR 4.10; $p = 0.020$). No substantial association was found between the Arg723Gln (2168G>A) polymorphism and chemotherapy response in Chinese lung cancer patients. The Arg723Gln (2168G>A) polymorphism of ABCC1 appears to be a potential susceptibility marker for lung cancer in the Chinese population, especially in older people [9].

44.3.2 ABCB1 and ABCC2

Some studies have found that ATP-binding cassette (ABC) efflux transporters play an important role in antiepileptic drug resistance, especially ABCB1 and ABCC2. We evaluated the relationship between the genetic polymorphisms of ABCC2 and ABCB1 and the therapeutic efficacy of antiepileptic drugs (AEDs) in Chinese epileptic patients. ABCB1 rs1045642 (3435C>T) and ABCC2 rs717620 (-24C>T), rs3740066 (3972C>T), and rs2273697 (1249G>A) polymorphism loci in 537 Chinese epilepsy patients (217 drug-resistant patients and 320 drug responders) were genotyped. ABCC2 rs717620-24TT genotype was found to be significantly associated with drug-resistant epilepsy (OR = 4.06, $p = 0.001$). The OR values of ABCC2 rs717620-24 CT+TT genotypes and ABCC2 rs3740066 (3972C>T) CT+TT genotypes were markedly higher in drug-resistant patients (OR = 1.57, $p = 0.018$; OR = 1.49, $p = 0.038$,

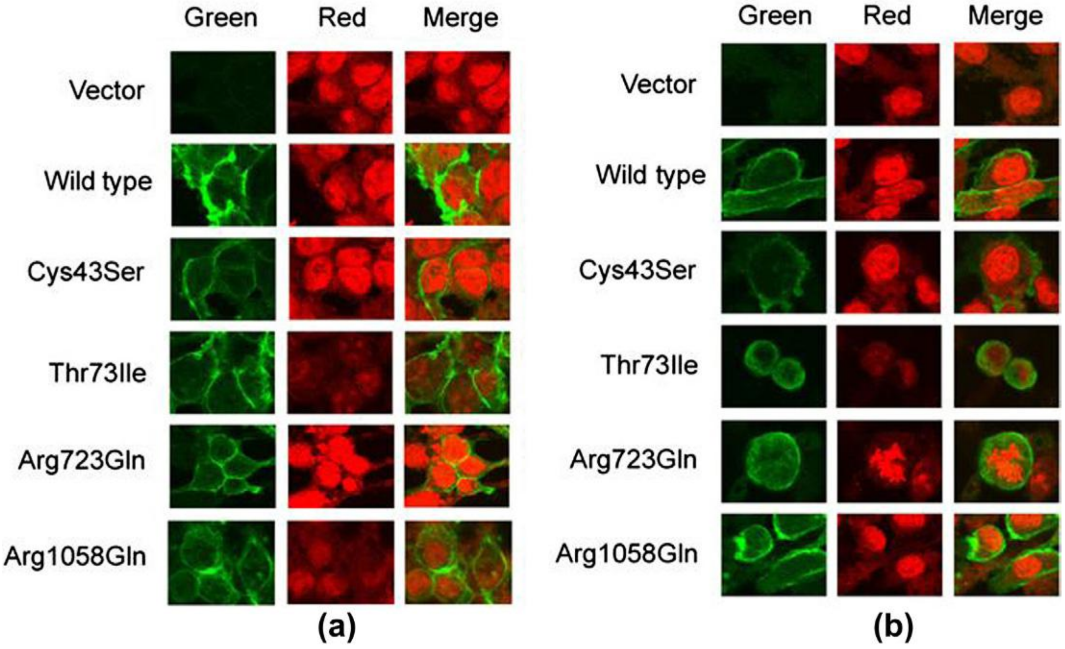

FIGURE 44.3 Confocal microscopy of wild-type and mutant ABCC1 expression in HEK293 and CHO-K1 cells. The subcellular localization of ABCC1 in HEK293(A) and CHO-K1(B) cells was detected by immunofluorescence. ABCC1's location is shown in green. Nuclei were stained with propidium iodide and are shown in red.

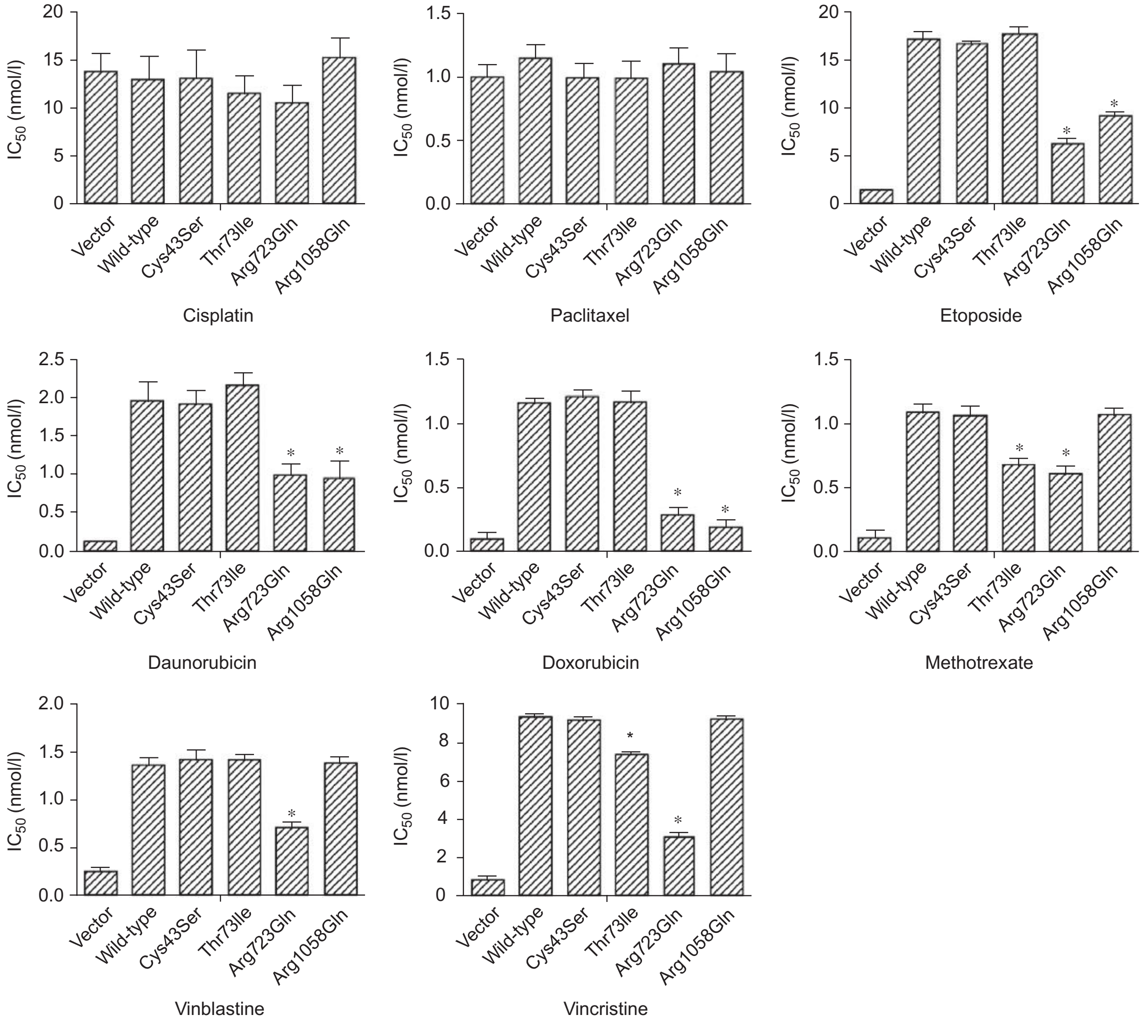

FIGURE 44.4 Effect of mutations on multidrug resistance-associated protein 1 (MRP1/ABCC1)-mediated multidrug resistance in HEK293 cells. HEK293 cells stably transfected with vector, wild-type, or Cys43Ser, Thr73Ile, Arg723Gln, and Arg1058Gln mutant MRP1/ABCC1 were exposed to cisplatin, paclitaxel, etoposide, daunorubicin, doxorubicin, methotrexate, vinblastine, and vincristine at various concentrations for 72 hours at 371 °C. Following was a methyl thiazolyl tetrazolium assay and determination of half maximal inhibitory concentration (IC50). The results shown are from six replicate determinations (*$p < 0.05$).

respectively) compared with responsive patients. ABCC2 rs2273697 (1249G>A) and ABCB1 rs1045642 (3435C>T) polymorphisms were not associated with drug-resistant epilepsy.

A linkage disequilibrium (LD) test showed that the ABCC2 rs717620 were in strong LD with rs2273697 ($D' = 0.694$) and rs3740066 ($D' = 0.699$). The frequencies of haplotypes TGT (ABCC2-24C>T/ABCC2 1249G>A/ABCC2 3972C>T) in resistant patients was significantly higher than those in responsive patients (21.0% vs. 14.2%, $p < 0.05$). These data suggest that ABCC2-24C>T, 3972C>T polymorphisms, and one ABCC2 haplotype, are associated with AED resistance and may affect the response to antiepileptic drugs [10].

44.3.3 ABCG2

Rosuvastatin, a novel, potent HMG-CoA reductase inhibitor, is excreted into bile mediated by breast cancer resistance protein (ABCG2). The association between the most frequent SNPs of the ABCG2 (421C>A) and the pharmacokinetics of rosuvastatin was studied in Chinese healthy volunteers. Prescreening of SLCO1B1 521TC and CYP2C9*1/*3 were performed before this pharmacokinetic study. Healthy volunteers who are SLCO1B1 521TT and CYP2C9*1/*1 wild-type homozygotes were selected to participate.

The pharmacokinetic parameters of rosuvastatin showed a significant difference between the two ABCG2 (421C>A) genotyped groups. The AUC (0–72) and AUC (0–) of rosuvastatin were much lower in the 421CC wild genotype group than in the mutation carriers (33.8 ± 11.4 vs. 59.6 ± 22.2 ng.h/ml, p = 0.018; 34.9 ± 11.9 vs. 62.2 ± 23.5 ng.h/ml, p = 0.018), respectively. The C(max) value was higher in the 421CA+421AA group than in the 421CC group (9.9 ± 5.4 vs. 5.1 ± 2.4 ng/ml, p = 0.048). The CL/F value was lower in the 421CA+421AA group than in the 421CC group (384.7 ± 161.2 vs. 674.0 ± 297.6 l/h, p = 0.043) (Figure 44.5).

The ABCG2 421C>A polymorphism may play an important role in the pharmacokinetics of rosuvastatin in healthy Chinese males after the exclusion of the impact of SLCO1B1 and CYP2C9 genetic polymorphisms. This was the first study on the association between ABCG2 polymorphism and rosuvastatin pharmacokinetics, which was further verified in a Finnish population and a Hong Kong Chinese population. Both PK and the low-density lipoprotein cholesterol response to rosuvastatin are associated with the ABCG2 421C>A polymorphism [11].

44.3.4 SLCO1B1

Organic anion transporting polypeptide 1B1 (OATP1B1) is a sodium-independent bile acid transporter, also known as liver-specific transporter 1 (LST-1) or OATP-C, encoded gene SLCO1B1. It is specifically expressed at the basolateral membrane of human hepatocytes and is responsible for the hepatocellular uptake of a variety of endogenous and foreign chemicals. A number of SNPs have been identified in the human SLCO1B1 gene. Our study clarified that common genetic polymorphisms occurred on OATP1B1 which had a potential impact on OATP1B1 function in Chinese populations.

For the first time, we found that the frequencies of the SLCO1B1 388G>A and 521T>C variant alleles in the Chinese population were 73.4% and 14.0%, respectively, which was close to that in the Japanese and Korean populations. The SLCO1B1*1a, SLCO1B1*1b, and SLCO1B1*15 are the three main haplotypes of SLCO1B1 in the Chinese population.

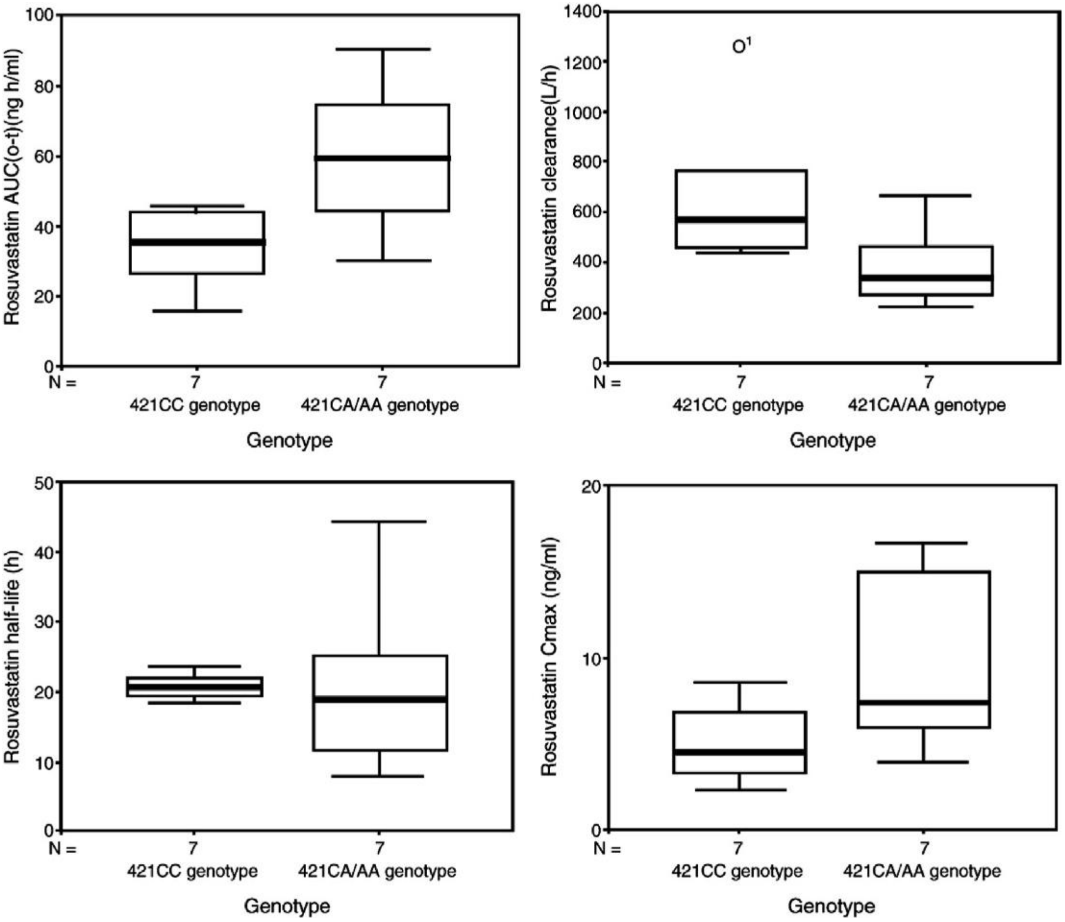

FIGURE 44.5 BCRP 421C>A genotype and the main pharmacokinetic parameters of a single dose of 20 mg rosuvastatin. Bars represent interquartile range; circles, outliers; lines across bars, mean. BCRP 421CC genotype group (n = 7), BCRP 421CA+421AA genotype group (n = 7).

Genetic polymorphism in SLCO1B1 is a major determinant of interindividual variability in serum bilirubin level. SLCO1B1 521T>C carriers had higher baseline serum UCB, T.BIL, and D.BIL levels compared with 521TT wild-type subjects. SLCO1B1 521CC subjects are more susceptible to hyperbilirubinemia. The serum bilirubin level could be increased by low-dose rifampicin administration, but the extent of elevation was not associated with the SLCO1B1 genotype.

We also found that OATP1B1-mediated hepatic uptake of nateglinide may be the prior step for its metabolism and elimination. SLCO1B1 521T>C SNP might play an important role in the pharmacokinetics of nateglinide. Total cholesterol level was significantly decreased after daily treatment with 20 mg pravastatin for 30 days in all patients. Moreover, subjects with the SLCO1B1 521C allele showed an attenuated total cholesterol-lowering effect compared with those homozygous for the 521T allele [12,13].

44.3.5 SLC30A8

Genome-wide association studies (GWASs) identified that SLC30A8 (zinc transporter) genetic polymorphism was a risk in type 2 diabetes mellitus (T2DM) in several populations. We investigated the association between SLC30A8 rs13266634 and rs16889462 polymorphisms and T2DM susceptibility and repaglinide therapeutic efficacy in Chinese T2DM patients. We conducted a case-control study of 443 T2DM patients and 229 healthy volunteers. The SLC30A8 rs13266634 risk C allele frequency was found to be higher in T2DM patients than in healthy controls ($P < 0.05$).

There was a better repaglinide response on FINS ($p < 0.05$) and PINS ($p < 0.01$) in patients with rs13266634 CT+TT genotypes compared with SLC30A8 CC genotype carriers. Patients with SLC30A8 rs16889462 GA genotype showed an enhanced repaglinide efficacy on FPG ($p < 0.01$), PPG ($p < 0.01$), and HbAlc ($p < 0.05$) compared with GG genotype individuals [14]. SLC30A8 rs13266634 and rs16889462 polymorphisms were associated with repaglinide therapeutic efficacy in Chinese T2DM patients.

44.4 PHARMACOGENOMICS OF DRUG RECEPTORS IN CHINESE POPULATIONS

44.4.1 β1-Adrenergic Receptor

The human β1-adrenergic receptor, an important therapeutic target in cardiovascular diseases, has two common functional polymorphisms (Ser49Gly and Gly389Arg). The distribution characteristic was clarified in Chinese Han healthy and those with essential hypertension. The allele frequencies of β1-adrenergic receptor 49Gly and 389Arg were 15.8% and 71.7% in healthy subjects, respectively. The effect of Gly389 polymorphism of the β1-adrenergic receptor on blood pressure and heart rate response to metoprolol was analyzed in a Chinese healthy population.

Exercise-induced heart rate increases were compared to determine the functional significance in vivo in 8 healthy Chinese men homozygous for Gly389 and 8 homozygous for Arg389. All of the subjects were given 25, 50, or 75 mg of metoprolol every 8 hours; the dosages were given in a random order, and each dosage was given for one day. The degree of β-blockade was measured as the reduction in resting and exercise heart rates and blood pressure. Plasma metoprolol concentrations were measured by the use of HPLC-fluorescence detection. Exercise led to a workload-dependent increase in heart rate. Oral metoprolol caused significant dose-dependent decreases in both resting and exercise heart rates in both groups. The reductions in the resting heart rate at 3 dosage levels of metoprolol were 6.3% ± 0.8% versus 4.1% ± 0.7%, 10.1% ± 1.0% versus 6.2% ± 1.1%, and 14.4% ± 1.4% versus 10.9% ± 1.3% in homozygous Arg389 subjects and Gly389 subjects, respectively ($p = 0.008$).

We also found differences with respect to the exercise heart rate (8.9% ± 0.5%, 14.0% ± 0.9%, and 20.1% ± 1.5% in Arg389 subjects and 6.6% ± 0.7%, 11.7% ± 1.0%, and 16.4% ± 1.3% in Gly389 subjects; $p = 0.017$) and systolic pressure (5.9% ± 0.7%, 9.2% ± 1.0%, and 11.6% ± 1.2% in Arg389 subjects and 4.6% ± 0.5%, 6.0% ± 0.8%, and 9.9% ± 0.9% in Gly389 subjects; $p = 0.011$). However, the difference in the fall in diastolic pressure was not statistically significant ($p = 0.442$). The Arg389 variant of the β1-adrenergic receptor was associated with a greater response to metoprolol than to Gly389 in young male Chinese subjects. These data suggested that the β1-adrenergic receptor Gly389Arg polymorphism is of major functional importance in Chinese healthy people.

In essential hypertension, the allele frequencies for 49Gly and 389Arg were 17.0% and 79.5%, respectively. There were significant differences in both genotype and allele frequency of Gly389Arg polymorphism between healthy and essential hypertension, which suggested that Gly389Arg may be involved in the pathophysiology of essential hypertension. The Arg389 variant of β1-adrenergic receptor was associated with a greater response to metoprolol than to Gly389 in young male Chinese subjects, which suggested that β1-adrenergic receptor Gly389Arg polymorphism is of major functional importance in vivo.

Therefore, we investigated the role of β1-adrenergic receptor polymorphisms on the blood pressure response to metoprolol monotherapy in the Chinese population with hypertension. Patients with certain β1-adrenergic receptor diplotypes—18 for 49Ser389Arg/49Ser389Arg, 15 for 49Ser389Arg/49Gly389Arg, 19 for 49Ser389Gly/49Gly389Arg, and 9 for 49Ser389Gly/49Ser389Gly—were selected for measurement of the antihypertensive effect of metoprolol. Patients were given 25 mg metoprolol every 12 hours for 4 weeks. The descent of systolic blood pressure after metoprolol administration was significantly different among genotype groups (10.4 ± 4.0%, 2.8 ± 4.7%, and 1.1 ± 1.5% for Arg389Arg, Gly389Arg, and Gly389Gly patients, respectively; p <0.001).

We also found a similar difference in changes of diastolic blood pressure (6.1 ± 4.3%, 2.2 ± 4.2%, and 0.9 ± 4.0%, respectively; p <0.001) and mean arterial pressure (8.1 ± 3.5%, 2.5 ± 3.0%, and 1.0 ± 2.5%, respectively; p <0.001) for Arg389Arg, Gly389Arg, and Gly389Gly patients. Ser49Gly variance exhibited a smaller contribution to the antihypertensive effect of metoprolol. Systolic blood pressure decreased significantly in Ser49 homozygous patients compared with Ser49Gly patients (8.4 ± 3.2% vs. 5.3 ± 5.2%; p = 0.047). There was a highly significant relationship between diplotype and blood pressure during treatment. Systolic blood pressure significantly decreased in 49Ser389Arg/49Ser389Arg (12.0 ± 3.8%, p <0.001) and 49Ser389Arg/49Gly389Arg (8.4 ± 5.5%, p <0.001) patients, with the decrease in the former being more pronounced (p = 0.023).

We also found a significant decrease in diastolic blood pressure (6.5 ± 4.7% vs. 5.7 ± 3.2%, respectively; both p <0.001) and mean arterial pressure (8.8 ± 3.2% vs. 6.9 ± 3.7%, respectively; both p <0.001) in 49Ser389Arg/49Ser389Arg and 49Ser389Arg/49Gly389Arg patients (Figure 44.6). β1-adrenergic receptor polymorphism was associated with different blood pressure responses to metoprolol therapy in patients with essential hypertension. 49Ser389Arg/49Ser389Arg and 49Ser389Arg/49Gly389Arg patients were good responders to metoprolol therapy; 49Ser389Arg/49Ser389Arg patients had a larger systolic blood pressure reduction than did 49Ser389Arg/49Gly389Arg patients. 49Ser389Gly/49Gly389Arg and 49Ser389Gly/49Ser389Gly patients were nonresponders to metoprolol antihypertensive therapy [15].

44.4.2 β3-Adrenergic rReceptor

β3-adrenergic receptor (ADRB3) belongs to the G protein-coupled receptor superfamily. It plays an important role in energy metabolism, which includes enhancing lipolysis, mobilization of free fatty acids into the circulation in white adipose tissue and thermogenesis in brown adipose tissue. ADRB3 is a potential target for antiobesity and antidiabetes therapy. We investigated the association between two novel ADRB3 gene polymorphisms (Ser165Pro and Ser257Pro) and type 2 diabetes (T2DM) in a Chinese population.

A total of 650 patients with T2DM and 1337 healthy volunteers were enrolled. Two candidate polymorphisms were recreated by site-directed mutagenesis and tested for their effect on ADRB3 expression and function in stable transfected human embryonic kidney 293 cells and Chinese hamster ovary-K1 cells. We found that both polymorphisms were significantly associated with T2DM (OR = 2.060 for Ser165Pro and 7.588 for Ser257Pro). T2DM patients with the Ser165Pro C allele had a higher hemoglobin A1c, fasting

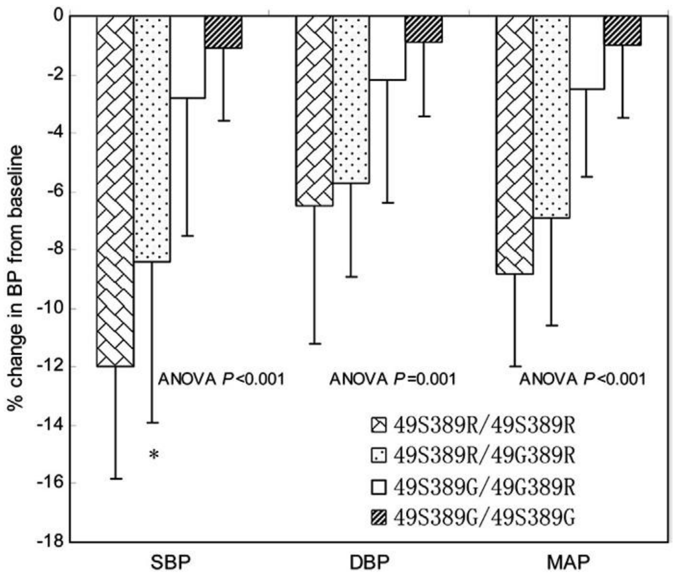

FIGURE 44.6 Blood pressure response to metoprolol monotherapy in patients with hypertension stratified according to β1-adrenergic receptor diplotypes. 49S389R/49S389R, n = 18; 49S389R/49G389R, n = 15; 49S389G/49G389R, n = 19; 49S389G/49S389G, n = 9. Data are presented as mean percentage decrease with SD. SBP—systolic blood pressure; DBP—diastolic blood pressure; MAP—mean arterial pressure. Asterisk denotes p = 0.023, compared with 49S389R/49S389R patients.

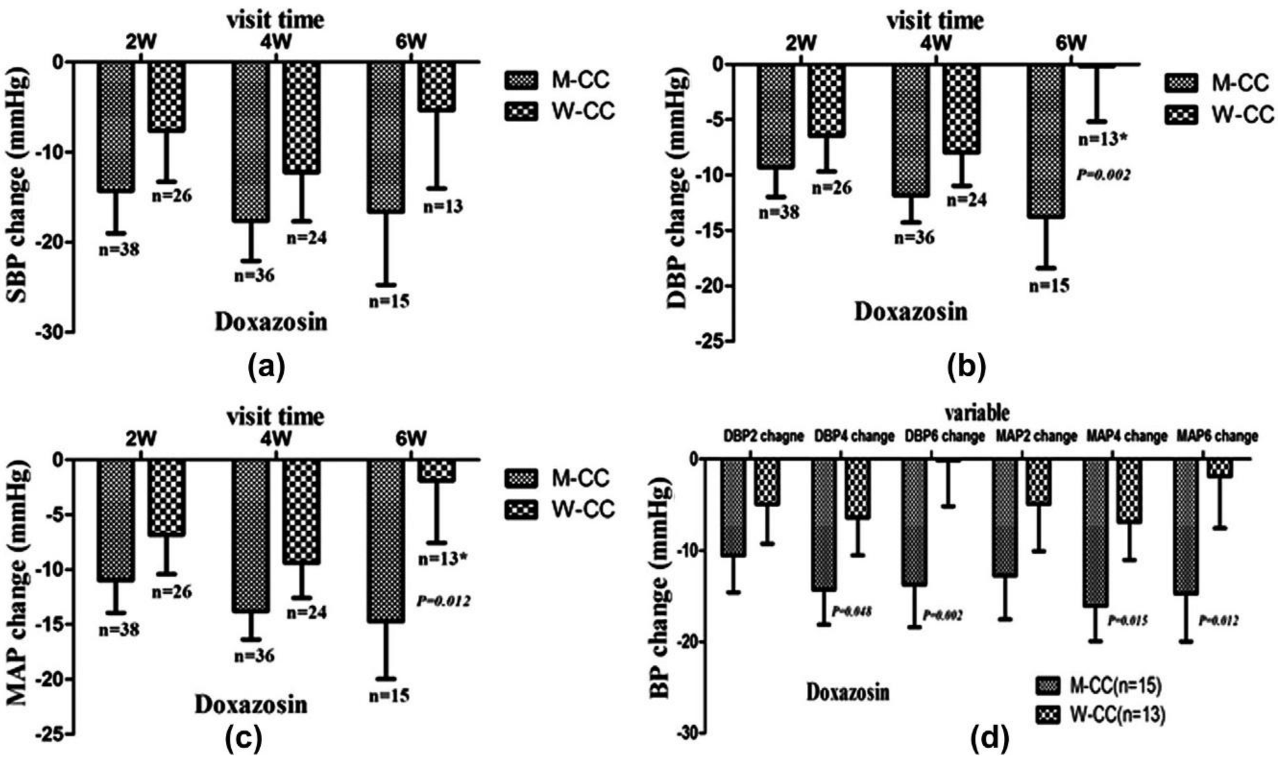

FIGURE 44.7 **KCNH2 (1956, C>T) genetic polymorphism in response to doxazosin is gender specific.** (a–c) depicts changes in systolic blood pressure, diastolic blood pressure, and mean arterial pressure in male CC genotype carriers versus female CC genotype carriers with essential hypertension after 2, 4, and 6 weeks of follow-up of those medicated with doxazosin. (d) No follow-up records were missed at the end of 2,4 and 6 weeks; the KCNH2(C195T) polymorphism related to doxazosin effect is gender-specific, *p <0.05 as compared with corresponding male CC carriers.

plasma glucose, and postprandial plasma glucose values than those in TT genotypes. We also found that patients with T2DM with the Ser257Pro C allele had lower fasting serum insulin, postprandial serum insulin, and homeostasis model assessment for insulin resistance levels than TT genotype carriers [16]. Further in vitro study indicated that cell lines stably expressing Ser165Pro and Ser257Pro mutants of the ADRB3 gene showed impaired cAMP accumulation activity.

44.4.3 PPAR-γ2

Pioglitazone is a prescription drug of the class thiazolidinedione (TZD) with hypoglycemic (antihyperglycemic, antidiabetic) action to treat diabetes. The influence of peroxisome proliferator-activated receptor γ2 (PPAR-γ2) gene polymorphism rs1801282 on the occurrence of type 2 diabetes and pioglitazone efficacy were studied in a Chinese Han population of 197 type 2 diabetes patients and 212 healthy controls. Among them, 67 T2DM patients were administered pioglitazone (30 mg/d, po) for three months. The PPAR-γ2 gene rs1801282 polymorphism was significantly associated with type 2 diabetes susceptibility (OR = 0.515). After pioglitazone treatment for three months, the T2DM patients with PPAR-γ2 rs1801282 CG genotypes showed significantly higher differential values of postprandial plasma glucose and serum triglyceride compared to those with rs1801282 CC genotype. Therefore, the diabetes risk allele in PPAR-γ2 (rs1801282) is also associated with pioglitazone therapeutic efficacy [17].

44.4.4 GABA Receptor

Carbamazepine (CBZ) is an anticonvulsant and mood-stabilizing drug used primarily in the treatment of epilepsy and bipolar disorder. The association between polymorphisms in gamma-aminobutyric acid (GABA) receptor genes and the tolerability and efficacy of carbamazepine monotherapy was investigated in 448 patients with partial-onset seizures. The effectiveness of CBZ treatment was evaluated with regard to efficacy by the decrease in seizures and tolerability by retention rates. Significant differences existed in the retention rates of CBZ over the 24 months of clinical follow-up with respect to the rs2290732 A/G polymorphism of the GABRA1 gene by Kaplan–Meier analysis (p = 0.001). For the CBZ treatment period, the overall retention rate was 50.7%. For the AA genotype, it was 62.9%; for the AG genotype 52.5%; and for the AA genotype only 28.2%. The rs2290732 A/G polymorphism of the GABRA1 gene might affect CBZ tolerability [18].

44.5 PHARMACOGENOMICS OF ION CHANNELS IN CHINESE POPULATIONS

44.5.1 KCNH2

KCNH2 (hERG) potassium channels have an integral role in regulating the excitability of smooth muscle cells. Some pathways driven by angiotensin II, nitric oxide, and adrenergic receptor blockers are involved in modulating the properties of KCNH2 potassium channels. These pathways are closely related to blood pressure regulation. Therefore, we hypothesized that KCNH2 genetic polymorphisms may affect blood pressure response to antihypertensive drug therapies. A total of 370 subjects with essential hypertension (EH) were studied to evaluate the interactions between KCNH2 genetic polymorphisms and individual blood pressure response to antihypertensive drugs. There were statistically significant interactions between KCNH2 (1956, C>T) polymorphism and DBP change ($p = 0.010$), and MAP change ($p = 0.014$) on azelnidipine or nitrendipine therapy patients at the end of six weeks. We found that the KCNH2 (1956, C>T) polymorphism was associated with the hypotensive effects of α,β-ADR blockers of DBP change at the end of four and six weeks of treatment in an age- and gender-dependent manner ($p = 0.007$ and 0.019, respectively).

Similar results were also observed for changes in MAP at the end of four and six weeks ($p = 0.035$ and 0.078, respectively). It was the first time that the KCNH2 (1956, C>T) polymorphism was found to be associated with the efficacy of antihypertensive CCBs and ADR blockers, and it may serve as a novel biomarker for individualized therapy for these antihypertensive drugs (Figure 44.7). We subsequently summarized the current pharmacogenomic studies on hERG potassium channels to provide a reference for developing individualized treatments and evaluating their safety. The genetic polymorphisms in hERG potassium channels are associated with many complex diseases and sensitivity to channel-related drugs. Genotypes may underlie different sensitivities to the same drug, and different drugs selectively repair the functional deficits caused by individual mutations (Figure 44.8).

In fact, not all drugs that block the hERG function have adverse affects, as previously thought. This suggests that the

TRENDS in Molecular Medicine

FIGURE 44.8 **Human hERG structure and polymorphisms.** Shown are a single hERG subunit containing 6-α helical transmembrane domains (S1–S6), a pore-forming loop (between S5 and S6), a C-terminal cyclic nucleotide-binding domain (cNBD), and N-terminal Per-Arnt-Sim (PAS) domains. Thirty KCNH2 SNPs are associated with hERG potassium channel sensitivity to about 70 drugs; polymorphisms leading to changes in channel properties are highlighted.

severe adverse reactions observed clinically may only occur in subjects with a certain genotype; others may be safe. Similarly, a drug that is ineffective in one population may be both safe and effective in another. Therefore, detecting KCNH2 polymorphisms is of great significance in guiding the prevention and treatment of related diseases, reevaluating drug safety, and individualizing treatment [19,20].

44.5.2 KCNQ1

KCNQ1 is a voltage-gated potassium channel present mainly in the cell membranes of cardiac tissue and in inner-ear neurons, among other tissues. We evaluated the effects of KCNQ1 rs2237892 and rs2237895 polymorphisms on repaglinide efficacy in Chinese patients with type 2 diabetes mellitus (T2DM). In all, 367 T2DM patients and 214 controls were genotyped. Forty of the T2DM patients were randomly selected to undergo 8 weeks of repaglinide treatment. The frequency of the rs2237892 allele was lower in the T2DM patients than in the control group ($p < 0.05$). The frequency of the rs2237895 C allele was higher in T2DM patients than in healthy control subjects ($p < 0.05$). Diabetic patients with the rs2237892 risk C allele had lower fasting insulin levels ($p < 0.01$) and homeostasis model assessment of insulin resistance (HOMA-IR; $p < 0.01$) values than carriers of the T allele.

Diabetic patients with the rs2237895 risk C allele had higher fasting plasma glucose ($p < 0.01$), postprandial plasma glucose (PPG) levels ($p < 0.01$) and HOMA-IR values ($p < 0.01$) than those with the A allele. Following repaglinide treatment, those T2DM patients with the rs2237892 T allele and rs2237895 C allele were more likely to have a positive response to repaglinide in terms of PPG levels ($p < 0.05$) than T2DM patients with the rs2237892 CC and rs2237895 AA genotypes [21]. Therefore, KCNQ1 rs2237892 and rs2237895 polymorphisms were associated with the therapeutic efficacy of repaglinide in Chinese T2DM patients.

44.5.3 KCNJ11

Kir6.2 is a major subunit of the ATP-sensitive K+ channel, an inward-rectifier potassium ion channel. The gene encoding the channel is called KCNJ11, and mutations in this gene are associated with congenital hyperinsulinism. We have shown that the polymorphism Lys23Glu is associated with a heightened risk of developing T2DM. We also explored the effects of the polymorphism on the efficacy of repaglinide therapy in Chinese patients with T2DM.

A total of 259 patients with T2DM and 188 healthy controls were genotyped. Forty patients with various genotypes were randomly selected to undergo an 8-week repaglinide treatment regimen. Patients with the G allele of the KCNJ11 Lys23Glu polymorphism showed higher levels of fasting plasma glucose (FPG) and postprandial plasma glucose (PPG) ($p < 0.05$). After repaglinide treatment, patients with the GA or AA genotype showed higher levels of FPG, PPG, and glycated hemoglobin (HbA(1c)) compared to patients with the GG genotype ($p < 0.05$) [22]. Thus, the KCNJ11 polymorphism was associated with repaglinide efficacy in this Chinese population.

44.5.4 SCN1A

The SCN1A gene belongs to a family of genes that provide instructions for making sodium channels, which transport positively charged sodium atoms (sodium ions) into cells and play a key role in a cell's ability to generate and transmit electrical signals. We investigated the tolerability and efficacy of carbamazepine treatment in patients with partial-onset seizures and the association with polymorphisms in the sodium channel α-subunit type 1 (SCN1A) among 448 Chinese Han patients. Monotherapy with CBZ was administered to the patients. The effectiveness of CBZ treatment was evaluated with regard to efficacy by the decrease in seizures and tolerability by retention rates. SCN1A rs3812718 A/G with CBZ tolerability ($p = 0.038$) throughout a 24-month clinical follow-up. The maintenance dose and serum level of CBZ in AA genotype carriers of rs3812718 A/G was significantly higher than those of GG genotype carriers between 3 and 12 months. The proportion of AA genotype carriers of rs2298771 A/G that were seizure free was significantly higher than that for AG+GG genotype carriers from 3 months to 15 months of follow-up ($p < 0.05$). Thus, SCN1A rs3812718 A/G polymorphism affected the tolerability of CBZ and rs2298771 A/G was associated with efficacy of CBZ treatment [18].

We subsequently investigated whether SNPs in the SCN1A gene could affect the retention rate of carbamazepine used to treat seizures in Chinese Han patients with epilepsy. In total, 448 patients were genotyped for SNPs selected in the SCN1A gene. The tag SNPs were selected using Haploview version 4.2 software (www.broad.mit.edu/haploview/haploview). Monotherapy with CBZ was administered to patients with new-onset focal seizures. In the present study, the retention rate of CBZ was defined as the percentage of patients with epilepsy who had continued with the treatment during the preceding three months.

Potential confounding variables were analyzed to evaluate the risk factors for nonretention. When adjusted for potential confounding factors (e.g., age, sex, body mass index, seizure type), the presence of the A allele of SNP rs3812718 predicted nonretention ($p = 0.015$; $OR = 3.122$). Beyond 12 months of treatment in those who continued with CBZ (retention cohort), analysis of covariance indicated that the maintenance dose ($p = 0.025$) and serum CBZ levels ($p = 0.021$) were significantly higher in carriers of the rs3812718 AA genotype than in those with the

GG genotype [23]. The results of the present study indicate that the rs3812718 SNP in the SCN1A gene is significantly associated with the retention rate of CBZ monotherapy in Chinese Han patients with focal epilepsy.

44.6 ENVIRONMENTAL FACTORS IN DRUG-METABOLIZING ENZYME AND TRANSPORTER ACTIVITY

44.6.1 CYP2C19-Mediated Herb–Drug Interaction

St. John's wort, an extract of the medicinal plant *Hypericum perforatum*, is widely used as an herbal antidepressant. More recently, its ability to induce both CYP3A4- and CYP2C19-mediated reactions has been well established. Twelve Chinese healthy adult men (6 CYP2C19*1/CYP2C19*1, 4 CYP2C19*2/*2, and 2 CYP2C19*2/CYP2C19*3) were enrolled in a two-phase randomized crossover design. After a 14-day treatment with St. John's wort, substantial decreases in plasma concentrations of omeprazole were observed. The peak plasma concentration (C_{max}) significantly decreased by 37.5% ± 13.3% (p <0.001) in CYP2C19*2/*2 or *3 and by 49.6% ± 20.7% (p = 0.017) in CYP2C19*1/*1; the area under the concentration–time curve (AUC) extrapolated to infinity—AUC (0–∞)—decreased by 37.9% ± 21.3% (p = 0.014) and 43.9% ± 23.7% (p = 0.011) in CYP2C19 mutant and wild genotypes, respectively.

Moreover, the C_{max} and AUC (0–∞) of omeprazole sulfone increased by 160.3% ± 45.5% (p <0.001) and by 136.6% ± 84.6% (p = 0.014), 155.5% ± 58.8% (p <0.001), and 158.7% ± 101.4% (p = 0.017) in mutant and wild genotypes, respectively. St. John's wort increased the C_{max} of 5-hydroxyomeprazole by 38.1% ± 30.5% (p = 0.028) and the AUC (0–∞) by 37.2% ± 26% (p >0.005) in CYP2C19 wild-type subjects, whereas it did not produce any significant alterations to the corresponding pharmacokinetic parameters in subjects with variant genotypes. Clinically relevant interactions with other drugs may occur and must be taken into account when St. John's wort is being taken [24].

44.6.2 OATP1B1-Mediated Herb–Drug Interaction

Baicalin is a flavone glucuronide purified from the medicinal plant *Radix scutellariae* through uridine diphosphate glucuronidation. Nowadays, baicalin has begun to be used in bilirubin-lowering therapy, both prescribed and over the counter, in China. We explored the potential herb–drug interaction between baicalin and rosuvastatin, a typical substrate for organic anion-transporting polypeptide 1B1 (OATP1B1) related to different OATP1B1 haplotype groups.

Eighteen unrelated healthy volunteers who were CYP2C9*1/*1 with different OATP1B1 haplotypes (six OATP1B1*1b/*1b, six OATP1B1*1b/*15, and six OATP1B1*15/*15) were selected to participate in this study. Rosuvastatin (20 mg orally) pharmacokinetics after coadministration of placebo and 50-mg baicalin tablets (three times/day orally for 14 days) were measured for up to 72 h in a two-phase randomized crossover study. After baicalin treatment, the area under the plasma concentration–time curve (AUC) (0–72) and AUC (0–∞) of rosuvastatin decreased by 47.0 ± 11.0% (p = 0.001) and 41.9 ± 7.19% (p = 0.001) in OATP1B1*1b/*1b, 21.0 ± 20.6% (p = 0.035) and 23.9 ± 8.66% (p = 0.004) in OATP1B1*1b/*15, and 9.20 ± 11.6% (p = 0.077) and 1.76 ± 4.89% (p = 0.36) in OATP1B1*15/*15, respectively (Figure 44.9). Moreover, decreases of both AUC (0–72) and AUC (0–∞) of rosuvastatin among different haplotype groups were significantly different (p = 0.002 and <0.001) [25]. Thus, baicalin reduces plasma concentrations of rosuvastatin in an OATP1B1 haplotype-dependent manner.

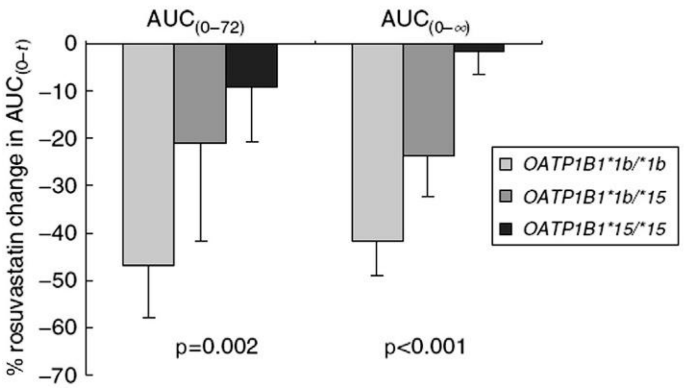

FIGURE 44.9 **Herb–drug interaction between rosuvastatin and baicalin is OATP1B1 genotype-related.** Comparison of mean change in the AUC (0–72) and AUC (0–∞) of rosuvastatin among *OATP1B1*1b/*1b*, *OATP1B1*1b/*15*, and *OATP1B1*15/*15* subjects after 14 days of treatment with baicalin compared with placebo. Data are expressed as mean ± SE.

44.7 TRANSLATIONAL APPROACHES TO PHARMACOGENOMICS IN CHINA

Translational medicine integrates research from the basic sciences, social sciences, and political sciences with the aim of optimizing patient care and preventive measures that may extend beyond healthcare services. The term was first used by the National Institutes of Health (NIH) in 2003 and was quickly picked up by the Chinese Natural Science Society. In 2006, AstraZeneca invested $100 million to fund an AstraZeneca Innovation Center and start translational medicine research in China; the aim is to develop Chinese-specific medicines.

In 2011, the first national translational medicine research center of China was funded in Shanghai; however, research on translational medicine had begun years before that. In 1993, Professor Hong-Hao Zhou funded China's first pharmacogenetics research institute. Contemporary common sense acknowledges the implementation of pharmacogenetics and genomics as the most successful and promising pathway of translational medicine. The work of Zhou is regarded as the actual start of translational medicine research in China. To date, more than nine translational research centers have been funded, including those at Peking University, Shanghai Institutes for Biological Sciences, Fudan University, Shanghai Jiao Tong University, Zhe Jiang University, Central South University, Wen Zhou University, Xia Men University, Guang Zhou Cancer hospital, and so on.

In the United States, the NIH and FDA play vital roles in sponsoring translational medicine research and keep expediting the translation of research from bench side to bedside. In China, institutions receive research funds from several different departments including the Ministry of Science and Technology, Ministry of Education, Chinese Academy of Sciences, and others. Key projects include the National High-tech R&D Program of China (863 Program), National Program on Key Basic Research Project (973 Program), National Basic Research Priorities Program of China, National Key Technologies R & D Program of China, National Natural Science Foundation of China (General Program; Key Program; Major Program), among others.

The Chinese government is spending millions of dollars each year to accelerate research and implementation in translational medicine. In addition, the whole field is overseen and regulated by the Ministry of Health (MOH). In the past few years, several companies have started businesses in pharmacogenomic molecular diagnosis and tried to provide personalized drug therapy via genotyping patients for certain genetic biomarkers. However, lack of legal permits has led to low-quality service from most companies. In 2013, MOH decided to issue the first regulations and standard operation procedures (SOP) for all laboratories involved in the clinical service of personalized medicine. Professor Hong-Hao Zhou's group has been selected to compile the regulations and SOPs, and is in charge of training and education for the nation. In addition, three model laboratories were selected: Xiang Ya Medical Lab Central South University, CapitalBio Corporation, and the first hospital of China Medical University to adopt the regulations and SOPs.

Pharmacogenomic translational research is still in an early phase in China, with many problems in application of the research findings. For instance, basic research needs to be strengthened and genetic markers that can definitely predict a drug's safety and efficacy need to be identified by comprehensive analysis based on pharmacokinetics and pharmacodynamics, efficacy, and toxicity as well. More attention should be given to translational research findings during the development of new drugs, and the clinical models of genetic tests for personalized medicine should be improved. In addition, education and training systems should be established for community health departments, medical institutions, medical students, doctors, and patients to promote public acceptance of personalized medicine.

44.8 CONCLUSION AND FUTURE PERSPECTIVES

The ideas of pharmacogenomics and personalized medicine have been accepted worldwide by medical institutions, drug administration agencies, and pharmaceutical companies; moreover, key technologies have gradually reached maturity with the support of major national programs. Thus, pharmacogenetics and pharmacogenomics will play more and more important roles in translational medicine and rational drug administration. It is believed that in the near future translational medicine and personalized medicine will become a major force in revolutionizing modern medicine in China and worldwide.

45.1 OVERVIEW

The study of pharmacogenomics in Latin American countries must take into account ethnic, cultural, socioeconomical, scientific, and technological disparities, in addition to the genetic heterogeneity and population diversity across the region. The Portuguese language distinguishes Brazil from all other Latin American nations in which Spanish is the official idiom. Although Native American (Amerindian), European, and Sub-Saharan African ancestral roots are common to all of Latin America, the relative proportions of each root vary markedly across nations: for example, the average Amerindian ancestry is considerably higher in Mexico and Peru, compared to Brazil and Cuba, whereas the opposite prevails with respect to African ancestry. Population heterogeneity is also present across geographical regions, among and within "ethnic/race/Color" categories in the same country, Brazil providing particularly rich examples [1,2].

Based on gross domestic product (GDP), Brazil ranks as the 6th and Mexico as the 14th largest world economies, whereas their neighbors, Argentina and Guatemala, rank 26th and 76th, respectively (Table 45.1). However, a considerably different picture emerges from the GDP per capita, with Brazil, Mexico, Argentina, and Guatemala appearing in the 78th, 65th, 52th, and 122th positions, respectively. Scientific and technological production, as assessed by the number of indexed publications by country of origin, has Brazil, Mexico, Argentina, and Guatemala in the 13th, 29th, 36th, and 125th positions, respectively. Not surprisingly, the extent of pharmacogenetics/genomics (PGx) investigation varies considerably across Latin America; Brazil, the focus of the present chapter, has been the main source of PGx information in Latin American countries (Table 45.1).

45.2 THE BRAZILIAN PHARMACOGENETICS NETWORK–REFARGEN

Brazil is the fifth largest country in the world and occupies an area of 8.5 million km^2. Its present population, in excess of 200 million individuals, is highly heterogeneous and admixed, a fact that has far-reaching consequences for PGx [3–5]. Recognition of this fact prompted the creation of a nationwide network—the Rede Nacional de Farmacogenética or Refargen [6], which presently comprises 20 research groups distributed over four of the five geographical regions of Brazil. These groups are described in the Refargen Internet site [7], and their major research interests are listed in Table 45.2.

Among Refargen's initiatives in recent years, we will mention the coordination of the Second Latin American Pharmacogenomics and Personalized Medicine Congress attended by a broad audience, mostly from Brazil, but also from Argentina, Chile, Colombia, Costa Rica, Cuba, Ecuador, and Mexico. Leading Brazilian and international

PGx experts were invited to contribute keynote lectures and to participate in a number of symposia. The conference covered topics related to the design, interpretation, and implications of PGx studies in Latin America, but also took on a more global approach to the growing contribution of genomic information and biotechnological tools to the way medicines are developed, regulated, and prescribed to patients [8].

In accordance with its mission to provide leadership in PGx research and education in Brazil, with impact on population health, Refargen has recently concluded a study of the distribution of PGx polymorphisms in a large, representative cohort of the overall Brazilian population [2,9–11]. The data generated by this study, available online [12], confirmed the substantial PGx diversity among Brazilians, depending on biogeographical ancestry,

self-reported “race/Color”[1] and geographical origin. The following sections review these findings and discuss their PGx implications.

45.2.1 Pharmacogenomic Diversity among Brazilians

The heterogeneity of the Brazilian population, well documented in a wealth of population genetic studies [2,13], is reflected in the distribution of PGx polymorphisms. Admixture of Amerindian, European, and sub-Saharan African parental populations is the major determinant of heterogeneity among Brazilians. Panels of ancestry-informative markers (AIMs) have been used to obtain estimates of the individual proportions of these ancestries in Brazilians. Figure 45.1 shows results obtained with a panel of insertion–deletion polymorphisms developed by Professor Sergio D. J. Pena from the Federal University of Minas Gerais, and validated as AIMs for the Brazilian population [2,14]. The data pertain to healthy, unrelated individuals, self-identified as white (n = 179) or black (n = 177), recruited in Rio de Janeiro and São Paulo, the two largest cities of Brazil. It is evident that the *individual* proportions of Amerindian, European, and African ancestry vary largely and in a *continuous* manner in both Color groups, especially among self-identified blacks for whom estimates of African and of European ancestry range between <0.01–0.99 and <0.01–0.96, respectively.

Another distinct feature of the plots in Figure 45.1 is the extensive overlap of the individual proportions of European and African ancestry in white and black individuals, which supports the notion that among Brazilians, correlation between Color categories and biogeographical ancestry is tenuous [2,15]. Despite the wide range and extensive overlap of individual proportions of European and African ancestry in both the black and the white cohorts in Figure 45.1, the average contribution of European ancestry is considerably higher in white (0.92, 0.86–0.95; median, first to third interquartile range) than black persons (0.34, 0.13–0.69), whereas African ancestry is much larger in self-identified blacks (0.54, 0.22–0.77) than whites (0.03, 0.02–0.06). The average proportion of Amerindian biogeographical ancestry in the white and black cohorts shown in Figure 45.1 is very similar, with median (interquartile range) values of 0.03 (0.02–0.06) and 0.04 (0.02–0.11), respectively.

The data used to construct the plots of Figure 45.1 were obtained from individuals recruited in the Southeast region of Brazil. Extrapolation to the overall Brazilian population must take into account the great variability in the relative proportions of Amerindian, European, and African ancestries among Color categories in different geographical regions [2]. Nevertheless, two major features of Figure 45.1 are common to the vast majority of Brazilians, and impact the distribution of PGx polymorphisms: (1) the European and African components together account for ∼90% of the biogeographical ancestry and (2) the individual proportions of European and African ancestry vary over wide ranges and, most important, as a continuum irrespective of self-reported color and geographical origin. Based on these two features, it is reasonable to anticipate that:

- The greater the difference in frequency of a given PGx polymorphism between European and sub-Saharan

---

[1] This chapter uses the race/Color classification adopted by the Brazilian Census, which relies on self-assessment of skin Color. Five categories are proposed: *branca* (white), *parda* (brown), *preta* (black), *indígena* (Amerindian), and *amarela* (yellow, meaning of Asian extraction). The term *Color* will be capitalized hereafter to call attention to its special meaning in the context of the Brazilian Census classification.

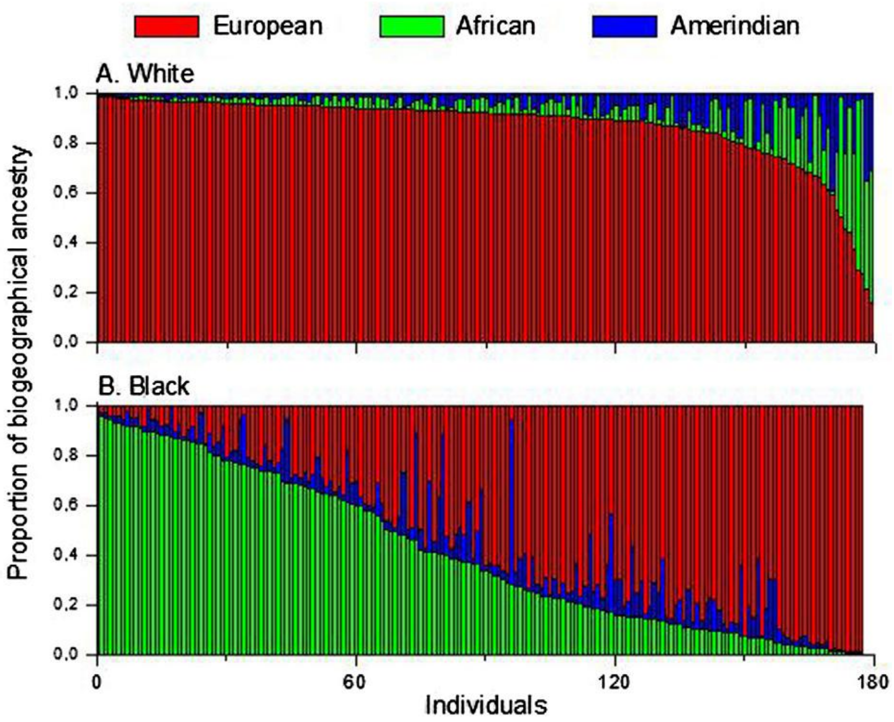

FIGURE 45.1 **Assignment of Brazilian samples to genetic clusters.** The genetic clusters are inferred from a panel of ancestry-informative markers and the program STRUCTURE. Data from unrelated, healthy adult residents in the Southeast region of Brazil, self-identified as white (n = 179) or black (n = 177), according to the color classification adopted by the Brazilian Census. Each individual is represented by a vertical line, which is partitioned in three colored segments corresponding to the estimated membership proportion in the African (blue), Amerindian (green), and European (red) clusters. *Source: Data from Suarez-Kurtz et al.* [9].

African ancestral populations, the more likely the polymorphism frequency will vary within the admixed Brazilian population.

- The difference in frequency of PGx polymorphisms between Europeans and Africans will be attenuated in white versus black Brazilians.
- The frequency of the PGx polymorphisms in Brazilians will vary continuously as a function of the individual proportions of European and/or African ancestry.

These predictions have been verified for a number of polymorphic pharmacogenes, including *CYP3A5* [16], *ABCB1* [11,17], *VKORC1* [9], and the *CYP2C* cluster [10]. The study of *VKORC1* was particularly informative since comparative data were obtained from Portuguese, by far the most important source of European migrants to Brazil, and sub-Saharan Africans from former Portuguese colonies—the origin of enslaved Africans brought to Brazil. The Brazilian cohort consisted of 1037 healthy, unrelated adults, self-categorized as white (n = 342), brown (350) or black (345), recruited in the context of a Refargen collaborative project in the North, Northeast, South and Southeast regions.

We consider this cohort representative of the present-day Brazilian population because 99% of Brazilians self-identify with one of these Color categories and 93% live in the geographical regions included in the study [18]. The African cohort consisted of 216 healthy adults from Cabinda, Angola (n = 73), Maputo, Mozambique (n = 143), and the Portuguese sample comprised 89 healthy adults recruited in Oporto.

The procedures used for allele discrimination of the *VKORC1* 3673G>A (rs9923231, standard coordinate –1639G>A, based on Genbank accession number AY587020), 5808T>G (rs2884737, 497T>G), 6853G>C (rs8050894, 1542G>C), and 9041G>A (rs7294, 3730G>A) single-nucleotide polymorphisms (SNPs) and for inference of their haplotypes were described in the original report [9]. Five haplotypes, namely GTGA, AGCG, GTGG, ATCG, and GTCG, occurred with frequencies >1% and accounted for >99% of the genetic diversity in Brazilians, Portuguese, and Africans (Table 45.3).

The haplotype frequency in white and black Brazilians was "weighted" according to the relative proportions of individuals self-identified with each Color in each geographical region, in the most recent Brazilian Census [19]. To give an example, white individuals in the North, Northeast, Southeast, and South regions represent, respectively, 18.3%, 4.4%, 52.1%, and 25.2% of the sum of white individuals in these four regions [18]. By multiplying these

TABLE 45.3 *VKORC1* Haplotype Frequency in Brazilians, Portuguese, and Sub-Saharan Africans (Angolans and Mozambicans)

Haplotype[a]	White Brazilians (347)[b]	Black Brazilians (353)[b]	Portuguese (89)[b]	Africans (216)[b]

[a] *VKORC1 haplotypes comprising rs9923231, rs2884737, rs8050894, and rs7294.* [b] *Number of individuals. Haplotype frequency expressed as mean (CI95%).*

Note: Sub-Saharan Africans include Angolans and Mozambicans.

percentages by the haplotype frequency in whites in the corresponding region, the weighted frequency for white Brazilians is obtained. A similar procedure was used to estimate the haplotype frequency in black Brazilians. The distribution of the *VKORC1* haplotypes did not differ between Angolans and Mozambicans ($p = 0.57$, χ^2 test) and the two datasets were combined in Table 45.3.

The distribution of the *VKORC1* haplotypes differed significantly ($p < 0.0001$) among the four cohorts shown in Table 45.3. Pairwise comparisons disclosed significant differences ($p < 0.0001$) in haplotype distribution between Portuguese versus Africans and white versus black Brazilians. However, as predicted by the European/African admixture of the Brazilian population (see preceding), the difference in frequency of each haplotype was markedly attenuated in white versus black Brazilians, compared to Portuguese versus Africans (Figure 45.2(a)).

In Figure 45.2(b), we contrast the differences in frequency of the *VKORC1* haplotypes by means of Wright's F-statistics (F_{ST}), a simple and efficient parameter to assess population diversity [20]. F_{ST} values are calculated using the expression

$$F_{ST} = \frac{(p_1 - p_2)^2}{(p_1 + p_2)(2 - p_1 - p_2)}$$

where p_1 and p_2 denote the frequency of a given allele or haplotype in population 1 and population 2, respectively. F_{ST} has a lower bound of 0, when the allele frequency is the same in the two populations, and an upper value of 1, when the allele frequency is 0 in one population and 1 in the other.

The extent of PGx divergence between any two populations is denoted according to Wright's qualitative guidelines [21]: F_{ST} values <0.05 represent low genetic divergence, between 0.05–0.15 represent moderate divergence, between 0.15 and 0.25 represent large divergence, and values >0.25, very large divergence. Accordingly, haplotypes AGCG and GTCG display large and moderate genetic divergence, respectively, in Portuguese versus Angolans/Mozambicans, but only low divergence in white versus black Brazilians, as a predicted consequence of Brazilian population admixture.

The F_{ST} analyses were extended to 44 individual polymorphisms in 12 important pharmacogenes affecting drug metabolism, transport, and effect, which had been genotyped in the Refargen cohort [19]. Pairwise comparisons between white, brown, and black groups in the entire cohort revealed low genetic divergence in general, with mean F_{ST} values of 0.005 (SD = 0.006), 0.013 (0.017), and 0.004 (0.005) for white versus brown, white versus black and brown versus black, respectively.

Only three SNPs, namely *CYP3A5*3* and the linked *SLCO1B3* 334T>C and 699G>A transitions exceeded the F_{ST} threshold for moderate genetic divergence (0.05) in white versus black Brazilians (Figure 45.3). For comparison, this figure shows the F_{ST}'s for the same polymorphisms in the HapMap CEU versus YRI groups, taken as proxies of European and sub-Saharan African ancestral populations. The F_{ST} values varied over a wide range (0.000–0.624) with a mean of 0.087 (SD = 0.118); 9, 4, and 4 SNPs displayed moderate, large, and very large divergence, respectively. The attenuation of pharmacogenetic divergence between white and black Brazilians compared to the HapMap populations is evident.

We suggested above that, as a predictable consequence of admixture, the frequency of PGx polymorphisms will vary continuously among Brazilians, as a function of the individual proportions of European and/or African ancestry. Logistic modeling using maximum likelihood estimation has been used by Refargen members to explore the association between PGx polymorphisms and the estimated individual biogeographical ancestry. A consistent finding in these analyses [9,10,16,17,22,23] is that the frequency

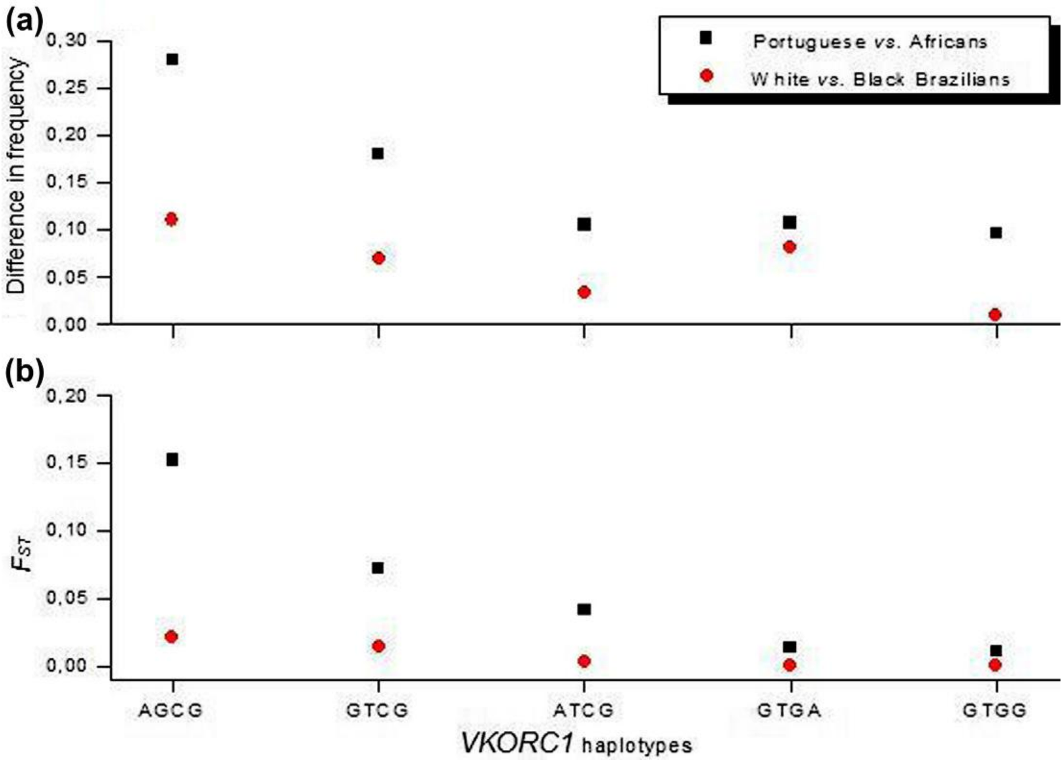

FIGURE 45.2 **Distribution of *VKORC1* haplotypes.** White (n = 347) and black (n = 353) Brazilians, Portuguese (n = 89), and Sub-Saharan Africans from Angola (n = 73) and Mozambique (n = 213). The haplotypes, comprising the rs9923231, rs2884737, rs8050894, and rs7294 SNPs, were inferred using the *Haplostats* software [61]. (a) Difference in haplotype frequency between white and black Brazilians and between Portuguese and Africans. FIGURE 45.3 **Allele-specific F_{ST} values.** F_{ST} values are for 40 PGx polymorphisms in HapMap CEU versus YRI and in white versus black Brazilians. The lines connect the F_{ST} values for each polymorphism in the two datasets and the box plots at the left and right summarize the ensemble of the data for each set. *Source: Data for Brazilians from Suarez-Kurtz et al.* [19] *and for CEU and YRI from the International HapMap project* [81].

distribution of PGx polymorphisms among Brazilians is best fit by continuous functions of the individual proportions of African and European ancestry. This is illustrated in Figure 45.4 with data for the *VKORC1* 3673G>A genotype, which is of major clinical relevance in relation to warfarin dosing and response in the Brazilian population (see below). The plot shows that the odds of having the heterozygous, and to a lesser extent, the homozygous variant genotype

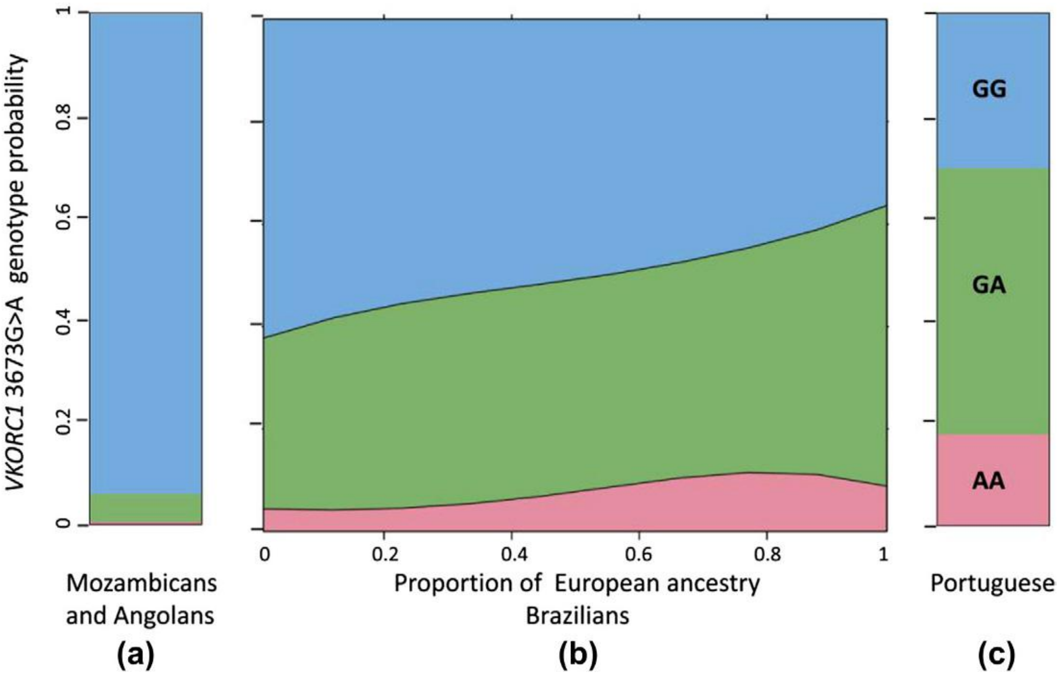

FIGURE 45.4 Effect display for the distribution of *VKORC1* 3673G>A genotypes in a logit model. The genotypes are fit to the data for African ancestry in 965 Brazilians (panel B). For comparison the frequency of each genotype in a cohort of Angolans (n = 73) and Mozambicans (143) (panel A) and in a Portuguese cohort (89) (panel C) are also shown. The individual proportion of African ancestry in Brazilians is shown on the x-axis. The y-axis represents the genotype probability for Brazilians and the observed genotype frequency for the African and Portuguese cohorts. *Source: Data from Suarez-Kurtz et al.* [9].

at the *VKORC1* 3673G>A locus increase progressively as the individual proportion of European ancestry increases in the overall cohort, irrespective of self-identified Color. For comparison, we also display in Figure 45.4 the distribution of *VKORC1* 3673G>A genotypes among Portuguese and sub-Saharan Africans, from Angola and Mozambique.

45.2.2 PGx Clinical Trials in Brazilians

The heterogeneity of the Brazilian population renders inappropriate the extrapolation of PGx data derived from well-defined ethnic groups. Only recently, recognition of this fact translated into PGx research on the clinical response to prescribed drugs in Brazilians, as illustrated in the following selected examples from studies carried out by Refargen groups:

- Rosario Hirata studied the PGx of HMG-CoA reductase inhibitors [24–26] and clopidogrel [27]
- Rosane Vianna-Jorge examined the impact of polymorphisms in the cyclooxygenase-2 gene and breast cancer risk and prognosis [28–30]
- Vanessa Mattevi investigated the *UGT1A1*28* variant allele as a predictor of severe hyperbilirubinemia in HIV-infected patients receiving highly active antiretroviral therapy (HAART) [31]
- Adalberto Santos and Ândrea K. Ribeiro dos Santos, in collaboration with Mara Hutz, explored the association between N-acetyltransferase 2 (NAT2) haplotypes and the hepatotoxicity induced by antituberculosis drugs in Southern and Northern Brazilians, respectively [32,33]

Our own studies covered the PGx of antipsychotics, HAART, immunosuppressants, L-thyroxine, levodopa, methylphenidate, nonsteroidal antiinflammatory agents (NSAIDs), statins, and warfarin. In the following sections, we review results from some of these studies.

45.2.2.1 Pharmacokinetics and Pharmacodynamics of NSAIDs

The implementation of regulatory legislation for generic drugs in Brazil during the late 1990s provided an impetus for local bioequivalence studies. The relatively large number of samples collected from healthy subjects under the rigorously controlled conditions of bioequivalence trials offer a favorable experimental setting for assessing the influence of PGx polymorphisms on pharmacokinetic parameters. We explored this opportunity to examine the impact of the defective *CYP2C9*2* and *CYP2C9*3* alleles on the pharmacokinetics and pharmacodynamics of NSAIDs, tenoxicam, and piroxicam [34,35]. Serial blood samples were collected for 240 hours following single oral doses (20 mg) of piroxicam (n = 35) or tenoxicam (n = 24); drug concentrations in plasma were measured by validated HPLC methods and

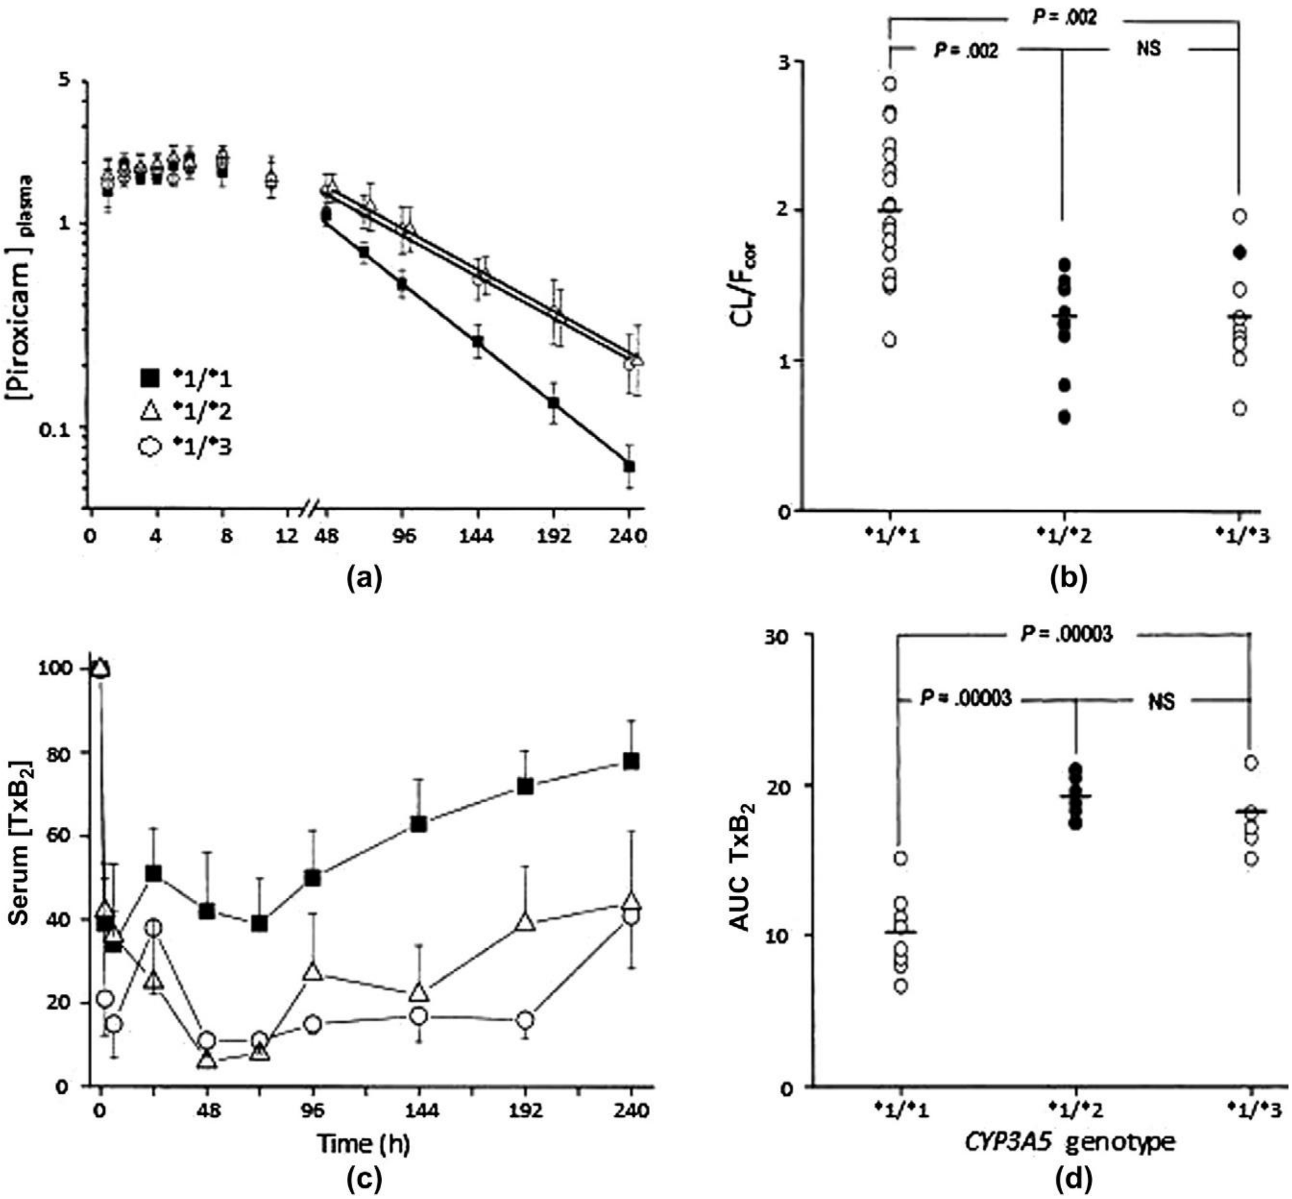

FIGURE 45.5 Influence of *CYP2C9* polymorphisms on the pharmacokinetics and pharmacodynamics of piroxicam. Data from 35 healthy subjects, expressing different *CYP2C9* genotypes (*CYP2C9*1/*1*, n = 19; *CYP2C9*1/*2*, n = 9; *CYP2C9*1/*3*, n = 9), after a single oral dose of piroxicam (20 mg) administered at time zero. (a) Piroxicam plasma concentration (μg/mL^{-1})-time curves; the lines are the best linear fit for the data points on the elimination phase (48–240 h). (b) Individual values of the oral clearance of piroxicam corrected for body weight (CL/F$_{cor}$, expressed as mL h^{-1} kg^{-1}. (c) Effect of piroxicam on the serum concentration time curves of TxB$_2$. Data are normalized to the baseline serum TxB$_2$ concentration and presented as mean ± SEM. (d) Individual values of the area above the time–effect curve from 0 to 240 h (TxB$_2$ AUC). To construct the plots in (d), the serum TxB$_2$ concentration at each time point was normalized to the respective baseline TxB$_2$ concentration, which was taken as 1 and the area above the time–effect curve from 0 to 240 h was integrated. The data are presented as TxB$_2$ h^{-1}). In (b) and (d), the horizontal bars are the median for each *CYP2C9* genotype, *P* values are for pairwise comparisons between *CYP2C9*1/*1* and either *CYP2C9*1/*2* or *CYP2C9*1/*3*, using the Student-Newman-Keuls test and individuals having one or two copies of the *CYP2C8*3* allele are identified by gray and black circles, respectively. NS = nonsignificant. *Source: Data from Perini et al.* [35].

noncompartmental pharmacokinetic analyses were applied to data analyses. Results obtained for both NSAIDS were similar and are illustrated here with data for piroxican.

Figure 45.5 shows the plasma concentration–time curves according to the *CYP2C9* genotypes. The area under the plasma concentration-time curve (AUC) was significantly greater in *CYP2C9*1/*2* or **1/*3* heterozygous, as compared to wild-type homozygous subjects (*CYP2C9*1/*1*). This effect was associated with and explained by the significantly lower oral drug clearance in heterozygous carriers of the *CYP2C9*2* or **3* alleles. There was no significant difference in the AUC or drug clearance between

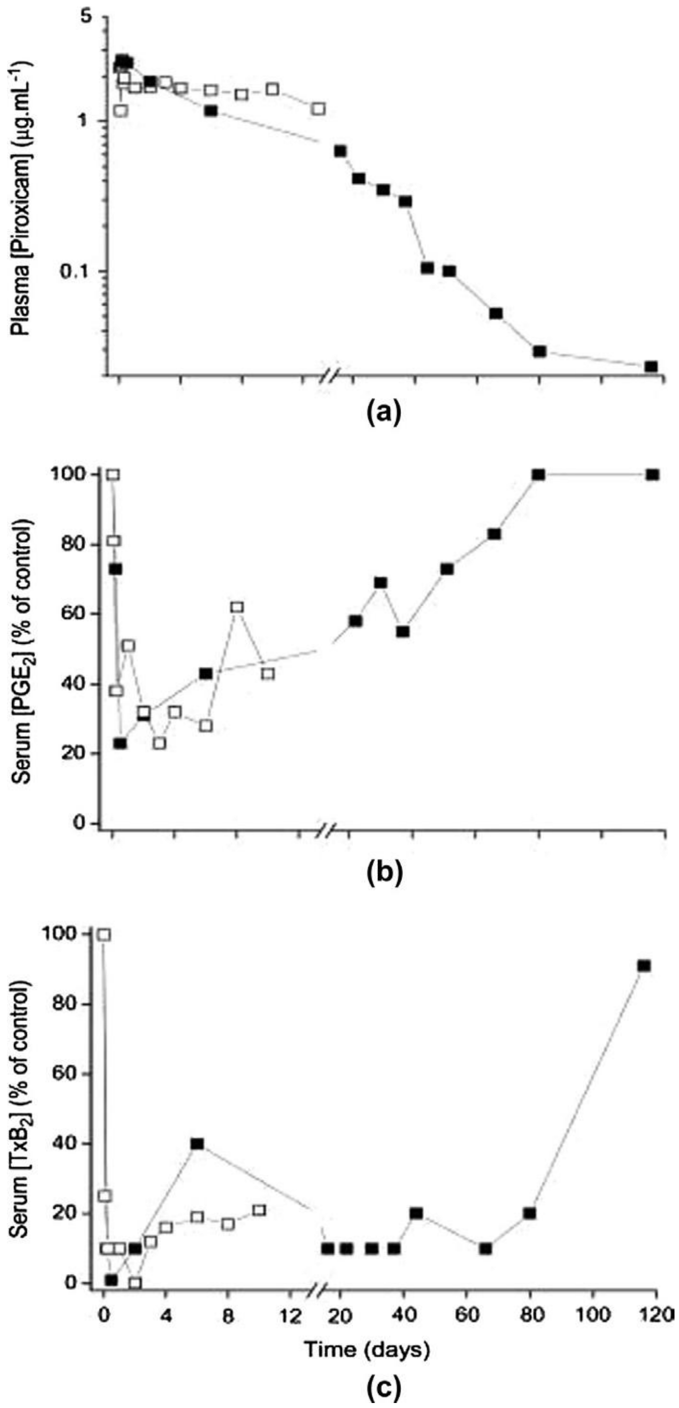

FIGURE 45.6 **Pharmacokinetic and pharmacodynamic data from a subject expressing the *CYP2C9*3/*3* genotype.** The data shown are for a period following administration of single doses of piroxicam (20 mg po) on two different occasions separated by six months. Blood samples were collected at various time intervals for 312 h and for 2784 h following administration of the first (open squares) and the second dose (solid squares), respectively. (a) Plasma concentration–time curves of piroxicam. (b, c) Serum concentration–time curves of PGE$_2$ and TxB$_2$, respectively; the data are normalized to the baseline serum PGE$_2$ and TxB$_2$ concentrations, measured 24 h (first dose) and 24–72 h (second dose) prior to each drug administration. *Source: Reproduced from Perini and Suarez-Kurtz* [36].

the *CYP2C9*1/*2* and **1/*3* heterozygous individuals. One individual in the piroxicam study had the *CYP2C9*3/*3* genotype, which is extremely rare in Brazilians [10].

The pharmacokinetic and pharmacodynamic consequences of this double-mutant genotype following a single dose of piroxicam were remarkable (Figure 45.6): (1) the

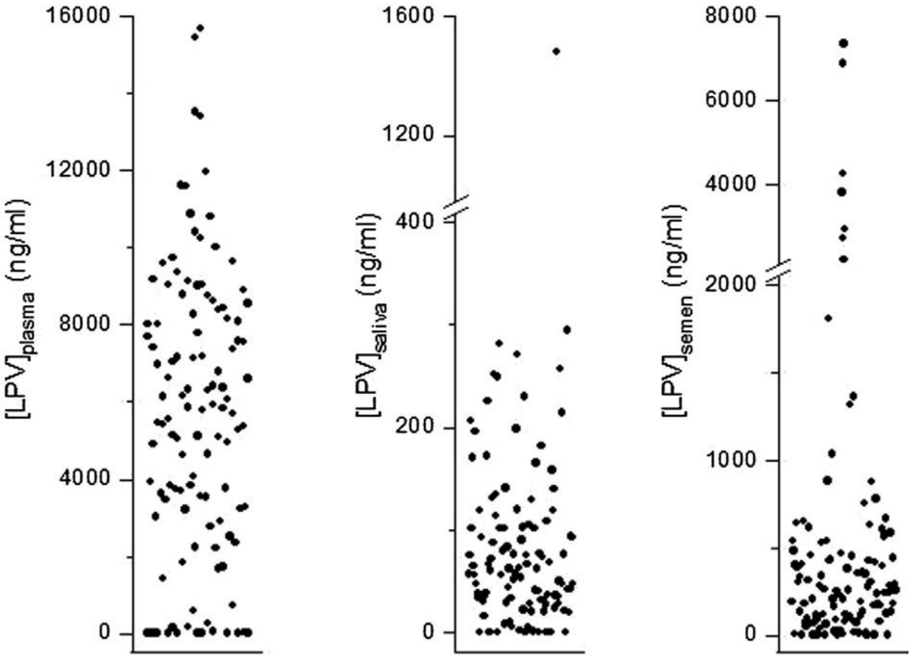

FIGURE 45.7 **Scatter plot of the distribution of trough (predose) concentrations of lopinavir.** Shown are the blood plasma (left panels), saliva (center), and semen (right) among 99 HIV-infected subjects. The individuals were under stable HAART treatment, including two daily doses of Kaletra® (400 mg lopinavir and 100 mg ritonavir). *Source: Data from Estrela et al.* [38].

half-life of elimination was extended to ~500 hours, the activity of cyclo-oxygenase 1 (COX-1), measured by the *ex vivo* production of thromboxane B2 (TxB_2), was maintained below 20% of its control value for more than two months; and (2) COX-2 activity, measured by *ex vivo* production of PGE_2, was reduced to <50% of its control value for more than one month! Nevertheless, no adverse effects were observed. These data led us to speculate on the potential advantages conferred by the PGx polymorphisms associated with impaired drug metabolism for long-term strategies in disease prevention and treatment [36].

45.2.2.2 Pharmacokinetics of Antiretrovirals

The Brazilian public health system pioneered, in the early 1990s, the universal access to HIV medications free of charge to all citizens who need it [37]. Ritonavir-boosted lopinavir formulations are frequently included in HAART regimens for HIV infection. Both these HIV protease inhibitors are substrates for CYP3A drug-metabolizing enzymes and the drug transporters ABCB1 (P-glycoprotein) and SLCO1B1. We studied the impact of polymorphisms in the *CYP3A5*, *SLCO1B1*, and *ABCB1* genes on the pharmacokinetics of lopinavir and ritonavir in 115 HIV-infected men under stable treatment with Kaletra® at the Hospital Universitário Clementino Fraga Filho, Universidade Federal do Rio de Janeiro. The study cohort was genotyped for *ABCB1* 1236C>T, 2677G>T/A and 3435C>T, *SLCO1B1* 521T>C, 388A>G, and 463C>A and CYP3A5*3 and *6 polymorphisms. The trough (predose) concentrations of lopinavir and ritonavir in blood plasma, semen, and saliva were measured and validated using LC/MS/MS methods.

Large interindividual variability in the concentrations of both protease inhibitors in the three matrices were observed, as illustrated in Figure 45.7 with data for lopinavir. Univariate and multivariate regression analysis revealed no influence of *ABCB1* genotypes or haplotypes on the concentrations of lopinavir and ritonavir in plasma, semen, and saliva [38].

We took advantage of the availability of plasma concentration data for lopinavir and ritonavir, from this cohort of HIV-infected men under stable HAART to examine the influence of CYP3A5 and SLCO1B1 polymorphisms on the pharmacokinetics of these protease inhibitors. The goal of the *CYP3A5* study [39] was to verify whether the reported impact of the *CYP3A5* genotype on the disposition of the HIV protease inhibitor (saquinavir) administered as a single dose and with no ritonavir boosting to Tanzanian healthy individuals [40] prevailed under a natural clinical setting.

The frequencies of *CYP3A5*3* and *CYP3A5*6* in the study sample were 0.67 (95% CI 0.61–0.74) and 0.05 (0.02–0.08), respectively. Assuming that alleles *CYP3A5*3* and **6* do not occur in the same DNA strand, the study participants were genotyped as **1/*1* (n = 11), **1/*3* (32), **1/*6* (1), **3/*3* (47), **3/*6* (6), and **6/*6* (1). The distribution of the trough concentrations of lopinavir and ritonavir in plasma among individuals having two (n = 11), one (33) or zero (54) *CYP3A5* functional alleles is plotted in Figure 45.8.

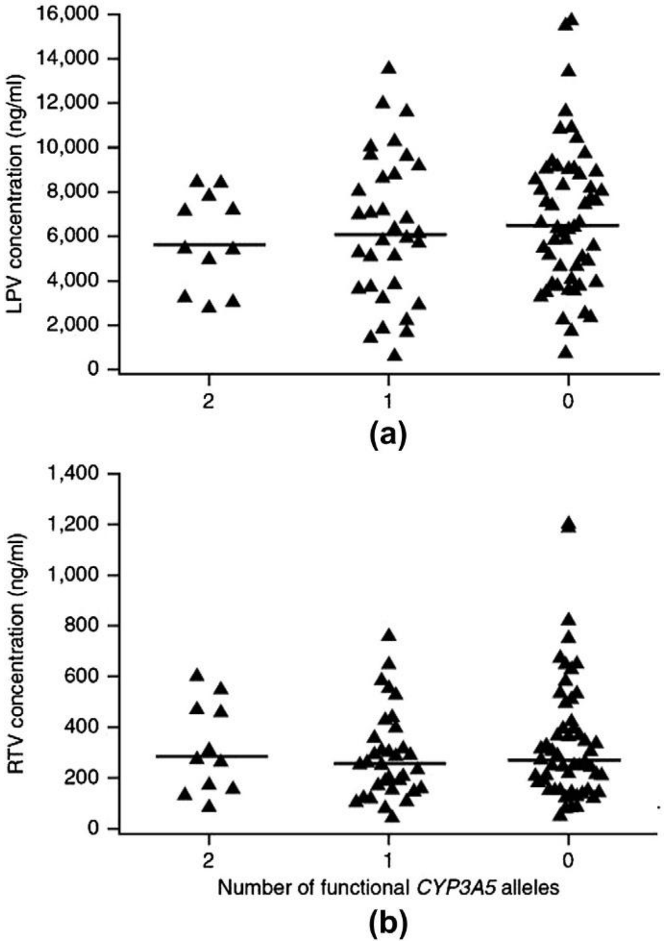

FIGURE 45.8 **Distribution of the trough concentrations of lopinavir (a) and ritonavir (b).** Shown are plasma among HIV-infected subjects with 2 (n = 11), 1 (n = 33), or 0 (n = 54) *CYP3A5* functional alleles (p = 0.65 for lopinavir and *P* = 0.78 for ritonavir; Kruskal-Wallis test). The lines denote the median values for each genotype. *Source: Reproduced from Estrela et al.* [39].

The overlapping of the plasma trough concentrations of each protease inhibitor among the three groups is evident and no statistically significant intergroup difference was detected for either lopinavir or ritonavir (Kruskal-Wallis test). We ascribed the apparent discrepancy between our results [39] and those of Josephson et al. [40] to ritonavir boosting, which was thought to occlude any pharmacokinetic consequences of functional polymorphisms in the *CYP3A5* gene. Together, the two studies highlight complementary steps towards the implementation of PGx in clinical practice: namely, the discovery of association(s) between genetic polymorphisms and pharmacological traits under specific experimental conditions, followed by examination of the impact of the association(s) in the targeted patient populations, studied in the relevant clinical setting.

HIV protease inhibitors are substrates of the SLCO1B1/OATP1 drug transporter, and a SNP (521T>C) in the SLCO1B1 gene was associated with plasma levels of lopinavir in HIV-infected individuals [41]. We examined this association in our cohort of HIV-infected men under stable HAART, and extended our analyses in two directions: (1) by examining two other SLCO1B1 SNPs (388A>G, 463C>A) and (2) by exploring the association of the SLCO1B1 polymorphisms with ritonavir plasma concentrations [42].

We observed no influence of the 388A>G and 463C>A SNPs on lopinavir or ritonavir plasma concentrations, but confirmed that carriers of the variant 521C had significantly higher lopinavir (but not ritonavir) plasma concentrations relative to the wild-type TT genotype. Reduced OATP-mediated uptake of lopinavir by the hepatocytes allele was thought to account for the increased plasma levels of lopinavir in carriers of SLCO1B1 521C. The clinical utility of this observation is uncertain, in view of both the extensive overlap of the trough concentrations of lopinavir in the plasma across the three 521T>C genotypes and the low prevalence (<3%) of the homozygous variant genotype (521CC) in Brazilians [43].

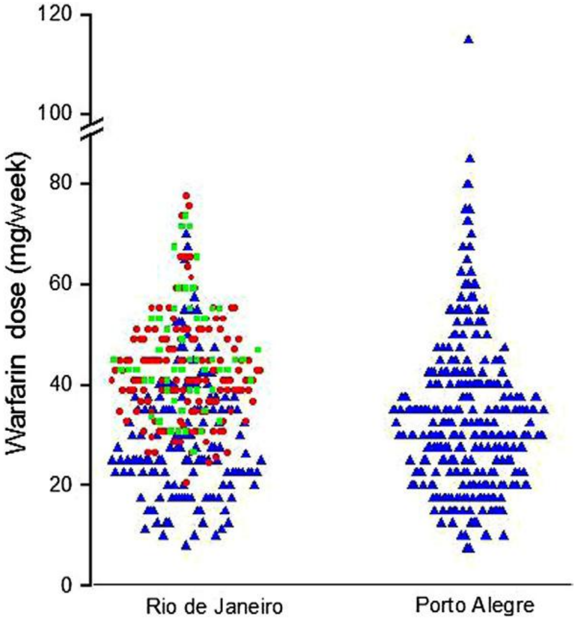

FIGURE 45.9 **Distribution of stable warfarin doses (mg week^{-1}) in two cohorts of Brazilian patients.** The Rio de Janeiro cohort (n = 390) included individuals who self-identified as white (n = 96, blue triangles) brown (118, red circles), or black (76, green squares). All Porto Alegre patients (n = 302, blue triangles) were white of exclusively European descent. *Source: Data from Suarez-Kurtz et al.* [47] *and Botton et al.* [4].

45.2.2.3 Warfarin-Dosing Algorithms for Brazilians

Warfarin combines several characteristics that make it a case study for personalized drug therapy. Several PGx algorithms have been described for the prospective estimation of individual warfarin dose requirements, but their performance varies considerably across populations [44]. This discrepancy is explained, in part, by the frequency distribution of polymorphisms in genes that influence warfarin pharmacokinetics (*CYP2C9*) and pharmacodynamics (*VKORC1, CYP4F2*). Our two groups examined the influence of polymorphisms in these and other pharmacogenes, as well as demographic and clinical variables on the interindividual variability in warfarin dose requirements for stable anticoagulation in Brazilian patients (Table 45.4). We then applied a two-step (univariate followed by multivariate) multivariate regression modeling to develop dosing algorithms for prediction of the appropriate warfarin dose for each patient [45–49].

The cohort studied by Suarez-Kurtz and colleagues consisted of 390 adult, ambulatory patients from a public hospital in Rio de Janeiro, self-identified as white (n = 196), brown (118), or black (76), under stable warfarin therapy. The individual warfarin dose requirement ranged from 3–78 mg/week (i.e., a 26-fold variation) and differed significantly ($P = 0.0004$, ANOVA) among white (28.9 ± 12.3, mean ± SD), brown (32.9 ± 12.4), and black patients (35.3 ± 14.6) (Figure 45.9). In the two-step regression analyses, the *VKORC1* 3673G>A genotype proved to be the most important predictor of warfarin dose, followed by the number of copies of variant *CYP2C9* alleles and cotreatment with amiodarone. Body weight, therapeutic indication for warfarin, age, and cotreatmtent with simvastatin were the other covariates associated with warfarin dose requirement.

A dosing algorithm with these covariates explained 51% ($R^2 = 0.51$) of the variability in warfarin dose requirement in the overall cohort and, most importantly, performed equally well in self-reported white and black individuals. This contrasts markedly with the considerably poorer performance of warfarin algorithms in African Americans versus white Americans (e.g., $R^2 = 0.51$ vs. 0.31) [50], which is not reversed by inclusion of a "race" term in the algorithms [50,51].

This discrepancy may be explained by greater admixture among Brazilians compared to Americans, in particular black Brazilians versus African Americans [1]. The *CYP4F2* rs2108622 (V33M) SNP had a marginal effect on the predictive power of the warfarin-dosing algorithm in this cohort [46], whereas the −401G>T and −402G>A SNPs in the coagulation Factor VII gene had no effect [52]. Subsequently, we showed that inclusion of a term relating the prescribed warfarin dose to the corresponding international normalized ratio (INR) value (INR/weekly dose) increased the predictive power of our warfarin-dosing algorithm to $R^2 = 0.61$ [47], which remains the highest among algorithms developed for admixed cohorts worldwide.

Data from the cohort studied by Suarez-Kurtz were included in the analyses carried out by the International Warfarin Pharmacogenetics Consortium [53], which led to the development of a "global" warfarin algorithm with "race" as a covariate, distinguishing white, Asian, black or African American, and mixed individuals. Despite the race

term, the performance of the IWPC algorithm was considerably better in white ($R^2 = 0.45$) than in Asian ($R^2 = 0.32$) or black patients ($R^2 = 0.29$), which supports the notion that the complexity of human diversity cannot be adjusted simply by a numerical coefficient.

A second, larger study of warfarin PGx in Brazilians was carried out by Mara Hutz and colleagues on 302 patients of exclusively European ancestry recruited in Porto Alegre, the largest the city in the South region of Brazil [48]. Extensive intraindividual variation in stable warfarin dose was observed (see Figure 45.9), and two dosing algorithms, comprising 12 and 18 PGx (polymorphisms in *VKORC1*, *CYP2C9*, and *CYP4F2*), clinical, demographic, and medication covariates, were derived.

The predictive power of these algorithms, $R^2 = 0.58$ and 0.63, respectively, are among the highest reported in the literature. However, when applied to the admixed Brazilian cohort from Rio de Janeiro, these algorithms did not reproduce their original performance: the R^2 values were 0.44 and 0.46, respectively, in the overall cohort, increasing to 0.49–0.50 in self-reported whites and declining to 0.37–0.40 in brown and black patients [49]. By the same token, the algorithm derived for the Rio de Janeiro cohort [45] had a comparatively inferior performance in the patients from Porto Alegre [48]. The poorer performance of the algorithms developed in one cohort when applied to the other may be in part a result of differences in biogeographical ancestry between the two study cohorts, exclusively European in Porto Alegre study versus admixed European/African/Amerindian in Rio de Janeiro.

Although these results seem consistent with the notion that warfarin-dosing algorithms "need to be population specific" [48], it is noteworthy that five algorithms derived from Caucasian patients performed poorly when tested in the Porto Alegre cohort of Brazilians of exclusively European ancestry [48]. Does that imply a "cohort specificity" *within* populations of European descent? Assuming that the frequency distribution of the relevant PGx polymorphisms is relatively constant among European-derived populations, does the observed discord in performance of warfarin algorithms reflect a greater than acknowledged contribution of nongenetic factors (e.g., diet, concomitant medication, concurrent diseases, compliance to warfarin prescription)? These are open questions at the present time that deserve further investigation.

45.2.2.4 Pharmacogenetics of L-Thyroxine in Differentiated Thyroid Cancer

Interindividual variation in T_4 doses required for adequate TSH suppression following thyroid ablation is considerable and involves multiple factors, including diet; comedication; comorbidities; and, possibly, genetic modulation of T_4 pharmacokinetics. T_4 has little biological activity per se, and is converted to the active form, triiodothyronine mainly in liver and kidney. Another major metabolic pathway for T_4 in humans is glucuronidation in the liver, mediated by UDP-glucuronosyl transferases (UGTs), mainly the UGT1A1 and UGT1A3 isoforms. We investigated the association between the required T_4 dose and a common *UGT1A1* polymorphism, namely *UGT1A1* –53$(TA)_n$, which consists of a variable dinucleotide repeat within the promoter TATA element, where $n = 5–8$; the longer the repeat allele, the lower the corresponding *UGT1A1* gene expression [54]. Patients were distributed in three groups according to the number (0, 1, or 2) of the low-expression $(TA)_7$ and $(TA)_8$ alleles they carried. A significant trend for decreasing T_4 dose with increasing number of copies of $(TA)_7$ and $(TA)_8$ and a significant difference in T_4 dose across the *UGT1A1* –53$(TA)_n$ genotypes were observed [55].

These results provided the first evidence for association between *UGT1A1*-53$(TA)_n$ and T_4 dose requirement for TSH suppression in a natural clinical setting. Of note, this study reflects real-life community prescribing and dispensing of T_4 in the context of public hospitals in a developing Latin American country. The relatively small (<20%), although statistically significant, difference in T_4 doses across the three *UGT1A1*-53$(TA)_n$ groups, combined with the considerable overlap in these doses, must be taken into consideration when assessing the clinical usefulness of the present results, which should be prospectively tested in an appropriately large cohort, and possibly extended to include polymorphisms in *UGT1A3* and *UGT1A9*.

45.3 PGX OF IMMUNOSUPPRESSANTS IN RENAL TRANSPLANT PATIENTS

The calcineurin inhibitors, cyclosporine A (CSA) and tacrolimus (TAC) are widely used to prevent allograft rejection after solid organ transplantation. Both these drugs display a narrow therapeutic index and high interindividual pharmacokinetic variability, such that monitoring their blood levels is required to improve efficacy and reduce toxicity. Achieving target therapeutic trough (predosing) blood levels (C_0) is of critical importance for CSA- and TAC-induced immunosuppression, especially during the initial period after transplantation when the risk of organ rejection is highest [56]. Multiple factors modulate the variability in C_0 of CSA and TAC, including polymorphisms in genes encoding for drug-metabolizing enzymes and transporters. CSA and TAC are metabolized by the CYP3A subfamily and are substrates of P-glycoprotein, a product of the *ABCB1* gene.

Polymorphisms in *CYP3A4, CYP3A5,* and *ABCB1* have been investigated as modulators of the pharmacokinetics and clinical effects of CSA and TAC in European, North American, and Asian populations with controversial results [57–60]. The extensive variation in worldwide frequency distribution of *CYP3A* and *ABCB1* polymorphisms is a caveat against extrapolation of these data to Brazilians. Recognition of this fact, and the availability of a large cohort of renal transplant patients from a reference center in Brazil,

[a] *Number of CYP3A5*3, *6, and *7 alleles.* [b] *Number of copies of the ABCB1 C/G/C (wild-type) haplotype.*

Source: Data from Santoro et al. [61], expressed as mean ± SD (number of observations).

provided the drive for our studies of the impact of *CYP3A* and *ABCB1* polymorphisms on the dose-adjusted trough concentrations (C_0/dose) of CSA and TAC in blood during the first three months after renal transplantation [61,62].

A total of 301 clinically stable patients were enrolled. Basic immunosuppression consisted of a combination of CSA/azathioprine (AZA, n = 97), CSA/sirolimus (SRL, n = 53), TAC/AZA (n = 101), or TAC/SRL (n = 50). Patient demographic characteristics and a complete description of the study protocol are presented in the original manuscripts. Fasting blood samples were obtained from all patients immediately before the scheduled morning dose, the C_0 of CSA and TAC was measured, and dose-adjusted trough concentrations (C_0/dose; ng.ml^{-1}/mg) in the first week (±3 days) and at 1, 2, and 3 months (±5 days) following renal transplantation were used for the statistical analyses. The target C_0 for CSA was 250–300 ng/mL during the first week, 200–250 ng/mL during the first and second months, and 100–150 ng/mL during the third month. For TAC, the target C_0 concentrations were 12–15 ng/mL in the first week, 10–12 ng/mL during the first month, and 8–10 ng/mL during the second and third months.

In our first study [61], all patients were genotyped for the defective *CYP3A5*3* (rs776746), *CYP3A5*6* (rs10264272), and *CYP3A5*7* (rs41303343) polymorphisms and for the *ABCB1* 1236C>T (rs1128503), 2677G>T/A (rs2032582), and 3435C>T rs1045642) SNPs. *CYP3A5* and *ABCB1* haplotypes comprising these alleles were input using the *haplostats* software [63]. We explored the effects of *CYP3A5* and *ABCB1* haplotypes, demographical, and clinical characteristics on the response variables CSA and TAC C_0/dose by fitting longitudinal mixed effects models to the data. The final multivariate model included covariates that achieved a significance level of $P < 0.05$.

The daily doses of CSA and TAC required to reach the target C_0 concentrations varied, respectively, 5- to 7.5-fold and 5.7- to 16-fold among patients at each observation time (1 week, 1, 2, and 3 months). Table 45.5 shows the CSA and TAC C_0/dose at these time points, according to the number of *CYP3A5* defective alleles and the number of copies of the wild-type *ABCB1* haplotype (C/G/C) at the 1236C>T, 2677G>T/A, and 3435C>T loci. In the longitudinal univariate analyses, the number of copies of the wild-type *ABCB1* haplotype—but not the number of variant *CYP3A5* alleles—associated with CSA C_0/dose throughout the observation period. However, this association was not confirmed in the multivariate analysis.

By contrast, the longitudinal univariate analyses revealed a highly significant association ($P < 0.0001$) between the TAC C_0/dose and the number of variant *CYP3A5* alleles; none of the other variables examined, whether pharmacogenetic, clinical, or demographic, were found to be associated with the TAC C_0/dose. These results precluded a multivariate analysis. The increasingly negative regression coefficients for the association between TAC C_0/dose and *CYP3A5*, as the number defective alleles decrease from two (default) to one (regression coefficient = −1.299) and then to 0 (regression coefficient = −1.907), pointed to a gene–dose effect consistent with the inferred CYP3A5 activity phenotype; that is, as the number of the defective

*CYP3A5*3*, **6*, and **7* alleles decrease, CYP3A5-mediated TAC clearance increases, requiring higher TAC doses to reach the target C_0 blood levels, which in turn leads to lower TAC C_0/dose values.

Although many studies have shown a clear association between the *CYP3A5*1/*3* polymorphism and TAC pharmacokinetics, our investigation disclosed two novel and important findings. First, we extended this PGx association to two other nonfunctional *CYP3A5* alleles, namely *CYP3A5*6* and *CYP3A5*7* which are common in black Africans and African-derived populations. A clinically relevant implication of these findings is that in populations of African descent, inference of CYP3A5 metabolic activity requires genotyping for *CYP3A5*6* and *CYP3A5*7* in addition to *CYP3A5*3*. Second, the inclusion of Brazilian patients with the *CYP3A5*1/*1* genotype, which is rare or absent in populations of European or Asian descent, allowed demonstration of a gene–dose effect of *CYP3A5* polymorphisms on TAC pharmacokinetics.

Our finding that the association of *CYP3A5* genotype and TAC C_0/dose was present throughout the observation period, including the first week after transplantation, supports the strategy, adopted in some transplant centers, of genotyping for *CYP3A5* polymorphisms prior to transplantation [64]. Of note, a recent prospective study showed that adaptation of the initial TAC-loading dose according to the patient´s *CYP3A5* genotype led to a faster achievement of TAC target blood concentration and increased the number of patients within the desired TAC target range early after transplantation [65].

We have recently extended our PGx studies of immunosuppressants to two *CYP3A4* polymorphisms, namely *CYP3A4*1B* (rs2740574) and *CYP3A4*22* (rs35599367), which were reported to associate with TAC pharmacokinetics and dose requirements in renal allograft recipients [58–60]. We genotyped the TAC patients in our Brazilian cohort for the *CYP3A4*1B* and *CYP3A4*22* SNPs and repeated the two-step (univariate followed by multivariate) regression modeling of the association between TAC C0/dose at three months after transplantation and *CYP3A* polymorphisms, including these two *CYP3A4* variants, in addition to the previously investigated C*YP3A5*3*, **6*, and **7* alleles. We observed strong linkage disequilibrium (LD) between *CYP3A4*1B* and *CYP3A5*3* ($D' = 0.798$) but no LD for any other allele pair.

Univariate linear regression analysis revealed no association between TAC C_0/dose and *CYP3A4*22* but highly significant associations with *CYP3A5* haplotype and *CYP3A4*1B* genotype. The latter two variables were entered into a bivariate regression model, which retained only *CYP3A5* haplotype as a significant predictor of TAC C_0/dose ($P < 0.0001$; see Santoro et al. [62]). The exclusion of *CYP3A4*1B* from the final model was ascribed to LD between *CYP3A41B* and *CYP3A5*3*.

In summary, we confirmed the significant impact of *CYP3A5* haplotypes—comprising the *CYP3A5*3*, *CYP3A5*6*, and *CYP3A5*7* alleles—on TAC C_0/dose in Brazilian renal allograft recipients but did not verify independent effects of *CYP3A41B* or *CYP3A4*22* on TAC dose requirements at three months after transplantation. Differences in the study cohorts and/or clinical settings may account for this discrepancy. This possibility supports the notion that extrapolation of PGx data across populations requires caution and may be inappropriate, pointing to the importance of performing clinical PGx trials in the target populations.

45.4 PGX OF ANTIPSYCHOTICS IN SCHIZOPHRENIC PATIENTS

Psychiatric disorders are common and have high levels of morbidity and mortality. They strike early in life and are usually lifelong and chronic disorders. Although there are a variety of pharmacological treatments available, response and tolerability to drugs are highly variable. In general, response and remission rates to pharmacological treatment are limited. There are several potential explanations for these poor drug response rates, including clinical heterogeneity and diagnostic uncertainty; comorbidity; and environmental, social, and genetic factors. PGx studies have been carried out with multiple classes of psychotropic drugs, with a primary focus on the interindividual variation in drug efficacy.

Most investigations performed in Brazil have used a candidate gene approach, usually based on the receptor pharmacology of the psychotropic agent. Antipsychotic drugs are the mainstay of schizophrenia treatment. When they were developed during the 1950s, typical neuroleptic drugs revolutionized the treatment of psychosis. These medications control the excitation, aggression, and restlessness as well as conceptual disorganization and thought disorders of psychosis in a considerable proportion of cases; however, they are limited in their use by their relatively narrow therapeutic index, especially because of extrapyramidal side effects. The Brazilian public health system considers the typical neuroleptics as the first choice to treat schizophrenia, due to their lower acquisition costs, availability of depot formulations and minimal metabolic risks, improving adherence to drug therapy and offering an affordable alternative.

Table 45.6 summarizes the major outcomes of pharmacogenomics studies on antipsychotics on Brazilians carried out by Mara H. Hutz and colleagues. Kolhrausch et al. [66] explored the influence of SNPs in *DRD2* and *DRD3* genes, as well as polymorphisms in the *CYP3A* subfamily (*CYP3A4* and *CYP3A5*), and the *CYP2D6* gene on typical neuroleptic response in a Brazilian sample of patients with schizophrenia. The schizophrenia diagnosis was based on

TABLE 45.6 Main Findings on Antipsychotics Response in Brazilian Patients

Drug	Gene	Outcome	p value	Reference
Typical neuroleptics		Treatment refractoriness		
	DRD2		NS	[66]
	DRD3		0.021	
	CYP3A4		0.014	
	CYP3A5		0.003	
	CYP2D6		NS	
Clozapine		Clinical response		
	GNB3		0.021	[70]
	5-HTT		0.03	[71]
		Tonic-clonic seizures		
	GNB3		0.018	[70]
	CYP1A2		0.033	[80]

Diagnostic and Statistical Manual of Mental Disorder-IV criteria. All patients were of European ancestry. The nonrefractory group (35%) consisted of patients who had experienced adequate and long-lasting response to treatment with typical neuroleptics, most patients receiving comedication (e.g., anticholinergics, lithium, or antidepressants).

The criteria for treatment resistance included treatment refractoriness (inadequate clinical response) and treatment intolerance (adverse effects). The *CYP3A4*–392A>G SNP was significantly associated with efficacy of neuroleptic treatment. Homozygous individuals for the –392A variant ($p=0.014$, $OR=3.32$) were more frequent in the treatment-resistant group compared with carriers of one copy of the –392G variant. The *CYP3A5* low-expressor genotype (*CYP3A5**3/*CYP3A5**3) was found to be associated with refractoriness to neuroleptic treatment ($P=0.003$, $OR=3.16$). Among the haplotypes observed in the *DRD3* gene, the T/A/G/A/C haplotype showed an association with refractoriness to neuroleptics ($P=0.021$, $OR=1.75$). This association showed that carriers of one copy of this haplotype presented intermediate values between noncarriers and homozygous individuals for the haplotype.

No association was observed with polymorphisms in the *DRD2* and *CYP2D6* genes. Multiple logistic regression analyses showed that the number of copies of *DRD3* T/A/G/A/C haplotype and *CYP3A5* low-expressor genotype were predictors of refractoriness to neuroleptics after controlling for selected risk factors. *CYP3A5*3* homozygous individuals carrying at least one copy of the *DRD3* T/A/G/A/C haplotype showed a higher risk to be refractory to neuroleptics than *CYP3A5*3* homozygotes *DRD3* non-T/A/G/A/C carriers ($P=0.019$, $OR=2.32$; 95% confidence interval = 1.08–5.02). These results suggest a role for *CYP3A5* and *DRD3* gene variants on refractoriness to neuroleptic treatment in Brazilians with schizophrenia; nevertheless, the effect sizes are small.

Among the repertoire of drugs used to treat the disorder, several meta-analyses have evidenced that the antipsychotic clozapine displays greater effectiveness compared to typical neuroleptic drugs. Although clozapine is associated to a superior clinical efficacy than other antipsychotics, only 30–60% of individuals resistant to typical antipsychotics respond to it. At the same time, clozapine displays undesirable adverse effects, such as agranulocytosis, weight gain, hypotension, somnolence, constipation, and several types of convulsive symptoms, including new-onset-generalized seizures [67–71]. Clozapine has a unique receptor-binding profile, which includes several target affinities, ranging from low to high, with dopamine D1-5; serotonin 5-HT1-3, 5-HT_6, and 5-HT_7; α_{1-2}, and β_{1-3}-adrenergic; muscarinic cholinergic M_{1-5}; and histaminergic H_1 and H_3 receptors [72].

Since genetic factors are believed to play a significant role in the variation of response to antipsychotics, and these drugs exert their therapeutic effects by competitive antagonism of postsynaptic GPCRs, Kolhrausch et al. [70] evaluated the effect of 825C>T polymorphism in the *GNB3* gene on the response of clozapine treatment in a Brazilian sample of patients of European ancestry with *DSM-IV* diagnosis of schizophrenia. An association between the *GNB3* 825C>T and clinical response to clozapine was observed. Homozygosis for the variant 825T allele was more frequent among nonresponders (27.3%) than among responders (10.6%), whereas homozygosis for wild-type 825C allele was observed with higher frequency among responders (47.0% vs. 27.3% among nonresponders) ($\chi^2=7.708$, $p=0.021$). When we pooled homozygous and heterozygous individuals for the 825T allele (825T carriers), significant difference between responders and nonresponders ($\chi^2=4.939$, $p=0,026$, $OR=2.36$ [95%CI 1.03–5.50]) was observed.

Since the serotonin transporter 5HTTLPR polymorphism is likely to influence 5HT concentrations at all synapses, allelic variation in 5HTT function may affect the response to almost any agent affecting the 5HT system, especially atypical antipsychotics that have a higher occupancy rate of serotonin receptors. The HTTLPR polymorphism has been found to be associated with antipsychotic drug response in several studies (reviewed in Wilffert, Zaal, and Brouwers [73]). Kolhrausch et al. [71] examined the possible association between polymorphisms in the *5-HTT* gene polymorphisms and response to clozapine in South Brazilian patients. Significant differences between responders and nonresponders to clozapine were observed in the 5′ regulatory region of the human *5-HTT*. The 5HTTLPR S allele was more frequent in patients who failed to respond to clozapine (60%) when compared to those who did respond (43%). Logistic regression analysis confirmed this association after controlling for confounding variables ($OR=3.15$; 95% $CI=1.13$–8.80; $p=0.03$).

New-onset-generalized seizures represent a great burden in schizophrenic patients' care and a substantial impact on medication adherence and response. Clozapine lowers the threshold for generalized seizures [74] but the exact mechanism is not fully understood. Kolhrausch et al. [69] observed that carriers of the *GNB3* 825T allele showed an increased risk for convulsive episodes ($\chi^2=5.607$, $p=0.018$); they also found that this association was independent of clozapine dose. The most plausible explanation for these findings is that G protein-activated inwardly rectifying K^+ (GIRK) channels play an important role in the inhibitory regulation of neural excitability in most brain regions through activation of various GPCRs [75].

It has been shown that GIRK channels are involved in seizure susceptibility [76], and dose-related inhibition of this function by antipsychotics can increase seizure susceptibility. Since clozapine strongly inhibits GIRK channels [77], this effect can explain the relationship between *GNB3* polymorphisms and seizures in patients exposed to this drug. Two recent studies [78,79] suggested that specific combinations of *CYP1A2* *1F and *1C alleles could induce lower messenger RNA (mRNA) expression and predispose to clozapine intolerance. In an attempt to partially corroborate this finding, we evaluated these two polymorphisms in a sample of South Brazilians with schizophrenia and their importance in the proconvulsive effect of clozapine [80]. We found the *1F/*1F genotype to be significantly associated with seizures under clozapine treatment ($p=0.033$, $OR=2.69$, 95% $CI=1.042$–6.940). Logistic regression analysis confirmed the importance of this genotype. No relationship was observed between combinations of *1F and *1C alleles.

At present, the challenge faced by research into the genetic basis of psychopharmacological drug responses is to identify genes with a relative small effect against a background of substantial genetic and environmental variations. Additionally, selection bias and factors, such as socioeconomic status or healthcare, may differ between individuals. Differences in studies' results may be due to heterogeneity among experimental protocols (i.e., treatment protocols, length of follow up, patient selection, allele classifications), as well as differences in allele frequencies between populations.

45.5 CONCLUSIONS

The kaleidoscopic diversity of the Brazilian population, with trihybrid biogeographical ancestry in Europe, Africa, and America affects the distribution of PGx polymorphisms and poses a caveat to extrapolation of PGx data from comparatively more homogeneous populations. These conditions prompted the creation of the Brazilian Pharmacogenetics Network, Refargen, the mission of which is to provide leadership in PGx research and education in Brazil and make an impact on population health.

A major challenge to PGx studies in Brazil is population stratification, which if not controlled for, may confound the outcomes of PGx association studies. Refargen researchers have developed ways to control for this challenge by combining ancestry-informative markers and appropriate statistical approaches. A distinct message that emerges from these analyses is that race/Color categorization does not capture the distribution of PGx polymorphisms among Brazilians, which is best modeled by continuous functions of the individual proportions of European and African ancestry, irrespective of self-identified Color. Recognition of this fact is important in the design and interpretation of PGx clinical trials in Brazilians but does not imply that PGx-informed drug prescription requires investigation of individual ancestry. Rather, individual genotyping should be directed to PGx polymorphisms of proven clinical utility for the specific medical condition being treated, irrespective of biogeographical ancestry.

Refargen groups have conducted PGx clinical trials involving a range of therapeutic medicines, and in the case of warfarin, derived dosing algorithms for clinical implementation. Adoption of these algorithms in the natural clinical setting of the Brazilian public health system and private practice faces the same barriers encountered worldwide, not only for warfarin but for PGx-informed prescription in general. The Refargen consortium contributes to overcoming these barriers through research, education, training, and consulting initiatives; these will benefit not only Brazilians but also other admixed Latin American peoples, who are infrequently enrolled in drug development programs by the international pharma industry.

Chapter 46

Pharmacogenomics in India

Umamaheswaran Gurusamy and Deepak Gopal Shewade
Pharmacogenomics Laboratory, Department of Pharmacology, Jawaharlal Institute of Postgraduate Medical Education and Research, India

Chapter Outline

46.1 Overview **1037**
46.2 Indian Population Structure and Diversity **1038**
46.3 Frequency Distribution and Pattern of Genetic Variants of Pharmacogenes **1039**
46.3.1 Drug-Metabolizing Genes 1039
46.3.2 Drug-Transporter Genes 1050
46.3.3 Drug-Target Genes 1051
46.4 Pharmacogenetic Studies in India **1052**
46.4.1 Anticancer Drugs 1052
46.4.2 Cardiovascular Drugs 1053
46.4.3 Oral Hypoglycemic Drugs 1054
46.4.4 Anticonvulsants 1055
46.4.5 Immunosuppressants 1055
46.4.6 Analgesics 1056
46.4.7 Antifolates 1056
46.5 Conclusions and Future Directions **1056**
References **1057**

46.1 OVERVIEW

In a given homogenous population, a significant proportion of patients confer resistance, some respond differently and some develop serious adverse effects when they are prescribed under the model of "one dose fits for all" medication [1]. The completion of the Human Genome Project and successive invention of comprehensive high throughput "omics" technologies has initiated a revolution in genomic medicine in the last few years [2]. Intriguingly, in spite of these advances in medical care, variability in drug efficacy and susceptibility to drug toxicity remains a major challenge in healthcare systems. Genetics not only plays a significant role in the elucidation of disease causation but also a major contributor to the disproportions in pharmacotherapy. Inherited (germline) or acquired (somatic) changes in the gene sequence that codes for the proteins involved in the absorption, distribution, metabolism, and excretion (ADME) of drugs are the principal cause of variability in treatment outcomes [3]. These genetic variations are now being applied to predict the dosage requirement, therapeutic response, and drug-induced toxicity in clinical medicine under the discipline pharmacogenetics and pharmacogenomics (PGx).

The goal of PGx-guided drug therapy lies in its ability to provide predictive, preventive, and personalized medicine with the application of genomic data in clinical practice. This aids researchers in understanding the causative genetic state for the altered pharmacokinetic and pharmacodynamic effect of a drug through assessment of an individual's genetic profile in conjunction with clinical and environmental covariates. Technological advances in human genetics have facilitated significant progress in PGx and stimulated its research from the level of single-nucleotide polymorphism (SNP) (monogenic) measurement to the comprehensive genome-wide approach (oligogenic). The adoption of new molecular-based methodologies and testing strategies has allowed both healthcare providers and pharmaceutical companies to expand and fine-tune the scope of clinical PGx beyond drug discovery, development, and clinical trials.

Interestingly, the concept and significance of interindividual variability was emphasized back in 460–370 BC by the Greek physician Hippocrates through his observation that "it is more important to know what sort of person has a disease than to know what sort of disease a person has." The hope of personalized medicine was foreseen in the 1800s by the Canadian physician Sir William Osler, who said, "variability is the law of life, and as no two faces are the same, so

Handbook of Pharmacogenomics and Stratified Medicine. http://dx.doi.org/10.1016/B978-0-12-386882-4.00046-3

no two bodies are alike, and no two individuals react alike and behave alike under the abnormal conditions we know as disease" [4]. Later, during the 1930s, the documentation of the racial variability in taste blindness for phenylthiocarbamide by Snyder marked the beginning of PGx [5]. Nevertheless, the term "pharmacogenetics" was first coined and published by the German physician Friedrich Vogel in 1959 [6]. Since then PGx has evolved into a major driving force as a result of a series of discoveries that have heightened its development.

As with most drugs, research focuses on identifying genetic markers that will predict the safety and effectiveness of a drug. Because of emerging genomic knowledge, the US Food and Drug Administration (FDA) now requires PGx-related information and warnings on drug labels [7]. The scope of this present chapter is intended to provide up-to-date information on the status of pharmacogenomics research in the Indian population. We focus on the pharmacogenetic studies in our laboratory on drugs such as anticancer drugs, antiestrogen agents, antiplatelets, anticoagulants, HMG-COA reductase inhibitors, oral hypoglycemic medications, anticonvulsants, and analgesics. Further, we summarize the data from other therapeutic groups in India and discuss the challenges, current controversies, knowledge gaps, and strategies surrounding the application of PGx testing in personalized medicine for Indians.

46.2 INDIAN POPULATION STRUCTURE AND DIVERSITY

India is the seventh largest country by area, occupying around 3,287,263 km^2 and contributing about one-sixth of the global population. Presently it is home to more than 1.2 billion and is the most peopled nation in the world after China [8]. The Indian population is encompassed of numerous subgroups that are extensively diversified by their genetic constitution, language, geography, and religious, sociocultural, and ancestry components. These distinguished features together render them a unique resource of PGx heterogeneity compared to the rest of the world. Today, there are 6 religions (Hinduism, Islam, Christianity, Sikhism, Buddhism, and Jainism), 4693 different communities with many thousands of endogamous groups, 325 functioning languages, and 25 scripts in the Indian subcontinent [9].

Modern-day Indians are morphologically classified into four primary ethnic strains and belong to the following groups: Caucasoid, Mongoloid, Proto-Australoid, and Negrito (Figure 46.1). The Caucasoids and Proto-Australoids predominate and are mostly confined to Northern and Southern India, respectively. The Mongoloids live along the Himalayan fringe of Jammu and Kashmir and in the northeastern region of the country, while the Negritos are restricted to the Andaman and Nicobar Islands.

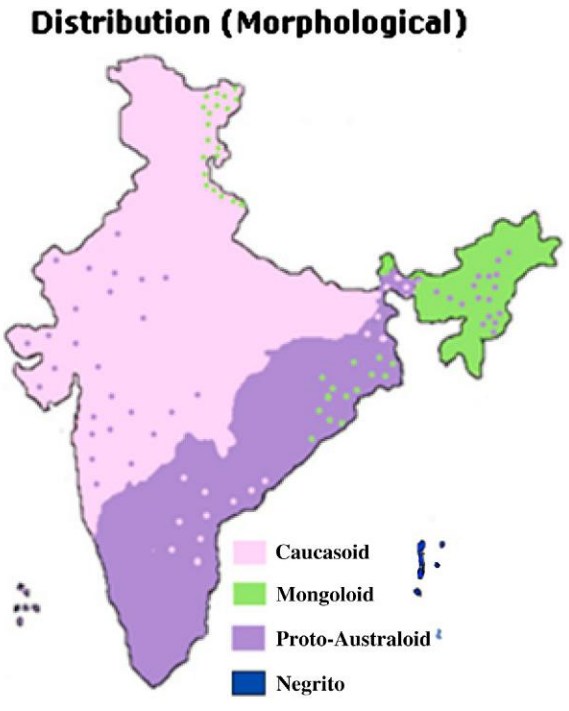

FIGURE 46.1 Morphological distribution of Indian populations. (*Reprinted from "The Indian Genome Variation database (IGVdb): a project review by Indian Genome Variation Consortium, 2005 Hum Genet"*)

The indigenous Negritos are believed to be the descendents of the first humans who migrated out of Africa about 65,000 years ago. The languages spoken by Indians have been broadly classified into four major linguistic families, as shown in Figure 46.2: Austro-Asiatic (Nishada) speakers are tribals and believed to be the most ancient inhabitants; their dialect is spoken by people mostly in Central, Eastern, and Northeastern India. Dravidian (Dravida) is predominantly spoken by Southern Indians. Indo-European (Aryan) is widely spoken in Northern India. And Tibeto-Burman (Kirata) is limited to the population of Northeast India, which is made up of immigrants from Tibet and Myanmar.

As a consequence of different waves of migration and invasion at different periods in history, India is also peopled by several recently drifted populations, and this has led to the admixture of various racial groups within the innate populations. Perhaps nowhere else in the world has the magnitude of genetic diversity in India been observed except for Africa. The contemporary populations are the intermixture of two contrasting ancestral groups—the ancestral North Indians (ANI) and the ancestral South Indians (ASI). About 30–70% of the ANI are genetically identical to the populations of the Middle East, Central Asia, and Europe. Conversely, the South Indians are Dravidian speakers who do not share their genetic signatures with any other global racial groups [10].

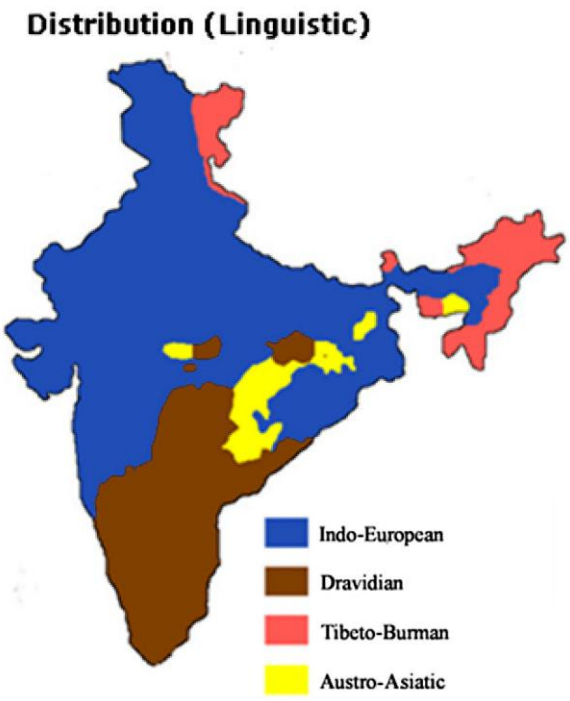

FIGURE 46.2 Linguistic distribution of Indian populations. (*Reprinted from "The Indian Genome Variation database (IGVdb): a project review by Indian Genome Variation Consortium, 2005 Hum Genet"*)

46.3 FREQUENCY DISTRIBUTION AND PATTERN OF GENETIC VARIANTS OF PHARMACOGENES

The frequency of polymorphic variants in ADME pharmacogenes are well known and exhibit wide inter- and intraethnic variability among global populations. Existing evidence suggests that knowledge of genetic variations is essential to better understand ethnic differences in disease occurrence, development, prognosis, therapeutic response, and toxicity. In addition, population-specific information regarding the normative frequency distribution of pharmacogenetic variants can serve as a basis for defining sample sizes for genotype–phenotype association studies.

Current studies in India have established the normative frequency of clinically important pharmacogenes, but most of them have analyzed a limited number of samples from South and North Indian populations [11–14]. Keeping in mind the extent of genetic heterogeneity, the results from these studies cannot be extrapolated to the entire Indian population. Recently, we compiled normative frequency data on genes coding proteins involved in drug metabolism and drug transport in various geographical regions of India and reported from different studies. These data have been pooled as North Indians (NI), South Indians (SI), and North East Indians (NEI) based on these population's ancestral ethnicity [11]. In this comprehensive review, we found that there is racial delineation between Indians and other major global populations. Also, we found significant intraethnic differences in the distribution of the molecular variants of ADME genes. In a previous study [15], we reported significant heterogeneity in the frequencies of *UGT1A1* and *MDR1* alleles among the four South Indian subpopulations.

Interestingly, allele frequency differentiation among Indian populations is greater than that of European populations. This is due to the strong founder effect and strict endogamy practice [10]. Table 46.1 presents normative frequency data on pharmacogenetic variants in ADME pharmacogenes that modulate drug action at various levels in Indian populations. These variants include *CYP1A1*, *CYP1A2, CYP2A6*, *CYP2C8*, *CYP2C9*, *CYP2C19*, *CYP2D6*, *CYP2E1*, *CYP3A4*, *CYP3A5*, *GSTT1*, *GSTM1*, *GSTP1*, *UGT1A1*, *UGT1A7*, *TPMT*, *SULT1A1*, *COMT*, *NAT2*, *MDR1*, *OCT1*, *SLCO1B1*, *CYP19A1*, *VKORC1*, *MTHFR*, and *ACE*.

46.3.1 Drug-Metabolizing Genes

46.3.1.1 CYP1A1

CYP1A1 is an important member of the CYP1A family that is responsible for the metabolic activation of procarcinogens (polycyclic aromatic hydrocarbons and aromatic amines) into reactive metabolites. It also participates in the metabolism of steroidal hormones including estrogens. The *CYP1A1* gene is mapped on chromosome 15q22-q24, spanning 5810 bp and composed of 7 exons and 6 introns. Though several polymorphisms have been previously identified for the *CYP1A1* gene, much attention has been given to *CYP1A1 *2A* or *m1* (also known as *Msp1*), *CYP1A1*2C* or *m2*, *CYP1A1*3* or *m3* and *CYP1A1*4* or *m4* polymorphisms.

Genetic polymorphisms of the *CYP1A1* gene alters the enzyme activity and has been shown to be associated with different cancers such as carcinoma of breast, colon, ovary, lung, oral cavity and acute lymphoblastic leukemia (ALL). The prevalence of polymorphic alleles *CYP1A1*2A* and *CYP1A1*2C* is significantly different among the Indian populations and also in comparison with other populations. On the other hand *CYP1A1*3* is absent in Indians, while *CYP1A1*2B* (9.5%) is seen only in NEI, which is significantly different from other populations. The frequency of *CYP1A1*4* in NEI (40.5%) is different from that in NI (3%), Caucasians (4.3%) and Africans (1.2%), but this allele is absent in Asians. Conversely, *CYP1A1*4* frequency in NI matches that in Caucasians but is different from that in Africans [11].

46.3.1.2 CYP1A2

Cytochrome P4501A2 (CYP1A2) is involved in the bioactivation of procarcinogens into carcinogenic substances. In addition, CYP1A2 contribute to the metabolism of

DME—drug-metabolizing enzymes; NI—North Indians; SI—South Indians; NEI—North East Indians; AA—aminoacid; nd—data not available.

Adapted from "Distribution of genetic polymorphisms of genes encoding drug metabolizing enzymes & drug transporters - a review with Indian perspective" by Umamaheswaran et al. 2014, Indian J Med Res [11].

therapeutic drugs including caffeine, clozapine, olanzapine, amitriptyline, R-warfarin, verapamil, theophylline, propranolol, clomipramine, imipramine, haloperidol, and acetaminophen. Further, the association of *CYP1A2* polymorphisms with increased risk of various cancers has been reported. The gene encoding CYP1A2 is located on chromosome 15q22 with 6 exons, extending 7.8 kilobases (kb).

In total, more than 150 different polymorphisms have been reported in *CYP1A2*. Nevertheless, the functional significance has been described only for *CYP1A2*1C (−3860G>A)* and *CYP1A2*1F (−163C>A)* polymorphisms. The only study that determined the frequency of *CYP1A2* in any of the Indian population was carried out in NI population with a frequency of about 8%, 24.5%, 9.5%, 50.7% and 0% respectively for *CYP1A2*1C, *1D, *1E, *1F* and **2* alleles [11]. Comparison between NI and other major populations exhibited significant interethnic differences.

46.3.1.3 CYP2A6

CYP2A6, a phase I drug metabolizing enzyme (DME) which metabolizes about 3% of pharmaceutical agents including letrozole, tegafur, coumarin, valproic acid, methoxyflurane, artesunate, disulfiram, halothane and fadrozole. Additionally, it also metabolizes nicotine, retinoic acids, environmental toxins, procarcinogens and steroids. The *CYP2A6* gene is mapped on chromosome 19q13.2 along with other subfamily members *CYP2A7* and *CYP2A13*. It consists of 9 exons and spans about 6 kb. Currently, 81 variant alleles are known for *CYP2A6* gene. The activity of *CYP2A6* is found to be influenced by the presence of genetic polymorphisms which may affect the efficacy and toxicity profiles of CYP2A6 substrates. Further, polymorphisms of *CYP2A6* have been linked to tobacco-related cancer risks. A wide interethnic variation exists in the frequency distribution of *CYP2A6* alleles.

Three *CYP2A6* functional alleles which result in abolished activity (**2, *4A*, and **5*) and a normal allele designated as **1B* have been well known. Of the above *CYP2A6* variants, **1B* is the most prevalent allele in Indians followed by **4*, whereas **2* and **5* are found to be rare. The polymorphic allele frequency of *CYP2A6*2* and **5* are available only for SI; similarly, for *CYP2A6*1B* is available only in NI population. The interethnic comparison between NI (32.7%) and other populations indicates similarity with that in Caucasians (27.6%) and significant difference with that in Africans (11.2%) and Asians (42.8%). The defective allele *CYP2A6*4A* is prevalent in Indians (NI, 11.3%, SI, 8.9%) and Asians (11%) but significantly lower than in Africans (0.5%) and Caucasians (3%). In contrast, the other variant *CYP2A6*2* allele is present at low frequency in SI (1%), Africans (0.3%), and Caucasians (2.3%), but is absent in Asians. In the same way, *CYP2A6*5* is lower in SI (0.7%), Asians (0.5%) and is completely absent in Africans and Caucasians.

46.3.1.4 CYP2C8

CYP2C8 is one of the most important members of the CYP2C subfamily and its protein sequence is different from other members. CYP2C8 accounts for the metabolism of approximately 5% of drugs used in routine clinical practice. It includes some antidiabetics (troglitazone, pioglitazone, rosiglitazone & repaglinide), antihypertensive (verapamil), antimalarial (chloroquine, amodiaquine), anticancer (paclitaxel), non-steroidal anti-inflammatory drugs (NSAID) (ibuprofen), 3-hydroxy-3-methylglutaryl-coenzyme (HMG-CoA) reductase inhibitor (cerivastatin), and antiarrhythmic (amiodarone) drugs; and endogenous compounds such as retinoic and arachidonic acid.

The *CYP2C8* gene is localized in the long arm of chromosome 10 and composed of 9 exons, spanning 31 kb. To date, 20 different variant alleles have been identified in the *CYP2C8* gene. The most widely studied variants responsible for reduced enzyme activity are *CYP2C8*2*, *CYP2C8*3, CYP2C8*4* and *CYP2C8*5*. Previous studies have reported that impaired metabolism of CYP2C8 substrates are associated with the presence of genetic polymorphisms in CYP2C8. Subjects carrying the homozygous genotypes (**2/*2* or **3/*3*) of *CYP2C8*2* and *CYP2C8*3* polymorphisms display greater AUC values and decreased drug clearance. In addition, relationship between *CYP2C8* polymorphisms and risk of myocardial infarction and gastrointestinal bleeding has been observed.

The only study that determined the frequency distribution of *CYP2C8* alleles in any of the Indian population was carried out in SI Tamilians with a frequency of about 0.8% and 2.9% for *CYP2C8*2* and **3*, respectively. Studies in different populations from around the world specify that *CYP2C8*2* is rare allele in SI and Caucasians (0.3%), whereas it is a common allele in Africans (17%). *CYP2C8*3* variant is common in Caucasians (10.9%) while it occurs at a small frequency in Indians (NI, 4%; SI, 2.9%), and is absent in Africans. Regarding Asians, the *CYP2C8* polymorphism is monomorphic for *CYP2C8*1* allele [11].

46.3.1.5 CYP2C9

CYP2C9 is a predominant member of CYP2C isoforms and constitutes about 20% of the CYP450 liver content. It participates in the oxidative metabolism of the following drugs: S-warfarin, rosiglitazone, tolbutamide, phenytoin, glyburide, glibenclamide, glimepiride, glipizide, losartan, irbesartan, torsemide, tamoxifen, fluvastatin, fluoxetine, amitriptyline and other commonly used anti-inflammatory drugs (diclofenac, ibuprofen, naproxen, piroxicam, aceclofenac, celecoxib). The *CYP2C9* gene is highly polymorphic and is located on chromosome 10q24.2.

Up to now, 41 genetic variants have been identified for the *CYP2C9* gene in different populations. The most common being *CYP2C9*2 (430C>T)* in exon 3, and *CYP2C9*3 (1075A>C)* in exon 7. These non-functional alleles have been described as a risk factor for various diseases such as MI, hypertension, colorectal cancer and major depressive disorders; also with certain life threatening adverse drug reactions including gingival hyperplasia, hypoglycaemia and gastrointestinal bleeding. Based on CYP2C9 metabolic activity, individual phenotypes are divided into extensive metabolizers (EMs), Intermediate metabolizers (IMs) and poor metabolizers (PMs).

The frequency of *CYP2C9*2* is higher in NI (9%) than that in SI (3.6%), however the *CYP2C9*3* (NI, 9.7%; SI, 8%) allele is equally distributed among the Indian populations (see Table 46.1). The distribution of *CYP2C9*2* in NI is in agreement with that in Caucasians (10.7%) but showed difference with that in Africans (2.8%). In contrast, the SI showed similarity with Africans but was different from that in Caucasians. The prevalence of *CYP2C9*3* is higher in Indians than that described in Africans (2%) and Asians (1.1%) but no difference was observed with Caucasians (7.4%).

46.3.1.6 CYP2C19

CYP2C19 is an essential member of the CYP450 superfamily and it contributes about 16% of total hepatic content. CYP2C19 is the principal enzyme involved in the hepatic metabolism of drugs such as antimalarial (proguanil), oral anticoagulants (R-warfarin), chemotherapeutic agents (cyclophosphamide), anti-epileptics (S-mephenytoin, diazepam, phenobarbitone), antiplatelets (clopidogrel), proton pump inhibitors (omeprazole, pantoprazole, lansoprazole, rabeprazole), antivirals (nelfinavir), and antidepressants (amitriptyline, clomipramine). The gene encoding CYP2C19 is located on chromosome 10q24 and currently 35 polymorphisms are known in the CYP2C19 gene. The variant genotypes of *CYP2C19*2 (681G>A), CYP2C19*3 (636G>A)* and *CYP2C19*17 (−806C>T & −340C>T)* are major factors attributed to interindividual differences in the pharmacokinetics and response to *CYP2C19* substrates. *CYP2C19*2* and **3* are associated with diminished enzyme activity, whereas *CYP2C19*17* results in increased activity.

Notably, the *CYP2C19*2* allele occurs at a higher frequency among Indian populations (NI, 33.1%; SI, 36.8%) than among Africans (16%), Caucasians (13.3%) and Asians (28.4%). The *CYP2C19*3* allele in Indians is 1.9% in NI and 1.1% in SI. The distribution of loss-of-function alleles (*CYP2C19*2* and **3*) show greater inter- and intraethnic variations among Indian populations compared to other major ethnics such as Asians (28.4% and 10.1%) and Caucasians (13.3% and 0.2%) individually. In contrast, *CYP2C19*17* resulting in ultra-rapid metabolism of *CYP2C19* substrates, studied only in SI Tamilians, showed a frequency of about 19.2%. The comparison of SI with Asian (1.5%) subjects indicates significant difference and matches with that in Africans (26.3%) and Caucasians (19.1%) for *CYP2C19*17* allele (see Table 46.1).

46.3.1.7 CYP2D6

Debrisoquine hydroxylase (CYP2D6), a major hepatic enzyme is encoded by the *CYP2D6* gene in humans. It plays a pivotal role in the metabolism and elimination of at least 25% of commonly prescribed drugs including opioids, antiestrogen, antiarrhythmic, antipsychotics, antidepressants, β-blockers, antihypertensives and antihistamines. The *CYP2D6* gene has polymorphic expression and is the most widely investigated gene in relation to interindividual and interethnic variability in the treatment outcome of CYP2D6 substrates. The *CYP2D6* gene locus has been mapped to 22q13.2 and composed of 9 exons with 8 introns. To date, 135 polymorphic variants have been reported in the CYP2D6 gene sequence and their frequencies differ markedly among the global populations. The most frequent polymorphisms are *CYP2D6*2, *3, *4, *5, *10, *14, *17* and **41*. Depending upon the *CYP2D6* allele combination, individuals phenotypes are classified into PMs, IMs and UMs.

The alleles associated with diminished CYP2D6 activity (**9, *17* and **29*) as well as the loss-of-function allele **14* were not detected in Indian populations. Of the several genetic variants, *CYP2D6*2* is the most prevalent functional allele in Indians, found at comparable frequencies between NI (29.3%) and SI (34.8%). SI showed significant difference compared with that in Asians (14%) and Caucasians (4%). On the other hand, NI showed similarity with Asians, but the differences are significant with Caucasians. The *CYP2D6*3* allele was found only in NI (9.2%) and its frequency is significantly higher as compared to that in Africans (0.4%), Asians (1%) and Caucasians (2.8%). The frequency of *CYP2D6*5* polymorphism, which lead to gene deletion was determined to be about 1.9% in NI and 1.8% in SI. A significantly lower *CYP2D6*5* frequency was observed in Africans (6.6%), Asians (7%) and Caucasians (6.9%).

The distribution of *CYP2D6*4* is higher in NI (11.5%) and Caucasians (14%), and is lower in Asians (4%) than those described in SI (7.3%), NEI (8.7%) and in Africans (6.8%). *CYP2D6*10* frequency difference is statistically significant between NI (27.2%) and SI (10.2%). The Indian populations showed significant difference compared with other populations with regard to *CYP2D6*10* (see Table 46.1). The *CYP2D6*41* has high allele frequency in NI (12.5%) and Caucasians (8.5%) and is low in Asians (1.9%).

The *CYP2D6* alleles responsible for gene duplication were studied only in NI Gujarati population. Overall, the ultra-rapid metabolism (*1xN* and *2xN*) and loss of enzyme activity (*4xN*) alleles were found at lesser frequencies in world populations, but abridged activity alleles (*10xN* and *41xN*) were found to be absent in NI [11].

46.3.1.8 CYP2E1

Human CYP2E1 is an N-nitrosodimethyl-amine demethylase, and belongs to the CYP450 super family. It is highly expressed in liver and the levels elevate in pathophysiological conditions such as fasting, diabetes, obesity and alcohol consumption. The *CYP2E1* gene is localized to chromosome 10q26.3, consists of 9 exons and 8 introns. The expressed enzyme catalyzes the biotransformation of several low molecular weight procarcinogens and protoxins, which includes N-nitrosamines, aniline, vinyl chloride, benzene, styrene, and urethane. In addition, it is involved in the metabolism of drugs such as acetaminophen, isoniazid, chlorzoxazone and fluorinated anesthetics.

The polymorphism *CYP2E1*1B* in intron 7, *CYP2E1*5B* in the 5'flanking region and *CYP2E1*6* in intron 6 have drawn much attention because of their association with inter-individual variation, altered gene function and expression. Many studies have reported the association of CYP2E1 genetic variations with liver disease and cancers. *CYP2E1*1B* frequency is evenly distributed in NI (13%), SI (14.2%) and Caucasians (13.5%), while it is significantly higher in Asians (18.1%) and even higher in Africans (65.9%). With regard to *CYP2E1*5B*, similarity was observed between SI (1.3%) and NEI (0.8%) but differences were seen in NI (8.4%). Likewise, there was observed similarity between NI and SI (17.7% vs. 22.2%) but differences in NEI (0.8%) with respect to *CYP2E1*6* (see Table 46.1). The frequency of *CYP2E1*5B* in NI is different from that in other ethnic populations whereas CYP2E1*6 is similar to that in Asians (19.6%) but different from that in Africans (10.1%) and Caucasians (7.7%). The SI are different from other major populations for *CYP2E1*5B* but matches with that in Asians (14%); for *CYP2E1*6* SI are different from that in Africans and Caucasians. The frequency of *CYP2E1*5B* and **6* alleles in NEI as compared to that in other ethnicities indicates statistically significant difference.

46.3.1.9 CYP3A4

The human cytochrome P450 3A4 (CYP3A4) is the largest member of the CYP3A subfamily and accounts for 30–60% of the total for CYP450 adult liver. The *CYP3A4* gene is localized on chromosome 7q21 and up to now, 41 CYP3A4 alleles have been identified. Among them *CYP3A4*1B (G>A)* and **22 (C>T)* are the defining alleles that have been reported. Genetic variations in *CYP3A4* are a major source for interpatient variability in plasma concentration, adverse events and therapeutic response to drugs such as paclitaxel, fentanyl, tamoxifen, tacrolimus, and statin. In addition, existing studies have reported the role of *CYP3A4* defective alleles in the disease predisposition to prostate cancer, estrogen receptor-negative breast cancer and type 2 diabetes. The prevalence of *CYP3A4*1B* is known in NI (1.2%) only and the comparison between NI and other populations indicates significant variations. The other *CYP3A4* variants such as **2, *4, *5, *6* and **10* were not detected in NI [11].

46.3.1.10 CYP3A5

Drugs undergoing oxidative metabolism including immunomodulators (tacrolimus, cyclosporine), antipsychotics (olanzapine), antiestrogen (tamoxifen), anticancer (irinotecan, docetaxel, vincristine), antimalarial (mefloquine, artemether, lumefantrine), antihistamines (chlorpheniramine, terfenadine, astemizole), antiplatelets (clopidogrel), antihypertensives (nifedipine, amlodipine, felodipine, verapamil), antivirals (indinavir, nelfinavir, ritonavir, saquinavir), antibiotics (clarithromycin), HMG-CoA reductase inhibitors (atorvastatin, cerivastatin, lovastatin) and steroids (testosterone, estradiol, progesterone and androstenedione), are mainly metabolized by CYP3A5 isoenzyme. Its aminoacid sequence is identical to CYP3A4.

The gene *CYP3A5* is located adjacent to *CYP3A4* on chromosome 7. It contains four major polymorphisms, *CYP3A5*2 (27289C>A), *3 (6986A>G), *4 (14665A>G),* and **6 (14690G>A)*. Out of them, *CYP3A5*3* and **6* alleles result in absence of enzyme activity. *CYP3A5* genetic polymorphisms cause variation in its enzyme activity, which markedly influences the pharmacokinetics of *CYP3A5* substrates. Further, individual susceptibility to hypertension, acute myeloid leukemia (AML) or ALL, and breast cancer may be increased by non-functional alleles of *CYP3A5*.

The only polymorphic allele determined in Indian population is *CYP3A5*3*. The other variants **2, *4* and **6* were found to be monomorphic for *CYP3A5*1*. Allele frequency of *CYP3A5*3* in SI (56%) is statistically significantly as compared to NI (68.2%). Likewise, Indian populations are statistically different compared with that in Caucasians (91.6%), Asians (80.6%) and Africans (15%). Further, a polymorphism *(−44A>G)* located in the promoter region of CYP3A5 was observed only in NI (34.7%) which frequency is higher than in Caucasians (9.2%) and similar to that in Asians (28.2%)

46.3.1.11 GSTM1, GSTT1, and GSTP1

Glutathione S-transferases (GSTs) are polymorphically expressed phase II drug metabolizing enzymes. They play a key role in the inactivation of a broad range of xenobiotics and endogenous substances and also protect cells from oxidative stress. The GST super family consists of 5 classes, namely alpha, mu, theta, pi, and gamma. The gene encoding the common members of GSTs are *GSTM1* mu (chr1p13.3), *GSTT1* theta (chr22q11.2), and *GSTP1* pi (chr11q13.2).

Among the 3 GSTs, *GSTM1* and *GSTT1* are the most polymorphic genes. The null genotypes *GSTM1 *0/*0* and *GSTT1 *0/*0* results in polymorphic gene deletions and are responsible for the complete absence of their respective enzymes. A coding region polymorphism in *GSTP1*, which substitute's isoleucine by valine at codon 105 is associated with diminished enzyme activity. Development of carcinogenesis in colon, bladder, lung, prostate and digestive tract are related to genetic polymorphisms in *GSTM1, GSTT1,* and *GSTP1* genes. Additionally, they have an impact on drug metabolism and thereby cause interpatient differences in disease prognosis, efficacy and toxicity of GST substrates.

GSTM1 and *GSTT1* null allele frequencies were found to be 30.6% and 16.7% in NI; 28.8% and 14.8% in SI and 34.4% and 19.7% in NEI (see Table 46.1). With regard to *GSTM1* and *GSTT1* null polymorphisms, a general uniformity was observed between NI *versus* SI and NI versus NEI. In contrast, uniformity is significantly dissimilar among SI and NEI. The frequency pattern of *GSTM1* in Indian population is statistically different from that in Africans, Asians and Caucasians. The frequency of *GSTT1* polymorphism in SI is similar with that in NI and different from that in NEI. Further, GSTT1 frequency in Indian population is significantly less as compared to that in Africans and Asians, but showed similarity with that in Caucasians (see Table 46.1). The *GSTP1 105Val* allele frequency is statistically significant in SI (14.6%), as compared to that in NI (23.8%), NEI (21.7%), Africans (36.8%), Asians (20.6%), and Caucasians (25.9%). A significant difference is also noted in Africans compared to NI and NEI.

46.3.1.12 UGT1A1

The uridine diphosphate glucuronosyl transferase 1A1 (UGT1A1) is an important member of the UGT1A family. It facilitates the metabolism and subsequent excretion of potentially toxic xenobiotics, carcinogens, estrogens, bilirubin and therapeutic drugs. The *UGT1A1* gene spans about 160 kb and is localized on chromosome 2q37. Polymorphisms in the *UGT1A1* gene confer low enzyme activity that eventually leads to interpatient differences in the pharmacokinetics of UGT1A1 substrates, particularly anticancer agent irinotecan. The *UGT1A1* gene is highly polymorphic, as of now, more than 50 polymorphisms have been reported, with the most characterized being *UGT1A1* (TA) 6>7 *(UGT1A1*28)* polymorphism in the 5'promoter region. This TATA box polymorphism is characterized by 7 thymidine-adenine (TA) repeats instead of 6, which results in lower promoter activity.

The only study to determine the frequency of *UGT1A1**28 in native Indians was carried out in SI. This study found *UGT1A1*28* frequency to be as follows: Andhrite (32.2%), Kannadiga (29%), Keralite (46.5%) and Tamilian (52.8%) (see Table 46.1). The highest prevalence of (TA) repeats was found in Keralites and Tamilians, which suggests that these two populations are more predisposed to development of cancer, Gilbert syndrome, Crigler-Najjar syndrome and severe toxicity when treated with irinotecan. Statistically significant differences in the frequencies of this variant were observed in SI (39.7%), Africans (55.3%), Asians (13.1%), and Caucasians (29.6%).

46.3.1.13 UGT1A7

Extra hepatic phase II DME, uridine 5′-diphosphate-glucuronosyltransferase 1A7 (UGT1A7) catalyzes the glucoronidation and detoxification of numerous endogenous and exogenous substances, such as bilirubin, drugs, steroid hormones, phenols, coumarin and environmental carcinogens. It is expressed in several tissues including lung, stomach, pancreas, oropharynx and esophagus. The human monooxygenase enzyme, UGT1A7 is encoded by the *UGT1A7* gene, which is located on chromosome 2q37. At present, 11 missense variants are known in the *UGT1A7* gene. Four of them are most common polymorphisms, *UGT1A7*1* (N129 R131 W208), *UGT1A7*2* (K129-K131-W208), *UGT1A7*3* (K129-K131-R208), and *UGT1A7*4* (N129-R131-R208).

Genetic susceptibility to cancers such as liver, oral, colon, gastrointestinal, and pancreas, as well as chronic pancreatitis are attributed to *UGT1A7* genetic variations, which modulates the enzyme's detoxification activity. *UGT1A7* gene polymorphism frequencies are available only in NI; they have not been studied in other Indian populations (see Table 46.1). On the whole, however, the *UGT1A7* polymorphic alleles seem to be more common in NI. Compared with those in Africans, Asians, and Caucasians significant interethnic differences have been observed for *UGT1A7*2, *3* and **4* alleles. Conversely, no such difference have been observed for *UGT1A7*12*.

46.3.1.14 TPMT

The gene thiopurine S-methyltransferse (*TPMT*) encodes the cytosolic enzyme TPMT which is mapped on chromosome 6p22.3 and has 10 exons spanning over 27 kb in size. TPMT, a rate limiting enzyme, plays a key role in the metabolism of thiopurine drugs (6-mercaptopurine, azathioprine and 6-thioguanine). Heritable deficiency of TPMT activity, regulated by genetic polymorphisms of the *TPMT* gene is an important factor causing interpatient variability in the clinical outcomes of thiopurine drugs. In erythrocytes, TPMT enzyme activity exhibit trimodal distribution in Caucasians. On the other hand, Southeast Asians show unimodal distribution.

Among the 24 genetic polymorphisms reported in *TPMT* gene, four common polymorphisms cause 80-95% intermediate and low enzyme activity. These are *TPMT*2 (238G>C),*3A (460G>A* and *719A>G),*3B (460G>A)* and **3C (719A>G)*. Patients who carry the defective alleles of TPMT are more likely to experience life threatening toxicity when they are treated with thiopurines. In Indians, *TPMT*3C* is the most common genetic variant; **2* and **3B* are scarce; and the African-specific allele, *TPMT*8* is absent.

*TPMT*3A* allele causing the largest decrease in TPMT activity, has been detected in NI (0.4%) but is absent in SI. Similarly, *TPMT*2* and *TPMT*3B* are present only in SI (0.1% and 0.1%) but not in NI (see Table 46.1). With regard to *TPMT*3A*, the NI (0.4%) are divergent from Caucasians (4.5%) and comparable to Asians and Africans. With respect to *TPMT*3C*, the NI (2.1%) and SI (1.1%) are different from that in Caucasians (0.4%), Africans (7.6%) and matches with that in Asians. On the whole, the Indians display higher TPMT activity due to less prevalence of TPMT alleles. Therefore, Indians are likely to be at lower risk of developing toxicity compared to Africans, Asians and Caucasians.

46.3.1.15 SULT1A1

Sulphotransferase 1A1 (SULT1A1) is the most widely expressed member of the sulphotransferase family. Through sulfation, it plays a significant role in the detoxification and bioactivation of several procarcinogens, toxins and xenobiotics. The catalytic activity and thermostability of SULTIA1 protein has been modified by the presence of genetic polymorphisms in the *SULT1A1* gene. Allelic variants and copy number variations of *SULT1A1* are implicated in the clinical efficacy and safety profiles of tamoxifen, as well as in susceptibility to hormone-dependent cancers.

The *SULT1A1* gene is extremely polymorphic and located on the short arm of chromosome 16; and is sized about 180,005 bases. Two coding variants *SULT1A1*2 (638G>A)* and *SULT1A1*3 (667A>G)* are the notable genetic polymorphisms; their frequency vary in ethnically diverse populations (see Table 46.1). The normative frequency of *SULT1A1*2* in Indians was established only in SI (22.6%) and NEI (27.2%) populations but not in NI. As shown in Table 46.1, *SULT1A1*2* frequency is significantly higher than those in Asians (8.7%) and lower than in Caucasians (41.5%), however, similar frequency is observed between SI, NEI and Africans (28.5%).

46.3.1.16 COMT

Catechol-O-methyltransferase (COMT), a phase II DME regulates the O-methylation of catecholamine neurotransmitters and catechol estrogen. The chromosome location of the gene encoding COMT protein is 22q11.2 which translates two different proteins, a low-affinity COMT (S-COMT) and high-affinity (MB-COMT) by alternative gene regulation. Until now, 30 different polymorphisms have been identified for the COMT gene. Among them, *COMT rs4680* (*472G>A*) in exon 4 is the most characterized functional polymorphism. This polymorphism contributes about 3 to 4 fold reduced methylation activity.

Individuals possessing the polymorphisms are susceptible to breast cancer, endometrial cancer, Parkinson's disease, and schizophrenia; and exhibit interindividual variation in pain sensitivity and therapeutic response to drugs used for chronic pain, including analgesics. The frequency of *COMT* polymorphic alleles namely *rs3788319, rs737865, rs6269, rs4818, rs4633,* and *rs165599* are available only in SI, excluding the SNP *rs4680*. That of *rs4680* is significantly different between the Indian populations (NI, 49% vs. SI, 41.6%). Compared to NI, significant differences are seen in Africans (34%) and Asians (27.5%). The differences in *COMT rs4680, rs737865* and *rs4633* frequencies for SI are statistically significant compared to Africans, Asians and Caucasians [11].

46.3.1.17 NAT2

Arylamine N-acetyltransferase enzymes NAT1 and NAT2 are polymorphic drug metabolizing enzymes. They participate in the detoxification and metabolic activation of arylamines, arylhydroxylamines, arylhydrazine and other drugs. The acetylation activity of the enzyme can be classified into slow, intermediate and rapid which is determined by the individual's *NAT2* genotype. The genes encoding both isoforms are mapped on chromosome 8p21.3-23.1. The common functional polymorphic alleles of *NAT2* are *191G>A* (Arg64Gln), *282C>T* (Tyr94Tyr), *481C>T* (Leu161Leu), *341T>C* (Ile114Thr), *590G>A* (Arg197Gln), *803A>G* (Arg268Lys) and *857G>A* (Gly286Glu). The most studied of these alleles are *NAT2*5, NAT2*6* and *NAT2*7* at respective positions 341, 590 and 857.

The variant *NAT2*6* corresponding to an inactive enzyme has a frequency of 37% in SI, which matches with that in NI (31.5%) and differs from that in NEI (26%). Likewise, *NAT2*7* accounts for 13.3% in NI, 11.1% in NEI and 25% in SI. The other polymorphisms *NAT*5* and **13* were studied only in SI and found to occur with frequencies of 30% and 44%, respectively, while **14* was not detected at all. The frequency of NAT gene polymorphism **11* is different between NI and SI (29.2% *vs.* 22%), whereas **12* is evenly distributed. A comparison of *NAT2* allele frequencies in Indians with those in Africans, Asians and Caucasians reveals significant interethnic differences (see Table 46.1). Carriers of these alleles show variation in the metabolism of isoniazid, hydralazine, ribavirin, retigabine, sulphamethoxazole and may have greater susceptibility to develop neoplasias.

46.3.2 Drug-Transporter Genes

46.3.2.1 ABCB1

Adenosine triphosphate binding cassette (ABC) superfamily of transport proteins exports the toxic xenobiotics and cellular metabolites from intracellular to extracellular space. Among the 49 ABC transporters, P-glycoprotein (P-gp) is the major energy-dependent transmembrane efflux transporter. The 170kD P-gp is the product of multidrug resistant 1 (*MDR1* or *ABCB1*) gene which plays a significant role in drug resistance and drug disposition. Genetic variations of *ABCB1* have been implicated in the development of breast cancer, colorectal cancer, upper aerodigestive cancer, Parkinson's disease and ulcerative colitis.

P-gp has a wide range of drug substrates which includes clinically relevant agents - anti-neoplasmics (doxorubicin, actinomycin D, paclitaxel), analgesics (morphine), antibiotics (erythromycin, levofloxacin, sparfloxacin, rifampicin), antivirals (nelfinavir, indinavir, efavirenz), antiepileptics (phenytoin, phenobarbital), antidepressants (amitriptyline), antiarrthythmics (digoxin, verapamil), antilipidemic (atorvastatin), immunosuppressants (cyclosporin A, tacrolimus, rapamycin), antihypersentive (losartan), and steroids (aldosterone, cortisol, dexamethasone). Inter-individual variability in the pharmacokinetics and pharmacodynamics of these drugs are attributed to the presence of genetic polymorphisms in the *ABCB1* gene which can alter the activity and expression of P-gp.

The gene *ABCB1* has 29 exons ranging between 49 to 209 bp in size and localized at chromosome 7q21.1. To date, more than 50 ABCB1 polymorphisms have been reported. Among them, *2677G>T/A/C* in exon 21, *3435C>T* in exon 26, and *1236C>T* in exon 12 are the most extensively studied polymorphisms. The polymorphic allele frequencies of these polymorphisms are more common in Indian populations. Conversely, the frequency (51.9%) of *1236C>T* polymorphism is presented only in NI. A greater inter and intra-ethnic difference was observed between Indian and other major populations with respect to *2677G>T/A/C, 3435C>T* and *1236C>T* variant alleles [11].

46.3.2.2 SLC22A1

There are 3 OCT isoforms with similar membrane topology (OCT1, OCT2 and OCT3) in the SLC22 superfamily of transporters. Among them, OCT1 is mainly expressed in the liver and involved in the transport of cationic drugs such as metformin, levodopa and imatinib. The gene *SLC22A1*, encoding the protein OCT1 is mapped onto chromosome 6q25.3 with 11 exons, spanning 37 kb. Individuals carrying genetic variation in the *SLC22A1* gene show variation in the distribution and elimination of OCT1 substrates because of differential transporter activity.

As of now, the frequency distribution of *SLC22A1* polymorphisms has been documented only in SI Tamil population for the following common genetic polymorphisms *rs2282143, rs628031* and *rs622342*. Their frequency are 8.9%, 80.3% and 24.5% for respectively, *rs2282143 (T)*, *rs628031 (G)* and *rs622342 (C)*. Comparison of the above frequency showed significant difference with that in Caucasians. However, a similar frequency is observed in Africans (73.5%) and Asians (74%) for *rs628031*. In contrast, *rs622342* showed similarity with Asians (20.6%) but not with Africans (15.6%). In the same way, similarity was observed with Africans (8%) but not with Asians (16.7%) for the SNP *rs2282143*. Existing evidence suggest marked interethnic difference in the allele frequency of *SLC22A1* gene polymorphisms that can eventually lead to dissimilarity in the pharmacokinetics and clinical outcomes of cationic drugs which are substrates of OCT1.

46.3.2.3 SLCO1B1

The gene organic anion transporting polypeptide 1B1 (*OATP1B1*, also known as *SLCO1B1*) encodes the transmembrane protein OATP1B1, which transports anionic drugs such as statins, irinotecan, rifampin, repaglinide and methotrexate. The *OATP1B1* gene is located on chromosome 12p12.2 with 14 coding and 1 non-coding exon, and spans 108.59kb in size. Genetic polymorphisms in

OATP1B1 diminish the transporter function, a major factor influencing inter-individual differences in toxicity and therapeutic efficacy of *OATP1B1* substrates. In addition, prevailing studies have reported the association of *OATP1B1* polymorphisms with increased risk of statin-induced myopathy, methotrexate-induced gastrointestinal toxicity and gallstone disease.

The prevalence of the most common genetic variations *OATP1B1*1B, OATP1B1*4* and *OATP1B1*5* is available only in NI population. The frequency of these polymorphisms is reported to be 45%, 2.6% and 1.4% for *OATP1B1*1B*, **4* and **5*, respectively. A comparison of the variant allele frequency shows statistically significant differences with other populations (see Table 46.1). The frequency of OATP1B1*1B allele is higher in Africans (87%) and Asians (64%); lower in Caucasians (37%). Likewise, the variants **4* and **5* are higher in Africans (6.2% and 9%) and Caucasians (15% and 15.8%), but regarding **4* Asians (1.1% and 11%) show similarity with NI.

46.3.3 Drug-Target Genes

46.3.3.1 CYP19A1

The 58-kDa protein aromatase (CYP19A1) is the product of the *CYP19A1* gene and belongs to the cytochrome P450 superfamily, which facilitates the biotransformation of estrogens (E1 and E2) from androgens (androstenedione and testosterone). Genetic variants in the sequence of *CYP19A1* cause changes in enzyme activity and have been associated with sex hormone levels, etiology of estrogen-dependent disease, and clinical outcomes of third-generation aromatase inhibitors (anastrazole, letrozole, and exemestane). The frequencies of the minor alleles of the pharmacogenetic variants associated with efficacy and toxicity of AIs—*rs4646 (T), rs10046 (T), rs700519 (T), rs700518 (G), rs727479 (G), rs4775936 (T), rs10459592 (G), rs749292 (A), rs6493497 (T),* and *rs7176005 (A)*—are 41.1%, 20%, 33.7%, 17.8%, 25.8%, 19.9%, 33.7%, 24.9%, 35.9%, and 35.9%, respectively, in SI. The frequency of *CYP19A1* polymorphisms in NI is limited to *rs4646* (36%) and *rs10046* (25%) with a similar frequency. Comparison of the allele frequency between SI and other major populations [17] shows statistically significant greater interethnic difference.

46.3.3.2 VKORC1

Vitamin K epoxide reductase complex subunit 1, encoded by *VKORC1* (chromosome 16), the drug target for the anticoagulants warfarin and acenocoumarol is used to prevent and treat thromboembolic cases. These drugs are metabolized primarily by the enzyme CYP2C9. Genetic variations in the *CYP2C9* and *VKORC1* genes cause changes in enzyme activity and thereby affect the metabolism and gamma carboxylation of clotting factors II, VII, IX, and X, and of the proteins C and S, respectively. Wide interethnic variability exists in the frequency of *VKORC1* variants in various populations. The frequency of the promoter region polymorphism *(−1639G>A)* associated with a lower dose requirement of warfarin is similar in Indian populations (14% vs.10%) and lower than those reported in other major populations [13,16]. The risk of bleeding is less in Indian patients on anticoagulants compared to that in Africans, Asians, and Caucasians because of low frequency of *−1639G>A*. The other polymorphisms, *2255C>T* and *3730G>A*, show a significant difference in their minor allele frequency between SI and other populations, while the *1173C>T* polymorphism frequency is similar to Africans and Caucasians but different from Asians [17].

46.3.3.3 MTHFR

Polymorphisms in the gene encoding methylene tetrahydrafolate reductase (MTHFR) have been implicated in the pathogenesis of cancers, migraine, cardiovascular disorders, rheumatoid arthritis, and neural tube defects. In addition, they have been suggested as putative markers in predicting the therapeutic efficacy and toxicity of methotrexate. This enzyme metabolizes 5,10-methylene tetrahydrofolate into 5-methyl tetrahydrofolate and affects the activity of cellular cycles participating in various cellular mechanisms.

The gene *MTHFR* is located on chromosome 15 and the two polymorphisms, one in exon 4 *(677C>T)* and another in exon 7 *(1298A>C)*, are the most characterized of *MTHFR*'s genetic variants. The frequency of the thermolabile T variant of *677C>T* in Indian populations shows similarity with that in Africans and differs from that in Asians and Caucasians. Within Indian populations, SI (2.4%) and NEI (15.1%) frequency is significantly different but NI (10.1%) frequency is comparable [18–20]. The prevalence of the variant that replaces the amino acid alanine instead of glutamate at codon 429 is 8.7% in SI, which is significantly more than the prevalence reported in NI and Caucasian, but is in agreement with African, Asian, and NEI prevalences. NEI (17.0%) frequency is similar to that in Africans and Asians but different from that in Caucasians.

46.3.3.4 ACE

The angiotensin-converting enzyme (ACE) belongs to the renin angiotensin system pathway, which plays a key role in blood pressure regulation. The insertion/deletion *(ID)* polymorphism of *ACE* is characterized by insertion or deletion of 287 bp in intron 16 of the gene-encoding ACE located on chromosome 17q23.3. This polymorphism is associated with many diseases, including essential hypertension, myocardial infarction, cardiomyopathy, diabetes, renal disorders, cancers, and serum ACE levels. A significant difference in the allele frequencies of the *D* allele was found between SI [21] and NI [22] populations (SI, 44% vs.

NI, 20%). A similar difference was observed between NI and NEI (36.1%) but not between SI and NEI [20]. Moreover, Indian populations exhibit significant differences in *D* allele frequencies compared to Africans and Caucasians, but, those frequencies are same in Asians [23].

46.4 PHARMACOGENETIC STUDIES IN INDIA

Over the last 10 years, we have gained much information pertinent to the genetic factors that determine disease risk, variable response, and vulnerability to drug-induced adverse events in the Indian populations. The studies described here analyzed the pharmacogenetic variants in genes encoding proteins of ADME pathways and those involved in the metabolism of carcinogens and other environmental toxins. Nevertheless, most of them are disease association studies that attempted to elucidate the heritability of diseases including cancer, diabetes, cardiovascular, neurological, and psychiatric disorders. Investigations of the molecular aspects of pharmacotherapy are scarce. Some molecular epidemiological studies have documented a few significant findings that highlight the unique genetic realm of Indian populations. There are several examples, including:

- The 25-bp deletion in the myosin-binding protein-C3 (MYBPC3) that is associated with inherited cardiomyopathy risk is present only in Indians [24].
- The *POLG-CAG* repeat variation, which increases male infertility in other world populations, is not associated in Indian men with infertility [25].
- A disease risk candidate gene (*SLC11A1)* for tuberculosis, leprosy, and leishmaniasis is seen in other populations but not in Indians [26].

In addition, studies have found several population- or regional-specific disorders such as Handigodu disease, Madras motor neuron disease, and pseudo-cholinesterase deficiency among Vyshyas and others [27–29] Thus, most of the genetic variations found to be associated with diseases in other international populations are not associated in Indian populations because of their unique genetic diversity. PGx investigations on clinically important drugs in India examined a limited number of samples from SI and NI populations with the candidate gene (SNP) approach. Because of the panorama of genetic heterogeneity, the results from these studies cannot be extrapolated to the entire Indian population.

46.4.1 Anticancer Drugs

46.4.1.1 Tamoxifen

The selective estrogen receptor modulator tamoxifen is a well-established antiestrogen in the treatment and prevention of estrogen receptor–positive breast cancer. To exert the anticancer effect, tamoxifen, a prodrug, should be converted into its active metabolite endoxifen. Although this biotransformation is mediated by a series of drug-metabolizing enzymes, CYP2D6 is the primary enzyme involved. Women with decreased CYP2D6 activity (poor metabolizers) have reduced endoxifen levels that can lead to therapeutic failure resulting in cancer relapse [30]. We conducted a study to evaluate the impact of *CYP2D6* gene polymorphisms on breast cancer recurrence in 132 South Indian patients receiving adjuvant tamoxifen. Those with a reduced CYP2D6 activity score (≤ 0.5) were associated with increased risk of recurrence and shorter recurrence-free survival ($HR = 7.29$, $p < 0.001$) compared to an activity score of ≥ 1 [31]. We did not find any association of *CYP2C19* variant alleles (**2/*17*) with recurrence [32].

Recently, Kalyan Kumar and coworkers found significant correlation of a shorter survival period with *CYP2D6*4* and *SULT1A1*2* polymorphisms [33] in 140 patients with five-year follow-up. However, neither study found any relationship between toxicity and genetic polymorphisms and both examined only limited pharmacogenetic variants. Even though there are conflicting results in terms of *CYP2D6* genotype and tamoxifen outcomes, *CYP2D6* is still useful in predicting tamoxifen responsiveness and resistance. Still, pharmacogenetic assessment of the genes involved in endoxifen formation and the active metabolite's measurement may be useful in predicting tamoxifen's effect.

46.4.1.2 Letrozole

Letrozole, a third-generation aromatase inhibitor, is the principal drug used in the treatment of postmenopausal patients with both early- and advanced-stage endocrine-responsive breast cancer (BC). Response to and tolerability of letrozole are influenced by germline polymorphisms in the *CYP19A1* gene [34]. In an unpublished study conducted in our lab, we evaluated the effect of *CYP19A1* and *TCL1A* gene polymorphisms on the clinical outcomes of adjuvant letrozole in 199 hormone receptor positive (HR+) BC patients on letrozole (2.5 mg, OD). There was a significant difference in the proportions of allele and genotype frequencies for the rs4646 polymorphism between recurrence and nonrecurrence groups. The carriers of two copies of the variant allele "T" were shown to be at a 6.69-fold increased risk of recurrence.

Furthermore, we found that patients with the *TT* genotype have significantly shorter RFS (100.71 vs. 210.93 months; $p < 0.02$). However, the *TCL1A* gene polymorphism is not associated with patient-reported letrozole-induced musculoskeletal pain. This is the first study assessing the association of *CYP19A1* variants with letrozole efficacy and toxicity in the adjuvant setting. The outcome of the study could be seen as an initial step toward achieving personalized letrozole treatment in SI postmenopausal HR+BC patients.

46.4.1.3 Anthracyclines

Treatment with a anthracycline-based neoadjuvant chemotherapy (NACT) regimen improves the clinical outcome of locally advanced breast cancer. Nevertheless, its effectiveness is limited by chemo resistance, resulting in marked interpatient variability and cardiotoxicity, which is genetically determined by polymorphic variants in genes coding drug-metabolizing and transporter proteins. SI patients carrying a homozygous mutant *(TT)* of *MDR1* have been shown to have 2.26 times better response to NACT compared to those with the wild genotype *(CC)*, but this difference is not statistically significant [35].

Subsequent study by Kumar and colleagues demonstrated that, according to WHO and RECIST criteria, patients with high *MDR1* expression have respectively 3.6 and 14.4 times greater chance of responding poorly to NACT [36]. The NACT response rate is better in NI BC patients with *GSTM1* (OR = 2.06) and *GSTT1* (OR = 1.45) null genotypes, but no statistical significance was attained [37]. Subjects heterozygous for the *MDR1 1236C>T* polymorphism were associated with NACT response. Regarding 2–4 grade toxicity, the *C* allele of *MDR1 1236C>T* was associated with NACT response, but no such association was described for the other polymorphisms *(2677G>T/A* and *3435C>T)* [38]. In the gene–gene interaction model, *GSTM1* and *GSTP1 Ile105Val*, *GSTM1* and *GSTT1*, and *GSTT1* and *GSTP1 Ile105Val* display significant association with response as well as toxicity [39].

46.4.1.4 Thiopurines

Thiopurine drugs—6-mercaptopurine (6-MP), 6-thioguanine, and azathioprine—are used in the treatment of leukemia, autoimmune disorders, and solid tumors, as well as in organ transplantations. Among these purine and pyrimidine metabolites, 6-MP is the most prescribed drug for acute lymphoblastic leukemia (ALL). In one study, epistatic interactions between the polymorphisms of *TPMT (*3C*, **12)* and *ITPA (ex2*, *ex3)* showed association with 6-MP-induced toxicity in 90 SI ALL children. In addition, the single-locus ITPA *94 C>A* showed a significant effect on toxicity [40]. The researchers, in subsequent investigations, demonstrated the synergistic interactions between genes involved in thiopurine and folate pathways (*GCPII C1561T*, *RFC1 G80A*, *cSHMT C1420T*, *TYMS 5′-UTR 2R3R*, *TYMS 3′-UTR ins6/del6*, *MTHFR C677T*, *MTR A2756G*) and cumulatively determined 6-MP–mediated toxicity in South Indian ALL children [41]. No association between TPMT gene polymorphisms and 6-MP–induced toxicities was observed in NI ALL children, but the maintenance dose therapy of 6-MP is 31% lower in TPMT heterozygous mutants [42].

46.4.2 Cardiovascular Drugs

46.4.2.1 Clopidogrel

Antiplatelet therapy with clopidogrel and aspirin is often used in the prevention of cardio, peripheral, and cerebrovascular events. Clopidogrel is oxidized into the active metabolite (thiol) by several hepatic CYP450 enzymes, which in turn inhibit ADP binding to the P2Y12 receptor on the surface of the platelet and is eliminated by the MDR1 transporter. The mechanism underlying clopidogrel resistance is attributed to the polymorphic variants in the genes encoding these proteins. A study involving 149 SI Tamil patients presenting with ischemic heart disease on clopidogrel maintenance therapy (75mg/DD) reported that carriers of the loss-of-function alleles of *CYP2C19* (**2* and **3*) and *MDR1 (T)* have significantly reduced response to clopidogrel because of higher impedence values. Conversely, residual platelet activity is lower among ultrarapid metabolizers *(CYP2C19*17)*, but the researchers observed no significance [43,44].

Another study, working with the previous cohort, found a 2.78- and 2.45-fold greater risk of developing clopidogrel resistance in subjects with *CYP3A5*3* homo- and heteromutants. Similarly, carriers of the defective alleles *CT* and *CC* genotypes of *P2Y12* were found to have a 2.2-fold greater risk [45]. Both studies failed to measure the active metabolite, thiol. On the contrary, clopidogrel resistance was not associated with variants of *P2Y12* and *P2Y1* in 100 NI coronary artery disease (CAD) patients [46]. However, Shalia and colleagues revealed a trend toward poor clopidogrel response with the variant genotypes of *CYP2C19*2* and *iT744C* of *P2Y12* genes compared to their respective wild-type genotype at 24 hours [47].

46.4.2.2 Warfarin

Warfarin is the most widely prescribed anticoagulant for the prevention of thromboembolic events. Because it is a narrow therapeutic index drug, routine therapeutic drug monitoring (international normalized ratio, INR) is required for dose adjustments to avoid adverse drug reactions. Warfarin's dose requirements exhibit interindividual variability and are influenced by both genetic and nongenetic factors. Pavani and coworkers developed an algorithm using a multiple linear regression model that includes Vitamin K intake, *CYP2C9* (**2* and **3*), and *VKORC1* (**3*, **4*, *D36Y* and *−1639 G>A)*. Using this algorithm, they explained the 44.9% variability in warfarin dose requirements [48]. Their following extended investigation explained the 61% variability [49].

Very recently, a new pharmacogenetic algorithm was developed to predict maintenance and starting warfarin indose in SI patients. This study explained a similar variability of ~62.1% in dosing requirements. The investigators reported that *CYP2C9*1/*2*, **1/*3*, and **2/*3* variant genotype carriers require a lower daily maintenance dose—2.8 mg, 2.3 mg, and 2.2 mg, respectively—than do carriers of the *CYP2C9*1/*1* genotype (5.2mg). The *CYP2C9*, *VKORC1*, and *GGCX* gene polymorphisms were associated with reduced dose, excluding the polymorphisms *rs7196161, rs7294,* and *rs2108622,* which were associated with an increased dose [50]. In 145 NI individuals, *VKORC1-1639 AA* and *CYP2C9 *3/*3* homozygous mutants were associated with risk of over anticoagulation and warfarin-related adverse events [51]. A significant effect of *CYP2C9* (**2* and **3*) and *VKORC1 (C1173T* and *G-1639A)* genotypes on warfarin dose was observed by Shalia and colleagues in 83 NI patients operated on for aortic/mitral valve replacement [52].

46.4.2.3 Acenocoumarol

Acenocoumorol, a coumarin derivative, is the counterpart of warfarin in the prevention and treatment of thromboembolic events. Its dosage requirements are affected by genetic variants and clinical parameters. Rathore and colleagues were the first to generate a population-specific algorithm in NI patients and to explain the 41.4% dosage variation. A multiple regression algorithm showed superiority over clinical data in terms of sensitivity, specificity, rate of overestimation, rate of underestimation, overall accuracy, accuracy in drug-sensitive cases, and accuracy in drug-resistant cases. The *VKORC1* and *CYP4F2* polymorphisms explained the 37% acenocoumarol dosage variability and turned out to be the main genetic determinants [53]. A trend toward lower maintenance doses of acenocoumarol was detected in NI patients on mechanical heart valve replacement who carry the *CYP2C9* and *VKORC1* polymorphisms [54].

A pilot study attempted to estimate coumarin sensitivity using *CYP2C9* and *VKORC1* gene polymorphisms in patients carrying the Factor V Leiden mutation. It concluded that genotyping of *CYP2C9* (**2* and **3*) and *VKORC1* (*-16539G>A*) polymorphisms before coumarin prescription is essential in inherited thrombophilia [55]. Attempts to quantify the influence of genetic and demographic factors on acenocoumarol maintenance dose were carried out in 170 SI patients who underwent heart valve replacement. Patients with at least one variant allele of *CYP2C9* (**1/*2* or **1/*3*) and *VKORC1 (GA)* required a lower maintenance dose compared to homozygous wild genotype patients. Demographic and genetic variables together predicted 30.4% of the acenocoumarol dose requirement. *VKORC1 (-16539G>A)* came out as the principal predictor of acenocoumarol dose maintenance [56]. The data from the Indian studies, irrespective of ethnicity, emphasize the importance of *CYP2C9* and *VKORC1* polymorphisms in determining the therapeutic dosage of anticoagulants (warfarin and acenocoumarol).

46.4.2.4 Statins

Statins are inhibitors of 3-Hydroxy-3-methylglutaryl coenzyme A reductase, the most widely prescribed cholesterol-lowering medication in the treatment of conditions associated with cardiovascular abnormalities. Despite the imperative role of statins in cardiovascular protection, some patients show degrees of intolerance and substantial differences in response. This variability is thought to be modulated by genetic factors in the proteins involved in the metabolic pathway of statins along with demographic and environmental factors.

One study explored the association of 18 polymorphisms (six genes) with atorvastatin response in 265 newly diagnosed NI CAD patients. It concluded that the polymorphisms *ABCB1 (-41A>G)*, *HMGCR SNP29 G>T*, *rs5908A>G*, *rs12916C>T*, and *CYP7A1-204A>C* were significantly associated with diminished low-density lipoprotein-C reduction. On the other hand, mutants of *CETP TaqI, −629C>A*, and *APOAI PstI* polymorphisms were associated with a greater increase in high-density lipoprotein cholesterol. Additionally, compared to single polymorphisms, three-way gene–gene interaction modules (*CYP7A1 rs892871AA*, *APOAI PstIP1P1*, and *HMGCR rs12916CT*) were found to be better predictors for LDL-C–lowering levels [57]. No association was observed with interindividual response to atorvastatin and *ABCG8 D19H* in 213 CAD NI patients [58].

46.4.3 Oral Hypoglycemic Drugs

46.4.3.1 Metformin

Metformin, an insulin-sensitizing biguanide agent, is the primary medication of choice in the treatment of T2DM; it scores higher than the other classes of oral antidiabetic drugs because of its additional allied beneficial effects. However, the glycemic response of metformin is highly variable. It has been suggested that the clinical consequences of metformin are altered by the molecular variants of the gene encoding organic cation transporter 1 (OCT1), with conflicting results. In the Indian scenario, Saranya and coworkers found significant association of the *OCT1* and *ATM* genes with metformin response in 165 SI diabetic patients. The homozygous mutant *(CC)* genotype of *OCT1 rs622342* is significantly higher in nonresponders than in responders (25% vs. 2.7%). Similarly, the homozygous wild genotype (AA) is higher in responders than in nonresponders (61.9% vs. 42.3%). On the other hand, the *C* allele of *ATM rs11212617* was found to be higher among responders than nonresponders (40% vs. 28.2%). No significant association was observed with regard to adverse side effects [59].

46.4.3.2 Glibenclamide

Glibenclamide belongs to the class of sulphonyl ureas that is used either as monotherpay or in combination with biguanides in the management of T2DM. Among the CYP450 enzymes involved in its metabolism, CYP2C9 is a major contributor. Carriers of the *CYP2C9*2/**3 variant alleles are likely to risk sulphonyl urea-induced hypoglycemia and variable glycemic response. Considering the role *CYP2C9* polymorphisms in glibenclamide response, Surendiren and colleagues investigated the influence of these variants on glibenclamide plasma levels and response in 80 SI T2DM patients.

In the study cohort, the genetic polymorphisms of *CYP2C9* and *MDR1* did not influence glibenclamide plasma levels. However, they had an influence on diabetic status with glibenclamide. The variant genotypes of *CYP2C9 *1/*3* and **1/*2* ($p<0.001$) and the normal genotype of *MDR1 CC* ($p<0.01$) were associated with controlled diabetic status in response to therapy, while the normal genotype of *CYP2C9 *1/*1* and the homozygous variant genotype of *MDR1 TT* were associated with uncontrolled diabetic status in therapy response. The study further revealed that the hypoglycemic adverse effects of glibenclamide are associated with its plasma concentration in the presence of normal genotypes for *MDR1*. The genotype of *CYP2C9 *1/*3* and *MDR1* variants did not influence the hypoglycemic adverse effects [60,61].

46.4.3.3 Pioglitazone

Pioglitazone, a peroxisome proliferator–activated receptor gamma (PPARγ) activator, is metabolized by CYP2C8. Pioglitazone response is greatly variable in T2DM patients carrying the genetic variants of the genes *CYP2C9* and *PPARγ*. In view of this interindividual variability, Mathur and coworkers studied pioglitazone monotherapy response in relation to the PPARγ *Pro12Ala* polymorphism in 30 newly diagnosed Indian patients. Since these patients were monomorphic for the *Pro12* allele, association between pioglitazone primary failure rate and the *Pro12Ala* polymorphism was not established [62].

46.4.4 Anticonvulsants

Pharmacoresistance to antiepileptic drugs (phenytoin, carbamazepine, phenobarbital, and valproate) is a major problem in the treatment of epilepsy, likely to be triggered by the combination of genetic and environmental variants. The first Indian study by Soundararajan and colleagues didnot find any association between the *CYP2D6 100C>T* and *2850C>T* polymorphisms and phenytoin-induced toxicity [63]. A later case report revealed phenytoin (DPH) toxicity in a 22-year-old Tamil woman carrying homozygosity for *CYP2C9*3*, a polymorphism associated with a marked decrease in enzyme activity. The woman's condition was reversed on switching to sodium valproate [64]. Studies from our lab indicated a 15.3-fold greater risk of phenytoin toxicity in subjects carrying the *CYP2C9*1/*3* genotype.

In our study, haplotype analysis of *CYP2C9* and *CYP2C19* gene polymorphisms revealed the association of the C-C-G-G haplotype with toxicity [65]. In addition, the contribution of under nourishment and *CYP2C9* genetic variants to phenytoin toxicity were found to be 37.3-fold. This result suggests the additive effect of undernourishment and *CYP2C9* variants in elevating free phenytoin levels individually as well as in combination [66]. Similarly, in an NI population the *CYP2C9*2/*3* polymorphisms were significantly associated with phenytoin toxicity in 259 patients [67].

Three polymorphisms of *MDR1* and *rs3773364 A>G* in synapsin-2 genes were analyzed in NI epileptic patients and neither was found to be associated with multidrug resistance [68,69]. The researchers in this study showed, in two additional studies, the association of the *"A"* allele of 9*SCN2A 56G>A* and *CYP2C9* variants with multidrug resistance [70,71]. They also found significant association of the *GABRA1 IVS11+15 A>G* variant with multidrug resistant but this was not true for the *GABRG2 588C>T*, *GABRA6 1512 T>C*, *GABRB2 1412 C>T*, and *GABRR2 IVS2C>G* genes of GABA (A) receptors and *SCN1AIVS5-91G>A* [72–74].

Balan and colleagues also found no association between *MVP* genes and multidrug resistance [75]. However, a recent report on the pharmacokinetics of phenytoin did find significant association between phenytoin toxicity and the *NAT2* polymorphisms **5A (481C>T)* and **5C (803A>G)*. The pharmacokinetic parameters for phenytoin toxicity in poor metabolizers showed a steady-state concentration of phenytoin compared to intermediate metabolizers and extensive metabolizers [76].

46.4.5 Immunosuppressants

46.4.5.1 Cyclosporine and Tacrolimus

Cyclosporine (CsA) and tacrolimus (Tac) are calcineurin inhibitors; they are the most common immunosuppressive drugs for prevention of graft rejection in organ transplant recipients. CsA and Tac have a narrow therapeutic range; individual dose assessment is thus accomplished by routine therapeutic drug monitoring (TDM). The pharmacodynamics and pharmacokinetics of these agents are influenced mainly by the genetic polymorphisms of *CYP3A4*, *CYP3A5*, and *MDR1*, as Csa and Tac are the substrates of the proteins encoded by these genes [77]. Using existing Indian pharmacogenetic data, researchers examined the association of *CYP3A4*, *CYP3A5*, *MDR1*, and *IL-2* genetic variants with dose requirements of calcineurin inhibitors only in NI renal transplant recipients. In 224 patients on CsA and in 73 on Tac, subjects expressing *CYP3A5* were significantly associated with lower dose-adjusted CsA/Tac blood concentrations; moreover, Tac patients were found to be at a greater risk for allograft rejection. However, no effect of *CYP3A4*1B* on CsA/Tac concentrations was observed [78]. Furthermore, the same researchers in another study reported lower dose-adjusted levels (1, 3, and 6 months) of CsA and Tac and a higher risk of allograft rejection with the wild-type homozygous genotype at *MDR1 2677G>T (GG)* and *3435C>T (CC)* loci, but no correlation was found with *MDR1* haplotypes [79].

An investigation of 100 patients (56 on CsA and 44 on Tac) showed a higher Tac level/dose ratio in recipients with the homozygous mutants *CYP3A5*3/*3* and *MDR1TT* [80]. A prospective study that investigated the impact of *CYP3A5*3 (6986A>G)* on Tac concentrations in 79 renal transplant patients on ketoconazole found significant lower dose-adjusted trough levels in patients carrying at least one **1* allele of *CYP3A5*. In addition, compared to baseline, the dose normalization of Tac was increased by about 112% and 79% in those with and without *CYP3A5*3*, respectively, in response to the metabolic inhibition by ketoconazole [81]. The pharmacogenetics of immunosuppression is not consistent, even though studies have shown strong associations between pharmacogenetic variants and CsA/Tac trough concentrations. The PGx of *CYP3A5* and *MDR1* genes is clinically relevant in optimization and individualized CsA and Tac dosage adjustments. Neverthless, haplotype analyses, along with confounding factors, are likely to be useful in better understanding the variability in the pharmacokinetics of these agents.

46.4.6 Analgesics

46.4.6.1 Opioids

Pain, either acute or chronic, is therapeutically managed by opioid analgesics. Morphine is one of the important and most commonly used opioids in clinical practice. However, variations in genes involved in opioid pharmacokinetics and pharmacodynamics cause interindividual differences in analgesic activity. The only Indian population study on the pharmacogenetic assessment of opioids was carried out with 83 SI women who had undergone a total abdominal hysterectomy. We observed a higher required per-kg dose (0.657±0.107) of morphine in patients with the heterozygous genotype *(CT)* of *MDR1* than was required in those with other genotypes to maintain the same level of analgesia. Similarly, patients with the homozygous variant *(TT)* genotype are at increased risk of developing morphine-induced side effects, such as nausea and vomiting, than are those with the *CC* and *CT* genotypes [82].

46.4.7 Antifolates

46.4.7.1 Methotrexate

Methotrexate (MTX) is a folate inhibitor used as a first-line agent in the treatment of autoimmune diseases and malignancies. As with any drug, a large proportion of patients respond differently to this therapy and develop unpredictable side effects. Such variation may be related to pharmacogenetic variants in the enzymes involved in the folate pathway. Indian studies have examined the pharmacogenetic aspects of methotrexate in rheumatoid arthritis (RA) patients. The first such investigation in 150 NI RA patients produced a negative association between the *MTHFR 677C>T* polymorphism and the therapeutic efficacy of MTX [83]. A second study analyzed two *MTHFR* polymorphisms, *677C>T* and *1298A>C*, to evaluate the relationship but did not find any association with MTX efficacy and toxicity [84]. It has been found that the *CT* heterozygous condition of *MDR1 3435C>T* conferred double the risk of poor MTX response [85]. RA patients with the *FPGS rs1544105 AA* and *AG* and *TYMS rs2853539 AA* genotypes were shown to be poor responders [86].

46.5 CONCLUSIONS AND FUTURE DIRECTIONS

The Council of Scientific and Industrial Research initiative known as the Indian Genome Variation Consortium(IGVC) is the first comprehensive genetic study of Indian populations that addressed genetic diversity, migration, and population relativity by exploring variations in thousands of genes. Although the database named IGV Browser currently harbors allele and genotype frequencies for 4229 SNPs from more than 900 genes in distinct Indian populations, it does not have information regarding ADME pharmagenes and has data only for disease susceptibility markers [87]. Considering this fact—along with the stringent mating practice (endogamy) and rich genetic diversity of Indian populations and the nonavailability of functional studies for these polymorphisms in Indians—there is an immediate need for a functional and molecular study that will characterize the clinically important ADME gene polymorphisms. These characterizations will eventually pave the way for an Indian database with the establishment of a nationwide PGx network among Indian researchers. Such a network will lead to the development of a population-specific PGx chip for Indian populations that should undergo multicenter validation of its clinical benefit and cost effectiveness.

For the precise estimation of allele frequencies, random sampling is essential in population genetics. Further, study subjects should be clustered based on their caste rather than on state of origin; this is imperative for proper population stratification. Moreover, it is essential to generate population-specific normative frequency data before initiating pharmacogenetic association studies. Even more important will be power and sample size calculations based on the normative frequency of the study variants, to be performed before genotype–phenotype correlation studies to avoid spurious false-positive and false-negative results.

Advancements in genetics have given rise to new methods and novel approaches for deciphering differences in treatment outcomes in genomic medicine. SNPs can define only a part of this interindividual variability; pharmacoepigenetics will add another level of understanding in this area. For this reason, studies should focus on epigenetic mechanisms (DNA methylation, miRNA, histone acetylation), copy number variation (CNV) analysis, and gene expression regulation to provide new insights into the inherited traits that cause the variability in pharmacotherapy. The result should be a significant platform for implementing personalized medicine in Indian populations.

Glossary

Agonist stimulates or activates the receptor to produce an effect

Allele one version of a gene at a given locus along a chromosome

Allosteric modulation indirect modulation of the effects of an agonist by binding to a separate binding site, leading to an increase or decrease the receptor's affinity for agonist

Alpha helix and beta sheet common secondary protein structures

Alternative splicing a regulatory mechanism by which multiple mRNA transcripts are generated from a single gene

Amino acid substitution matrix a matrix describing how common each type of amino acid change is, to facilitate scoring of similarity between protein sequences

Andersen-Tawil syndrome a condition characterized by episodic paralysis, ventricular arrhythmias, and prolonged QT interval. Approximately 60% of individuals with Andersen-Tawil have a mutation in KCNJ2. This encodes the inward rectifier potassium channel 2 protein, Kir2.1

Antagonist prevents the action of an agonist but does not have any effect itself

Argonaute 2 a protein that binds to small RNAs and is a component of RISC. In mammals, there are four Ago proteins, Ago1–4, which function in translational repression; only Ago2 has slicer activity

Band During cell division, the specific staining pattern (light and dark stripes) is observed for chromosomes. Such patterns can help in identifying chromosomes and evaluating their structure

Biallelic pertaining to both alleles of a gene (in a heterozygote)

Binary fission a type of cell division that applies to prokaryotes, such as bacteria. One cell is divided in two, with two complete and identical genomes present in the two daughter cells

Biomarker a measurable characteristic that is an indicator of normal biologic processes, pathogenic processes, and/or response to therapeutic or other interventions

BLAST a popular algorithm for sequence alignment

Bootstrapping the scoring of a tree or nodes of a tree by resampling and counting outcomes of each pseudoreplicate dataset

Cascade screening method of ascertaining gene carriers by testing the patient's close family members

Centromere a constricted chromosomal region that holds sister chromatids together during cell division. The centromere also separates a chromosome into a short arm and a long arm

Character a heritable feature that varies among individuals

Chromatid during the S phase of the cell cycle, each chromosome is duplicated. Following replication, each chromosome consists of two identical sister chromatids, which contain matched copies of the DNA sequence at every locus

Chromatin fiber the 30 nm coil of DNA and proteins that forms the basic structure of chromatin

Clinical annotation a genotype-based, evidence-rated summary of PharmGKB's literature evidence for a particular variant and drug phenotype association

Companion diagnostics an *in vitro* diagnostic device that provides information essential for the safe and effective use of a corresponding therapeutic product

Copy number variant form of DNA variation in which a certain sequence is present in differing numbers of copies, and is different across individuals. Many CNVs are nonpathogenic common variants

Copy number variants deletions, duplications, and insertions in the germline genome that are >1 kb in length

Cytochrome P450 a large superfamily of heme-thiolate proteins involved in the metabolism of a wide variety of exogenous and endogenous compounds

Cytochrome P450s the human cytochrome P450 superfamily, which comprises 57 genes. P450 sequences that display greater than 40% amino acid identity are classified in the same family; sequences that have greater than 55% identity are classified in the same subfamily. Members of CYP1–3 subfamilies are involved in the metabolism of xenobiotics, including drugs

Cytokinesis the division of the cytoplasm. Cytokinesis immediately follows the division of the nucleus

Cytoskeleton protein filaments within cells that maintain cell shape and cell movement

Delimiter separated value a plain text file in which rows are separated by EOL characters and columns by a specified delimiter (e.g., tab or comma)

De novo structure prediction the prediction of a protein's structure without the use of templates

Desensitization repeated exposure to a drug leading to a diminishing effect

Dicer an endoribonuclease that cleaves pre-miRNAs into 20–25-nucleotide, double-stranded miRNAs

Digenic Pertaining to two genes interacting to produce the phenotype. Often the mode of inheritance is Mendelian with another gene modulating disease severity

Discrete method a method that considers differences in nucleotides directly

Distance method a method that considers only the number of differences between nodes

DNA the molecule that encodes the genes responsible for the structure and function of an organism. Genetic information carried by DNA molecules is transmitted from one generation to the next

DNA methylation methyl groups, consisting of one carbon atom and three hydrogen atoms, attach to DNA molecules at cytosine bases, resulting in reduced transcription of the gene

Dot-matrix a graph representing similarities between two sequences

Endomembrane system all membranes, which are suspended in the cytoplasm within a cell, can divide the cell into structural and functional compartments/organelles. In a eukaryotic cell, endomembrane organelles include the nuclear envelope, the

Handbook of Pharmacogenomics and Stratified Medicine. http://dx.doi.org/10.1016/B978-0-12-386882-4.00056-6

© 2014 Elsevier Inc. All rights reserved.

endoplasmic reticulum, the Golgi apparatus, lysosomes, vacuoles, vesicles, and the cell membrane. The endomembrane system does not contain mitochondrial membranes

Epigenomics the study of global gene expression changes caused by epigenetic processes that do not involve any change in the underlying DNA sequence

Epistasis the expression of one gene depends on the expression of one or more independently inherited genes

Ethnic fractionalization (EF) the probability that two individuals selected at random from a country will be from different ethnic groups

Eukaryote an organism whose cells contain a nucleus and other membrane-bound components. Many unicellular organisms, such as protozoa, are eukaryotes. All multicellular organisms—animals, plants, and fungi—are eukaryotes

Exome the part of the genome that corresponds to exons, which are the coding sequences of DNA present in mature messenger RNA. The exome constitutes about 1% of the total human genome

Expression quantitative trait loci genetic loci that regulate gene expression

F-statistics (F_{ST}) the proportion of the total genetic variance contained in a subpopulation (subscript S) relative to the total genetic variance (subscript T). Values can range from 0 to 1. High F_{ST} implies a considerable degree of differentiation among populations. F_{IS} (inbreeding coefficient) is the proportion of the variance in the subpopulation contained in an individual. High F_{IS} implies a high degree of inbreeding

Gamete a cell/gamete that carries half the genetic information of an individual fuses with another cell/gamete in organisms that reproduce sexually. There are two types of gametes: a sperm is produced by a male and an ovum is produced by a female

Gap penalty a penalty on a sequence alignment score, made for the introduction of a gap

Gene the basic physical unit of heredity. For example, a segment of DNA that is arranged in a linear manner along a chromosome is a gene. A gene codes for a specific protein that has a particular characteristic or function

Gene ontology a standardized way of classifying genes and their products

Genome the entire genetic material found in a cell. In the case of humans, the genome includes 23 pairs of chromosomes in the nucleus and the chromosomes contained in a cell's mitochondria

Genome-wide association study (GWAS) analysis of DNA markers across the genome to identify variants associated with particular phenotypes

Genotype the genetic make-up of a cell or organism. Also, a set of alleles inherited at a locus

Haplotype a set of alleles or single-nucleotide polymorphisms found on the same chromosome, tending to be inherited together

HAT (sleeping sickness) Human African trypanosomiasis is the correct term for human infections caused by the African trypanosomes of the *T. brucei* species: *Trypanosoma brucei gambiense* and *T. b. rhodesiense*. The disease is commonly referred to as sleeping sickness when in its second, CNS involved stage. At this stage, trypanosomes cause various perturbations to the neurological system, including the changes to sleep/wake patterns that led to the disease acquiring its common name

Heuristic a "rule-of-thumb" method; not as accurate as, but faster than, an exact method

Homology relation by descent, inferred by similarity. Often used synonymously with 'similarity'

Homology modeling the use of similar protein sequences with known structures in protein modeling

Imputation in statistics, imputation is a process of replacing missing data with other estimated probable values. In genetics, imputation is a method used to fill in missing genotypes in a study dataset

Inverse agonist produces an opposite effect to that of the agonist

Kinetochore a protein structure on chromatids, allowing the spindle fibers to attach and pull the sister chromatids apart during cell division

Label a description of a drug product, including what it is used for, who should take it, side effects, instructions for use, and safety information

Linkage disequilibrium nonrandom association of alleles at two or more loci

Linked genes genes on the same chromosome tend to be segregated and inherited together

Locus the location or the physical site of an individual gene or DNA sequence on a chromosome

Minor allele frequency the frequency of the least common allele in a given population

MIM number an ID from OMIM specifying a disease with a genetic component

miRISC an RNA-induced silencing complex that contains mature miRNA and guides its inhibitory function to the target mRNA

Molecular evolution the study of the evolution of DNA, RNA, or proteins

Monogenic Pertaining to a disorder occurring as a direct consequence of single gene defects

Multiple-sequence alignment an alignment of several sequences, often used in phylogenetics and protein modeling

Mutation an alteration in a DNA sequence from its natural state. The effect of any mutation might be deleterious or benign

Next-generation sequencing a high-throughput sequencing technology relative to capillary electrophoresis–based Sanger sequencing, producing thousands or millions of sequences simultaneously. This technology can be applied to DNA analysis, RNA analysis, and gene regulation analysis

Noncoding RNA a biologically functional RNA actively transcribed from a gene that contains no open reading frame

Organ bath standard for *in vitro* pharmacodynamic dose-response experiments involving suspension of an isolated section of organ/tissue in a controlled solution and sensors to measure the contraction or relaxation of the tissue when drugs are added

Organelle a subcellular structure within a cell. An organelle is usually enclosed by its own membrane for executing its specific function independently of other organelles in a cell, particularly a eukaryotic cell

Organism any living system that has the ability to grow, reproduce, maintain homeostasis within itself, and function independently. An organism may be either unicellular or multicellular. All organisms on Earth can be further divided into eukaryotes and prokaryotes

Ortholog a corresponding gene in different species that has descended from the same ancestral gene

Orthology homology where the sequences have deviated by speciation

Paralog a gene that is derived from the same ancestral gene but reside in different locations in the same genome

Paralogy homology where the sequences have deviated by gene duplication

Partial agonist stimulates the receptor to a limited extent but also prevents any further stimulation by naturally occurring agonists

Pathway an illustration of the pharmacokinetics or pharmacodynamics of a PGx-relevant drug, accompanied by informative text

PDB file a file listing coordinates for the atoms of a protein

Penetrance probability of a characteristic being present given a certain genotype

Pharmacodynamics the study of the physiological and molecular effects of drugs on their recipient and the relationship between plasma drug concentration and drug effect

Pharmacogene a gene involved in drug response

Pharmacogenetics (PGt) the study of variations in DNA sequence as related to drug response

Pharmacogenomics (PGx) the study of variations in DNA and RNA characteristics as related to drug response

Phenotype an organism's observable characteristic or trait, such as biochemical or physiological properties or behavior. Phenotypes result from the expression of an organism's genes as well as the influence of environmental factors and the interactions between the two

Phylogenetics the identification of evolutionary relationships between organisms or between genes

Pleiotropy multiple physical effects caused by a single gene. The underlying mechanism of pleiotropy may be a gene involved in different metabolic pathways that contribute to different phenotypes

φ and ψ angles rotation angles of certain bonds of a protein backbone

Polymorphism a variation in DNA sequence that is present at an allele frequency of $\geq 1\%$ of the population

Prokaryote an organism lacking a membrane-enclosed nucleus. Most prokaryotes are unicellular. No membrane-bound organelles are present in the prokaryotic cells. The intracellular components of a prokaryotic cell are gathered together and enclosed only by the cell membrane

Protein modeling the estimation of a protein's structure using its sequence

Receptor a component of the organism with which a drug interacts

Recombination the new combinations of the traits in offspring that are inherited from its parents, now more commonly known as the exchange of a DNA segment between two homologous chromosomes during meiosis, which causes new combinations of hereditary material in a gamete

Relational database a database with a complex structure, driven by a relational database management system (RDBMS)

RNA a molecule synthesized from the DNA template, with the alternating sugar ribose to replace the deoxyribose present in a DNA molecule. Different types of RNA exist in a cell: messenger RNA, ribosomal RNA, transfer RNA, and some small RNAs

rsID (reference SNP identification) an identification number assigned by the National Center for Biotechnology Information (NCBI) SNP database (dbSNP) to a cluster of SNPs that map to the same location

Second messenger a molecule that relays signals from receptors to the cell surface target

Sequencing the technique for determining the exact DNA sequence or nucleotides (A, C, G, and T). DNA-sequencing technology is developing fast and becoming less expensive. For example, whole-genome and whole-exome sequencing is now available for studying the association between a DNA sequence and a disease

Serum resistance–associated (*SRA*) gene The *SRA* is found in *Trypanosoma brucei rhodesiense*. It is derived from a *VSG* gene and is expressed from a single expression site; hence, trypanosomes carrying the gene are only resistant to serum when the particular *VSG* expression site with which they are associated is expressed. Expression sites are found at the telomeres of the parasite's chromosomes and contain a strong RNA polymerase 1 promoter that allows expression of a single *VSG* gene at a time, in addition to several expression site–associated genes (*ESAGS*) that are also found there

Single nucleotide polymorphism a change in a single nucleotide at a genetic locus with a minor allele frequency of 1% or higher in a population

Somatic cell the cell forms the body of an organism. For example, in humans, somatic cells form all internal organs, skin, bones, and connective tissues. Somatic cells are diploid

Synapsis the pairing of two homologous chromosomes at the early stage of meiosis. This allows the matching of homologous chromosomal pairs and prepares for possible crossover between them

Syncope transient loss of consciousness

Tachyphylaxis decrease in response to a drug following repeated administration

***T. b. gambiense*–specific glycoprotein gene (*TGSGP*)** *TGSGP*, like *SRA* in *T. b. rhodesiense*, is found only in one subspecies. It is also a mutated version of a variant surface glycoprotein gene and can confer resistance against trypanosome lytic factors in human serum, apparently by influencing membrane fluidity in ways that affect uptake of TLF

Therapeutic index the relationship between therapeutic and toxic doses of a drug

Threading aligning a protein sequence to known structures

Time complexity describes the relationship between the input size n and the time taken for an algorithm to run

Timothy syndrome Rare childhood condition that leads to cardiac arrhythmia, cognitive abnormalities, and syndactyly. It is caused by a mutation in the Cav1.2 calcium channel

Torsades de Pointes (TdP) distinctive form of polymorphic ventricular tachycardia characterized by twisting of the QRS complexes around the isoelectric line. It is associated with QT prolongation

Trait a variant of a character, which may be determined by genes, the environment, and the interactions between the two

***trans* configuration** the two alpha carbon atoms of the connected amino acids are on the opposite sides of the peptide bond

Trypanosome lytic factors (TLFs) TLFs are components of human blood that are capable of killing trypanosomes. Initially identified as being part of the high-density lipoprotein fraction of plasma, it was shown that a key individual component was apolipoprotein L1 (APOL1). APOL1 is capable of lysing trypanosomes other than those subspecies that have evolved molecules that neutralize its activity. Other components—such as a haptoglobin-like protein that is part of the complex particle that also contains APOL1—are required for the binding of these particles to the trypanosome and contribute to activity since specific receptors are required for this binding

Tsetse fly The tsetse fly is a dipteran insect of the genus *Glossina*. Various species can transmit trypanosomes, which replicate within the tsetse fly midgut as procyclic forms. Some of these forms migrate to the salivary gland, where they transform to metacyclic forms that are preadapted to survive within the insect host

Variant surface glycoproteins (VSGs) AQ8 VSGs are expressed one at a time, and acquire a glycosylphosphatidyl inositol (GPI) anchor that links them to the plasma membrane. The trypanosome has up to a thousand different *VSG* genes, but expresses only one of them at a time. The proteins form dimers that pack tightly at the parasite's surface and prevent host immunological proteins, including components of the complement complex and immunoglobulins, from reaching the cell surface. Eventually the host produces antibodies that bind to a given antigen type, and cells carrying that VSG are killed. However, a small number of parasites change expression to a new VSG that is not recognized by those antibodies. These cells then proliferate until a specific antibody response is raised to them. In this way, the parasites can evade the immune system *ad infinitum*

Ventricular fibrillation (VF) rapid, chaotic, nonrepetitive wave form in which there is uncoordinated contraction of the cardiac muscle of the ventricles. VF is clinically associated with loss of effective blood circulation and, if not immediately treated, death

Ventricular tachycardia (VT) sequence of three or more beats in a row, with wide QRS complex (QRS > 120 ms) at a ventricular rate exceeding 100 beats/min.

VIP (very important pharmacogene) summary a pharmacogenetic-based overview of an important gene involved in drug response

VNTR the location in a genome where a short nucleotide sequence is organized as a tandem repeat, often showing variations in length between individuals

Yotiao A-kinase (PRKA) anchor protein 9 that directly associates with the slow outward potassium ion current (I_{Ks}) in heart.

Xenobiotic a foreign chemical, which can be manufactured or natural, such as a drug, an industrial chemical, a pollutant, a pyrolysis product in cooked food, an alkaloid, or a secondary plant metabolite.

XML a text file with a hierarchical structure

Acronyms and Abbreviations

2D-PAGE	2D polyacrylamide electrophoresis
3C	chromosome conformation capture
5-FU	5-fluorouracil
6-MP	6-mercaptopurine
A1AT	alpha 1 anti-trypsin
AA	arachidonic acid
AACE	American Association of Clinical Endocrinologists
Aβ	amyloid beta EAD early afterdepolarization
ABCB1	ATP-binding cassette, subfamily B (MDR/TAP), member 1
AC	amoxicillin-clavulanate
ACE	American College of Endocrinology
ACE	angiotensin-converting enzyme
ACS	acute coronary syndromes
AD	antidepressant
AD	Alzheimer's disease
ADA	American Diabetes Association
ADAMTS13	a disintegrin and metalloproteinase with a thrombospondin type 1 motif, member 13
ADE	adverse drug event
ADME	absorption, distribution, metabolism, and excretion
ADP	adenosine diphosphate
ADR	adverse drug reaction
ADRs	adverse drug reactions
AF	amniotic fluid
AFP	alphafetoprotein
AfSHG	African Society for Human Genetics
AG	agamous
AGEP	acute generalized exanthematous pustulosis
Ago2	argonaute 2
AGTR	angiotensin receptor 1
AHR	abacavir hypersensitivity reaction
AhR	aryl hydrocarbon receptor
AHS	abacavir hypersensitivity syndrome
AKAP	A-kinase anchor protein 9
ALK	anaplastic lymphoma kinase
ALL	acute lymphoblastic leukemia
ANK2	ankyrin 2
APC	activated protein C
APD	action potential duration
APEX	absolute protein expression
aQTL	activity quantitative trait loci
ARNT	aryl hydrocarbon receptor nuclear translocator
AS	alternative splicing
AsO	antisense oligonucleotide
ASPE	Allele Specific Primer Extension
ATM	ataxia telangiectasia mutated
ATP	adenosine triphosphate
ATX	Ataxin
AUC	area under the concentration-time curve
AZA	azathioprine
BF	Bayes factor
bFGF	basic fibroblast growth factor
BLA	Biologics Licensing Application
BM	bone marrow
Bmax	maximum specific binding
BMP	bone morphogenic protein
BMS	Bristol-Myers Squibb
BMS	bare metal stent BS-seq bisulphite sequencing
BOC	boceprevir
CACNA1C	calcium voltage-dependent channel, L-type, α-1C subunit
CAD	coronary artery disease
cAMP	cyclic adenosine monophosphate
CARDS	Collaborative Atorvastatin Diabetes Study
CAV3	caveolin 3
CBZ	carbamazepine
CCR4	CC chemokine receptor 4
CD	cluster of differentiation
CDx	companion diagnostics
CE	capillary electrophoresis
CEIVD	European Communities *In Vitro* Diagnostic
CEVR	complete early virological response
CF	cultural fractionalization
CFTR	cystic fibrosis transmembrane conductance regulator
CFU-f	colony-forming unit of fibroblasts
cGMP	cyclic guanosine monophosphate
CHCA	α-cyano-4-hydroxycinnamic acid
CHCT	caffeine halothane contracture test
CHMP	Committee for Medicinal Products for Human Use
CID	collision induced dissociation
CK	creatine kinase
CK	cytokeratin
CNV	copy number variant
COMT	catechol O-methyltransferase
COX	ciclooxigenase; cyclo-oxygenase
C-path CAMD	Critical path coalition against major diseases
CpG/CG	phosphodiester bond between cytosine guanine

CPIC	Clinical Pharmacogenetics Implementation Consortium
CSF	cerebrospinal fluid
cTnI	cardiac troponins I
cTnT	cardiac troponins T
CYP	cytochrome P450; P-450
CYP450	cytochrome P450
CYP1A2	cytochrome P450, family 1, subfamily A, polypeptide 2
CYP2B6	cytochrome P450, family 2, subfamily B, polypeptide 6
CYP2C19	CYP2C19 cytochrome P450, family 2, subfamily C, polypeptide 19
CYP2C9	CYP2C9 cytochrome P450, family 2, subfamily C, polypeptide 9
CYP3A4	CYP3A4 cytochrome P450, family 3, subfamily A, polypeptide 4
DAA	direct-acting antiviral therapy
DAG	diacylglycerol
dbSNP	single-nucleotide polymorphism database
dbSNP	National Center for Biotechnology Information (NCBI) SNP database
DCS	diabetes care system
DDT	dichlorodiphenyltrichloroethane
DES	drug eluting stent
DHFR	dihydrofolate reductase
DHS	drug hypersensitivity syndrome
DHS	DNase I hypersensitivity sites
DIGE	difference gel electrophoresis
DIHS	drug-induced hypersensitivity syndrome
DILI	drug-induced liver injury
DISI	drug-induced skin injury
DMF	N,N-dimethyl formamide
DMEM	Dulbecco's modified essential medium
DMSO	dimethylsulfoxide
DNA	deoxyribonucleic acid
DPD	dihydropyrimidine dehydrogenase
DPP	Diabetes Prevention Program
DRESS	drug reaction with eosinophilia and systemic symptoms
DVT	deep venous thrombosis
DWPG	The Royal Dutch Association for the Advancement of Pharmacy Pharmacogenetics Working Group DZ dizygotic
EASD	European Association for the Study of Diabetes
EBs	embryoid bodies
EBV	Epstein-Barr virus
EC	extracellular
ECC	excitation-contraction coupling
ECD	electron capture dissociation
ECG	electrocardiogram
ED_{50}	therapeutically effective dose in 50% of people given drug
EDTA	ethylenediaminetetraacetic acid
EED	embryonic ectoderm development
EET	epoxyeicosatrienoic acid
EF	ethnic fractionalization
EFV	efavirenz FDA Food and Drug Administration
EG	embryonic germ
EGF	epidermal growth factor
EGFR	epidermal growth factor receptor
EM	extensive metabolizer
EMA	European Medicines Agency
EMF	electromagnetic field
EMHG	European Malignant Hyperthermia Group
emPAI	exponentially modified protein abundance index
ENCODE	Encyclopedia of DNA Elements
END2	endoderm-like cell 2
eNOS	endothelial nitric oxide synthase
ENU	*N*-ethyl-*N*-nitrosourea
eQTL	expression quantitative trait loci
ER	estrogen receptor
ES	embryonic stem
ESI	electrospray ionization
eSNP	expression single-nucleotide polymorphism
EST	expressed sequence tag
ETD	electron transfer dissociation
EZH2	enhancer of zeste
FASP	filter-aided sample preparation
FACS	fluorescence-activated cell sorting
FBS	fetal bovine serum
FD	familial dysautonomia
FDA	U.S. Food and Drug Administration
FDR	false discovery rate
FGF	fibroblast growth factor
FGF20	fibroblast growth factor 20
FH	familial hypercholesterolemia
G6PD	glucose 6 dehydrogenase deficiency
GABA	gamma-aminobutyric acid
GEO	Gene Expression Omnibus
GLP	good laboratory practice
GO	Gene Ontology
Go-DARTs	Genetics of Diabetes Audit and Research Tayside
GPIa	glycoprotein Ia
GPIb/V/IX	glycoprotein Ib/V/IX complex
GP IIb/IIIa	glycoprotein IIb/IIIa
GPCR	G-protein coupled receptor
gPS	germline-derived pluripotent stem
GPVI	glycoprotein VI
GSCs	germline stem cells
GSST1	glutathione S-transferase theta 1
GST	glutathione S-transferase
GTEx	genotype tissue expression
GWAS	genome-wide association study
H3Africa	Human Heredity and Health for Africa project
HAART	highly active antiretroviral therapy
Hb	hemoglobin
HbA1c	glycated hemoglobin
HCD	high-energy collision-induced dissociation
HCV	hepatitis C virus
hERG	human *ether-à-go-go*–related gene
HER2	human epidermal growth factor receptor type2
HGF	hepatocyte growth factor
HIF-1α	hypoxia inducible factor 1α
HIV	human immunodeficiency virus
HLA	human leukocyte antigen
HNF	hepatocyte nuclear factor
HPR	high platelet reactivity
HSCs	hematopoietic stem cell
HSS	hypersensitivity syndrome

HUCB-NSC	human umbilical cord blood–neural stem cell line
IC	imprinting center
IC	intracellular
ICAPS	International Consortium for Antihypertensives Pharmacogenomics Studies
ICAT	isotope-coded affinity tag
ICH	International Conference on Harmonization of Technical Requirements for Registration of Pharmaceuticals for Human Use
ICM	inner cell mass
ICPC	International Clopidogrel Pharmacogenomics Consortium
IEF	isoelectric focusing
IFNL	*interferon-lambda*
IGF1	insulin-like growth factor 1
IKBKAP	inhibitor of kappa light polypeptide gene enhancer in Bcells, kinase complex-associated protein
IKr	rapid delayed rectifier potassium current
IKs	slow delayed rectifier potassium current
ILSI/HESI	International Life Sciences Institute/Health and Environmental Sciences Institute
IM	intermediate metabolizer
IMDM	Iscove's modified Dulbecco's medium INDELs insertion and deletions
IND	investigational new drug IL interleukin
INH-DILI	isoniazid drug induced liver injury
INR	international normalized ratio
IPA	Ingenuity pathway analysis
iPS/C	induced pluripotent stem/cell
ISG	interferon-stimulated gene
ITP	inosine triphosphate
ITPA	inosine triphosphatase
IUPHAR	International Union of Basic and Clinical Pharmacology
IVCT	*in vitro* contracture test
IWPC	International Warfarin Pharmacogenetics Consortium
JLNS	Jervell and Lange-Nielsen syndrome
K_{ATP} channel	ATP-dependent potassium channel
KCNE1	potassium voltage-gated channel, ISK-related subfamily, member 1
KCNE2	potassium voltage-gated channel, ISK-related subfamily, member 2
KCNH2	potassium voltage-gated channel, subfamily H, member 2
KCNJ2	potassium channel, inwardly rectifying, subfamily J, member 2
KCNJ5	potassium channel, inwardly rectifying, subfamily J, member 5
KCNQ1	potassium voltage-gated channel, KQT-like subfamily, member 1
KD_{50}	agonist dissociation constant
KIM-1	kidney injury molecule-1
Klf4	Kruppel-like factor 4
KOSR	knockout serum replacement
KRAS	Kirsten rat sarcoma 2 viral oncogene homolog
LABA	long-acting $\beta 2$ adrenoceptor agonist
LC	liquid chromatography
LCL	lymphoblastoid cell line
LC-MS/MS	liquid chromatography–tandem mass spectrometry
LD	linkage disequilibrium
LDL	low-density lipoproteins
LEOPARD	lentigines, ECG anomalies, ocular hypertelorism, pulmonic stenosis, abnormal genitalia, retarded growth and sensorineural deafness
lncRNA	long noncoding RNA
LRRK2	leucine-rich repeat kinase 2
LTG	lamotrigine
MACE	major adverse cardiovascular events
MAF	minor allele frequency
MALDI	matrix-assisted laser desorption-ionization
MARS	Multiple Affinity Removal System
MATE1	multidrug and toxin extrusion 1
MCI	mild cognitive impairment
MDD	major depressive disorder
MDR1	multidrug resistance 1
MEA	microelectrode array
MeCP2	methyl CpG-binding protein 2
MEFC2C	myocyte enhancer factor 2
MEF/s	mouse embryonic fibroblast/s
MeHg	methylmercury
MethylC-seq	methylC sequencing
MELDI	material-enhanced laser desorption/ionization
MH	malignant hyperthermia
MHC	major histocompatibility complex
MHCI	major histocompatibility complex class I
MHCII	major histocompatibility complex class II
MHLW	Ministry of Health, Labor and Welfare
MiMI	Michigan Molecular Interactions
MI	myocardial infarction
miR-eQTL	microRNA quantitative trait loci
miRNA	microRNA
MMC	mitomycin C
MNNG	*N*-methyl-*N*-nitro-*N*-nitrosoguanidine
MPE	maculopapular eruption
MPE	maculopapular exanthema
MPP	1-methyl-4-phenylpyridinium
MRI	magnetic resonance image
MRM	multiple reaction monitoring
mRNA	messenger ribonucleic acid
MRE	microRNA recognition element
MSC	mesenchymal stem cell
MS	mass spectrometry
MTT	3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide
MudPIT	multidimensional protein identification technology
MYH7	myosin-heavy polypeptide 7
MZ	monozygotic
N-2	neutropan-2
NADPH	nicotinamide adenine dinucleotide phosphate
NAMHG	North American Malignant Hyperthermia Group
NAT-2	(v) N-Acetyl Transferase-2
NAT	N-acetyltransferase
NCBI	National Center for Biotechnology Information

NCE	new chemical entity
NDA	new drug application
NEAA	nonessential amino acid
NGS	next-generation sequencing
NHS	National Health Service
NI	nucleotide inhibitor
NIH	National Institutes of Health
NKX2.5	NK2 Transcription Factor-Related
NLP	natural-language processing
NME	new molecular entity
NNI	nonnucleos (t) ide inhibitor
NNK	4-(methylnitrosamino)-1-(3-pyridyl)-1-butanone
NNT	number needed to test/treat
NRTI	nucleoside reverse transcriptase inhibitor
NPV	negative predictive value
NSC	nearest shrunken centroid
NSTEMI	non ST elevation myocardial infarction
NT	neurotrophic
NVP	nevirapine
OATP1B1	organic anion–transporting polypeptide 1B1
OCP	oral contraceptive pill
OCT	organic cation transporter
Oct4/OCT4	octamer-binding protein 4
OR	odds ratio
OSM	oncostatin M
OXC	oxcarbazepine
P2Y$_{12}$	Purinergic receptor P2Y, G-protein coupled, 12
PAD	peripheral arterial disease
PAGE	polyacrylamide gel electrophoresis PGRN Pharmacogenomics Research Network
PAHs	polycyclic aromatic hydrocarbons
PANK	pantothenate kinase
PC	pheochromocytoma
PCA	principal component analysis
PcG	polycomb group
PCI	percutaneous coronary intervention
PCR	polymerase chain reaction
PCR-RFLP	polymerase chain reaction–restriction fragment-length polymorphism
PD	Parkinson's disease
PD	pharmacodynamics
pegIFN	pegylated interferon-α, RBV, ribavirin
pES	parthenogenetic embryonic stem
PET	positron emission tomography
PGC1β	peroxisome proliferator-activated receptor-γ co-activator 1β
PgWP	Pharmacogenomics Working Party
PGx	pharmacogenetics or pharmacogenomics
PharmGKB	Pharmacogenomics Knowledgebase
pI	isoelectric point
PI	protease inhibitor
PK	pharmacokinetics
PKL	Paxillin Kinase Linker
PM	poor metabolizer
PMDA	Pharmaceuticals and Medical Devices Agency
PMID	PubMed ID
POP	PMDA Omics Project
PPAR	peroxisome proliferator-activated receptor
PPARα	peroxisome proliferator-activated receptor α
PPARγ	Peroxisome proliferator-activated receptor γ
PPIs	Proton pump inhibitors
PPP	pentose phosphate pathway
PPV	positive predictive value
PRC	polycomb repressive complex
Pre-miRNA	precursor miRNA
Pri-miRNA	primary miRNA PTM post-translational modification
PRP LTA	light transmission aggregometry on platelet rich plasma
PSTC	Predictive Safety Testing Consortium
PTE	pulmonary thrombosis/thromboembolism
PXR	pregnane X receptor
QT	Q wave T wave
RA	retinoic acid
RC	Repressive Complex
RCT	randomized control trial
RISC	RNA-induced silencing complex
RNA	ribonucleic acid
ROCK	rho-associated protein kinase rsID Reference SNP identification
RPA-1	Renal papillary antigen-1
rtPCR	real-time polymerase chain reaction
RVR	rapid virological response
RWS	Romano-Ward syndrome
RYR1	ryanodine receptor gene
SABA	short-acting β2 adrenoceptor agonist
SAND	Sp100, AIRE-1, NucP41/75, DEAF-1
SCN5A	sodium voltage-gated channel, type V, α-subunit
SCN4B	sodium voltage-gated channel, type IV, β subunit
SCZD	SNP single-nucleotide polymorphism
SELP	P-selectin
SILAC	stable isotope labeling by amino acids in cell culture
SJS	Stevens-Johnson syndrome
SMA	spinal muscular atrophy
SMN1	survival motor neuron 1
SMX	sulfamethoxazole SCAR severe cutaneous adverse reaction
SNP	single-nucleotide polymorphism
sSNP	splicing single-nucleotide polymorphism
SNTA1	syntrophin α1
Sox2/SOX2	SRY (sex-determining region Y)-box 2
SPA	sinapinic acid; SRM, selected reaction monitoring
sQTL	splicing quantitative trait loci
SSC	spermatogonial stem cell
SSEA4	stage-specific embryonic antigen 4
STEMI	ST elevation myocardial infarction
SULT	sulfotransferase SELDI surface-enhanced laser desorption-ionization
SUR1	sulfonylurea 1 receptor
SUZ12	Suppressor of Zeste 12
SVM,	support vector machine
SVR	sustained virological response
T2DM	type 2 diabetes mellitus
TB	tuberculosis

TCF7L2	transcription factor 7-like 2	UCSCs	umbilical cord stromal cells
TCR	T-cell receptor	UGT	uridine diphosphate glucuronosyltransferase
TEN	toxic epidermal necrolysis	UKPDS	UK Prospective Diabetes Study
TFF3	Trefoil factor 3	ULT	ULTRAPETALA
TGF-β	transforming growth factor-β	ULvWF	ultra large von Willebrand factor
TI	therapeutic Index	UM	ultrarapid metabolizer
TIA	transient ischemic attack	URM	ultrarapid metabolizer
TOF-MS	time-of-flight mass spectrometry	UTR	untranslated region
TOF	time-of-flight TSS transcription start site	VASP	platelet vasodilator-stimulated phosphoprotein
TPMT	thiopurine methyl S-transferase	VDR	vitamin D receptor
TRBP	TAR RNA binding protein	VIP	very important pharmacogene
TRIPOD	Troglitazone in the Prevention of Diabetes	VIP	variable importance in the projection
TrxG	trithorax group	VKOR	vitamin K epoxide reductase
TS	thymidylate synthase	VKORC	vitamin K epoxide reductase complex
T-tau	total tau	VKORC1	vitamin K epoxide reductase complex subunit 1
TVR	telaprevir	VKORC1	vitamin K 2,3-epoxide reductase C1 subunit
TxA2	thromboxane A2	VNTR	variable number of tandem repeats
UA	unstable angina	vWF	von Willebrand factor
UCB	umbilical cord blood	VXDS	voluntary exploratory data submission
UCMSC	umbilical cord matrix system cell	WHO	World Health Organization
UCPVC	umbilical cord perivascular cell	ZFN	zinc-finger nuclease

  disease-associated gene polymorphisms, 705–706
  inward rectifier K+ channel Kir6.2, 705
  sulfonylurea pharmacokinetics, 703–705
Sulfotransferases (SULT), 345
Sulphobutylether beta cyclodextrin sodium (SBECD), 883
Sulphonomides (sulfa antimicrobials), 445–449

Sulphotransferase 1A1 (SULT1A1), 1049
*SULT*1A1 gene, 396
Support vector machines (SVM), 163
Suramin, 910–911
Swiss-Prot, 279
Synovial membrane hyperplasia, 654
Systemic lupus erythematous (SLE), 663–664
Systolic blood pressure (SBP)
  APOE-related, 582–583
Systolic BP (SBP), 747

T

T allele, 396
T box 21 and neurokinin 2 receptor genes, 619
Tacrine, 582
Tacrolimus (TAC), 1028, 1055–1056
Tacrolimus, PGxplore images for, 304
TAILOR-PCI (Tailored Antiplatelet Therapy Following PCI), 925
Tamoxifen, 5–10, 395, 1052
Tangier disease. *See* Analphalipoproteinemia
TaqMan, 529, 532
TAR RNA binding protein (TRBP), 385
Tarceva®, 807
Tardive dyskinesia, 410
Targeted whole-exome, 985
TATA-binding protein (TBP), 46
Taxanes (paclitaxel), 357–358
T-cell activation, 654
T-cell receptor (TCR), 438
*TCF7*L2 gene, 684
Telaprevir, 7–9
Telophase, 32
Temazepam, 825
Terbinafine, 7–9, 885–886, 893, 895
Termination step of transcription, 45
Tet-assisted bisulphite sequencing (TAB-seq), 61
Tetrabenazine, 7–9
2,3,7,8-Tetrachlorodibenzo-p-dioxin (TCDD), 3, 7–8, 394
Tetrahydrofolate (THF), 655
Tetramethylsilane (TMS), 197
Therapeutic drug monitoring (TDM), 313
Therapeutic index, 371
Thiazide diuretics, 756, 758–761
  alpha adducin (*A*DD1), 759
  *G*NB3, 759
  GWAS signals, 760–761
  *NED*D4L, 759–760
Thiazolidinedione (TZD), 707–709, 1008
  organic Anion–Transporting *Polypeptide* 1B1, 708
  pharmacodynamics, 708–709
  pharmacokinetics, 707–708
Thienopyridine, 511
Thioguanine, 7–9
6-Thioguanine, 345
Thiopentone, 820
Thiopurine, drug metabolism, 663
Thiopurine methyltransferase (TPMT), 10–11, 345, 355, 663–664, 937, 945–946, 1049, 1053
Thiopurines, 410–411
  adverse effects of, 410–411
  cost-effectiveness, 411
  perspectives of professional and regulatory bodies, 411
  TPMT genotype, 411
  TPMT phenotype, 411
Thioridazine, 7–9
Thiouric acid (TU), 663–664
Third-generation methods (TGS), 128
Threading, 275–276
Thrombin, 481, 510
Thrombin-activatable fibrinolysis inhibitor (TAFI), 481
Thromboxane A2 (TxA2), 373, 509–510
Thymidylate synthase (TYMS), 655
Thymine-DNA glycosylase (TDG), 58
Ticagrelor, 7–9, 514
Ticlopidine, 333, 422, 424
Tissue, 150–152
Tissue factor pathway inhibitor (TFPI), 481
TNF/IL-10, 667–668
TNRC6 protein, 49–50
Tocilizumab, 674
Tolbutamide, 701
Toll-like receptors (TLRs), 668, 865–866
Tolterodine, 7–9
Toluene, 389
Tophat maps, 134
Torsades de pointes (TdP), 469, 780–781, 796
  drug-induced (diTdP), 787, 791
  drugs associated with, 792–793
  -related pharmacodynamic interactions, 795
  risks of, 789, 794
Tositumomab, 7–9
Total body surface area (TBSA), 441
Total cholesterol, 719–721
TOtal Correlation SpectryoscopY (TOCSY), 189
Totipotent stem cells, 207
Toxic epidermal necrolysis (TEN), 417
Toxicity modeling, use of stem cells for, 221–226
  in cardiotoxicity studies, 221–223
  in hepatotoxicity studies, 223–224
  in neurotoxicity studies, 224–226
Toxicity of drug, predicting, 10–12
Toxicogenomic studies, use of stem cells for, 219
*T*PMT, 664
TPMT genotype, 411
TPMT phenotype, 411
Tramadol, 830
  and Acetaminophen, 7–9
Tramatenib, 18
Transcript reconstruction, 134–135
Transcription activator-like effector nucleases (TALENS), 78
Transcription factors (TFs), 278
Transcription start site (TSS), 115–116, 278
Transcriptomic applications, 133–135
  differential expression, 135
  library preparation, 133
  quantification of transcript abundance, 135
  sequencing, 133–134
    reference sequence, 133–134
    RNA-seq read-mapping process, 134
  transcript reconstruction, 134–135
Transcriptomic family of applications, 129
*T*rans-eQTL, 115
Transfer RNAs (tRNAs), 42, 60
Transformation efficiency, 90–92
Transgenic rodent models, 77–79
  Cre-LoxP Technology, 77
  recent transgenic advances, 77–79
Translational medicine, in China, 1012
Translational Pharmacogenetics Program, 927
Transmembrane proteins, 815
Transport receptors, 369
Transporter genes, 657–658
Transposable elements, 58
Trastuzumab, 7–9, 16–18
Treating to New Targets (TNT) trial, 721
Tree inference
  methods of, 267–269
  principles of, 266–267
Tree terminology, 265–266
Tretinoin, 7–9
Triangle association model, 101
